Introduction

Based on previous editions of *Veterinary Parasitology*, this fourth edition has been further developed into a two-part reference text with enhanced and updated parasite taxonomic classification systems.

Part 1 contains expanded individual parasite descriptions and taxonomic status within three new chapters on Veterinary helminthology (Chapter 1), Veterinary protozoology (Chapter 2) and Veterinary entomology (Chapter 3). As with previous editions of *Veterinary Parasitology*, further updated chapters include Laboratory diagnosis of parasitism (Chapter 4), Antiparasitics (Chapter 5), The epidemiology of parasitic diseases (Chapter 6) and Host resistance to parasitic diseases (Chapter 7). Host species chapters have been retained and updated and are now in Part 2 of the edition. Additional information on non-obligate ectoparasites that may be found on several hosts are grouped in a separate chapter, Facultative parasites and arthropod vectors (Chapter 17). In keeping with the third edition of *Veterinary Parasitology*, extensive indexing and cross-referencing are provided throughout this edition.

There are several slightly different definitions of parasitism and parasites. In the context of this book parasites are considered as organisms which live for a considerable portion of their lives in (**endoparasites**) or on (**ectoparasites**) another different kind of organism, the host. Ectoparasites are also frequently vectors of pathogens that may cause disease. Parasites are dependent on that host and benefit from the association, at the host's expense. They derive nutrition from the host and may also gain other benefits such as a protected habitat in which to grow and reproduce. Parasites are generally harmful to their host, although this is not always easy to demonstrate as an individual parasite may cause no recognisable damage. Disease is frequently a population phenomenon, with small numbers of parasites having no discernible impact but large numbers causing effects ranging from subclinical damage to

debilitating fatal disease. Damage to the host may also result from the host's defence mechanisms reacting to the presence of parasites.

Many parasites are entirely dependent upon a specific host or hosts in order to complete their life cycle and survive and these organisms are known as an **obligate** parasite of that particular host. Where an organism can either survive or complete its life cycle independently from a host, or can have a parasitic existence, then it is called a **facultative** parasite. There are instances where for various reasons parasites become established in hosts other than their definitive host and in which they cannot complete their normal life cycle. These hosts are termed **accidental** hosts and in the case of some zoonotic parasites of veterinary importance, humans are an example.

Every parasite must have at least one host in its life cycle and many species have several hosts. The host in which the parasite is best adapted and in which it develops to an adult or sexually mature stage and reproduces is known as the **definitive, primary** or **final** host. If there is only a single host in the life cycle, then transmission is said to be direct and the parasite to have a **direct** life cycle. Many parasites have more complex life cycles with additional hosts in which essential development to a new parasite stage occurs. These stages either do not reproduce or if they do then it is by asexual multiplication. These hosts are known as **intermediate** or **transitional** hosts. Some of these hosts can also be **vectors** (such as ticks, mosquitoes), which carry and spread disease-causing parasites from one host to another. These life cycles with more than one host are known as **indirect** or **complex** life cycles. There are some parasites that use additional hosts to overcome adverse environmental conditions or to increase the likelihood that the parasite will be transmitted to the definitive host. There is no further development of the parasite in these hosts. They are known as **paratenic** or **transport** hosts.

Part 1: General parasitology including taxonomy, diagnosis, antiparasitics

2 VETERINARY PROTOZOOLOGY

Kingdom Protozoa

| Phylum | Class | Order (Suborder) | Family | Genus | Chapters | |
|-------------|----------------|------------------|--------------------|--------------------------|-------------------------------------|-------------------------------------|
| Amoebozoa | Archamoeba | Amoebida | Entamoebidae | <i>Entamoeba</i> | 2, 8, 9, 10, 11, 12, 13, 16 | |
| | | | | <i>Iodamoeba</i> | 2, 10 | |
| | | | | <i>Endolimax</i> | 2 | |
| | | | Acantamoebidae | <i>Acanthamoeba</i> | 2 | |
| | | | Percolozoa | Heterolobosea | Schizopyrenida | Vahlkampfidae |
| Euglenozoa | Kinetoplasta | Trypanosomatida | Trypanosomatidae | <i>Leishmania</i> | 2, 12 | |
| | | | | <i>Trypanosoma</i> | 2, 4, 8, 9, 10, 12, 13, 14, 16 | |
| Parabasalia | Trichomonadea | Trichomonadida | Trichomonadidae | <i>Tritrichomonas</i> | 2, 8, 11, 13, 15 | |
| | | | | <i>Trichomonas</i> | 2, 12, 13, 16 | |
| | | | | <i>Tetratrichomonas</i> | 2, 8, 9, 11, 12, 13, 15 | |
| | | | | <i>Trichomitus</i> | 2, 11 | |
| | | | | <i>Pentatrichomonas</i> | 2, 12, 16 | |
| | | | | <i>Cochlosoma</i> | 2, 13 | |
| | | | Dientamoebidae | <i>Histomonas</i> | 2, 13 | |
| | | | Monocercomonadidae | <i>Monocercomonas</i> | 2, 8, 16 | |
| | | | | <i>Chilomitus</i> | 2, 15 | |
| | | | | <i>Dientamoeba</i> | 2, 15 | |
| | | Honigbergiellida | Hexamastigidae | <i>Hexamastix</i> | 2, 15 | |
| | | Proteromonadida | Proteromonadidae | <i>Proteromonas</i> | 2, 15 | |
| Fornicata | Retortamonadea | Retortamonadida | Retortamonadidae | <i>Retortamonas</i> | 2, 8, 9, 15 | |
| | | | | <i>Chilomastix</i> | 2, 11, 13, 15, 16 | |
| | Trepamonadea | Diplomonadida | | Hexamitidae | <i>Spironucleus</i> | 2, 13, 15, 16 |
| | | | | | <i>Caviomonas</i> | 2, 15 |
| | | | | Enteromonadidae | <i>Enteromonas</i> | 2, 15 |
| | | Metamonadea | Giardiida | Giardiidae | <i>Giardia</i> | 2, 8, 9, 10, 11, 12, 15 |
| Preaxostyla | Anaeromonadea | Oxymonadida | Polymastigidae | <i>Monocercomonoides</i> | 2, 15 | |
| Apicomplexa | Conoidasida | (Eimeriorina) | Eimeriidae | <i>Eimeria</i> | 2, 8, 9, 10, 11, 13, 14, 15, 16 | |
| | | | | <i>Cystispora</i> | 2, 11, 12, 14, 16 | |
| | | | | <i>Isospora</i> | 2 | |
| | | | | <i>Cyclospora</i> | 2, 16 | |
| | | | | <i>Tyzzeria</i> | 2, 13, 16 | |
| | | | | <i>Wenyonella</i> | 2, 13, 16 | |
| | | | | <i>Caryospora</i> | 2, 16 | |
| | | | | <i>Hoarella</i> | 2, 16 | |
| | | | | <i>Octosporella</i> | 2, 16 | |
| | | | | <i>Pythonella</i> | 2, 16 | |
| | | | | <i>Atoxoplasma</i> | 2 | |
| | | | | Cryptosporidiidae | <i>Cryptosporidium</i> | 2, 8, 9, 10, 11, 12, 13, 14, 15, 16 |
| | | | | Sarcocystiidae | <i>Besnoitia</i> | 2, 8, 9, 12, 14, 16 |
| | | | | | <i>Hammondia</i> | 2, 12 |
| | | | <i>Sarcocystis</i> | | 2, 8, 9, 10, 11, 12, 13, 14, 15, 16 | |
| | | | <i>Neospora</i> | | 2, 8 | |
| | | | <i>Frenkelia</i> | | 2 | |
| | | | <i>Toxoplasma</i> | | 2, 8, 9, 10, 11, 12, 13, 14, 15, 16 | |
| | | | Lankesterellidae | <i>Lankesterella</i> | 2 | |
| | | | (Adeleorina) | Klossiellidae | <i>Klossiella</i> | 2, 10, 15, 16 |

| | | | | | | |
|---------------------|-----------------------|--------------------------|--------------------------|-----------------------|------------------|-------------------------|
| | | | Haemogregarinidae | <i>Haemogregarina</i> | 2, 16 | |
| | | | Hepatozoidae | <i>Hepatozoon</i> | 2, 12, 15, 16 | |
| Aconoidasida | Haemospororida | Plasmodiidae | | <i>Haemoproteus</i> | 2, 13, 16 | |
| | | | | <i>Leucocytozoon</i> | 2, 13, 16 | |
| | | | | <i>Plasmodium</i> | 2, 13, 16 | |
| | | | | <i>Hepatocystis</i> | 2, 15 | |
| | | Piroplasmorida | Babesiidae | | <i>Babesia</i> | 2, 8, 9, 10, 11, 12, 14 |
| | | | Theileriidae | | <i>Theileria</i> | 2, 8, 9, 10, 14 |
| | | | | <i>Cytauxzoon</i> | 2, 12 | |
| Ciliophora | Litostomatea | Trichostomatorida | Balantidiidae | <i>Balantidium</i> | 2, 11, 16 | |
| | | | Pycnotrichidae | <i>Buxtonella</i> | 2, 8, 14 | |
| | | | Nyctotheridae | <i>Nyctotherus</i> | 2, 16 | |

Kingdom Fungi

| Phylum | Class | Order | Family | Genus | Chapters |
|----------------------|-----------------------------|-------------------------|---------------------------|------------------------|-----------|
| Microsporidia | Microsporea | Microspororida | Enterocytozoonidae | <i>Encephalitozoon</i> | 2, 12, 15 |
| | | | | <i>Enterocytozoon</i> | 2 |
| Ascomycota | Pneumocystidomycetes | Pneumocystidales | Pneumocystidaceae | <i>Pneumocystis</i> | 2, 8 |

Kingdom Chromalveolata

| Phylum | Class | Order | Family | Genus | Chapters |
|------------------|---------------------|----------------------|-----------------------|---------------------|-----------|
| Opalinata | Blastocystae | Blastocystida | Blastocystidae | <i>Blastocystis</i> | 2, 13, 16 |

Kingdom Bacteria

| Phylum | Class | Order | Family | Genus | Chapters |
|------------------------|----------------------------|----------------------|------------------------|------------------------|-------------------------|
| Proteobacteria | Alphaproteobacteria | Rickettsiales | Rickettsiaceae | <i>Rickettsia</i> | 2, 8, 9, 12, 15 |
| | | | Anaplasmataceae | <i>Anaplasma</i> | 2, 8, 9, 10, 12, 14 |
| | | | | <i>Ehrlichia</i> | 2, 8, 9, 12 |
| | | <i>Aegyptianella</i> | | 2, 13 | |
| | | Rhizobiales | Bartonellaceae | <i>Rochalimaea</i> | 2 |
| | | | | <i>Bartonella</i> | 2 |
| | | | | <i>Grahamella</i> | 2 |
| | | Legionellales | Coxiellaceae | <i>Coxiella</i> | 2 |
| | | | | <i>Neorickettsia</i> | 2, 10, 12 |
| | | Firmicutes | Mollicutes | Mycoplasmatales | Mycoplasmataceae |
| <i>Haemobartonella</i> | 2, 12 | | | | |

3 VETERINARY ENTOMOLOGY

Kingdom Animalia

| Phylum | Class | Order (Suborder) | Family (Subfamily) | Genus | Chapters | |
|---------------------|-----------------------|---------------------|-----------------------|----------------------|--------------------|-------|
| Arthropoda | Insecta | Hemiptera | Cimicidae | <i>Cimex</i> | 3 | |
| | | | Reduviidae | <i>Triatoma</i> | 3, 17 | |
| | | | | <i>Rhodnius</i> | 3, 17 | |
| | | | | <i>Panstrongylus</i> | 3 | |
| | | Diptera | | | | |
| | | (Nematocera) | Ceratopogonidae | <i>Culicoides</i> | 3, 17 | |
| | | | Simuliidae | <i>Simulium</i> | 3, 17 | |
| | | | Psychodidae | <i>Phlebotomus</i> | 3, 17 | |
| | | | | <i>Lutzomyia</i> | 3, 17 | |
| | | | Culicidae | <i>Aedes</i> | 3, 17 | |
| | | | | <i>Anopheles</i> | 3, 17 | |
| | | | | <i>Culex</i> | 3, 17 | |
| | | | (Brachycera) | Tabanidae | <i>Chrysops</i> | 3, 17 |
| | | | | | <i>Haematopota</i> | 3, 17 |
| | | | | | <i>Tabanus</i> | 3, 17 |
| | | Muscidae | | <i>Musca</i> | 3, 17 | |
| | | | | <i>Hydrotaea</i> | 3, 17 | |
| | | | | <i>Stomoxys</i> | 3, 17 | |
| | | | | <i>Haematobia</i> | 3, 17 | |
| | | Fanniidae | | <i>Fannia</i> | 3, 17 | |
| | | Hippoboscidae | | <i>Hippobosca</i> | 3, 17 | |
| | | | | <i>Melophagus</i> | 3, 9 | |
| | | | | <i>Lipoptena</i> | 3, 17 | |
| | | | | <i>Pseudolynchia</i> | 3, 16 | |
| | | Glossinidae | | <i>Glossina</i> | 3, 17 | |
| | | Calliphoridae | | <i>Lucilia</i> | 3, 8, 9, 17 | |
| | | | | <i>Calliphora</i> | 3, 8, 17 | |
| | | | | <i>Protophormia</i> | 3, 9, 17 | |
| | | | | <i>Phormia</i> | 3, 9, 17 | |
| | | | | <i>Cochliomyia</i> | 3, 17 | |
| | | | | <i>Chrysomya</i> | 3, 17 | |
| | | | | <i>Cordylobia</i> | 3, 17 | |
| | | | | Sarcophagidae | <i>Sarcophaga</i> | 3, 17 |
| | | | | | <i>Wohlfahrtia</i> | 3, 17 |
| | | | | Oestridae | | |
| | | (Oestrinae) | | <i>Oestrus</i> | 3, 9, 14 | |
| | | | | <i>Rhinoestrus</i> | 3, 10 | |
| | | | | <i>Geddoelstia</i> | 3, 9 | |
| | | | <i>Cephenemyia</i> | 3, 14 | | |
| | | | <i>Cephalopina</i> | 3, 14 | | |
| <i>Oedemagena</i> | 3, 14 | | | | | |
| <i>Pharyngomyia</i> | 3, 14 | | | | | |
| (Gasterophilinae) | <i>Gasterophilus</i> | | 3, 10 | | | |
| (Hypodermatinae) | <i>Hypoderma</i> | | 3, 8, 14 | | | |
| | <i>Przhevalskiana</i> | | 3, 9 | | | |
| (Cuterebrinae) | <i>Cuterebra</i> | 3, 15 | | | | |
| | <i>Dermatobia</i> | 3, 17 | | | | |

| | | | | |
|----------------------|---------------------|---------------------------|------------------------|-----------|
| Phthiraptera | | | | |
| (Anoplura) | Haematopinidae | <i>Haematopinus</i> | 3, 8, 10, 11 | |
| | Linognathidae | <i>Linognathus</i> | 3, 8, 9, 12 | |
| | | <i>Solenopotes</i> | 3, 8 | |
| | Microthoraciidae | <i>Microthoracius</i> | 3, 14 | |
| | Polyplacidae | <i>Polyplax</i> | 3, 15 | |
| | | <i>Haemodipsus</i> | 3 | |
| | (Amblycera) | Menoponidae | <i>Menacanthus</i> | 3, 13 |
| | | | <i>Menopon</i> | 3, 13 |
| | | | <i>Holomenopon</i> | 3, 13 |
| | | | <i>Ciconiphilus</i> | 3, 13 |

4 Laboratory diagnosis of parasitism, 259

- Helminth infections, 259
 - Faecal examination, 259
 - Collection of faeces, 259
 - Methods of examination of faeces, 259
 - Identification of nematode eggs, 261
 - Identification of trematode eggs, 261
 - Larval recovery, 268
 - Recovery of alimentary nematodes, 269
 - Key to the identification of gastrointestinal nematodes of ruminants, 271
 - Recovery of adult lungworms, 274
 - Recovery of trematode and cestode parasites, 275
 - Other aids to diagnosis of ruminant nematodes, 275
 - DNA-based methods, 276
- Protozoal infections, 283
 - Examination of faecal samples for coccidia, 283
 - Examination of faecal samples for other protozoa, 283
 - Examination of blood and lymph, 289
 - Examination of skin, 290
 - Xenodiagnosis, 290
- Ectoparasites, 290
 - Insects, 290
 - Ticks and mites, 301
 - Mounting and preservation, 309
- Chemicals and solutions, 311
 - Flotation solutions, 311
 - Worm count solutions, 311
 - Stains, 311

5 Antiparasitics, 313

- Anthelmintics, 313
 - Anthelmintics and their mode of action, 313
 - Properties of anthelmintic compounds, 317
 - Use of anthelmintics, 317
 - Methods of administration, 318
- Antiprotozoals, 318
 - Antiprotozoals and their mode of action, 319
 - Use of antiprotozoals, 323
 - Methods of administration, 323
- Ectoparasiticides (insecticides/acaricides), 323
 - Ectoparasiticides and their mode of action, 324
 - Methods of pesticide application and uses, 327
- Parasiticide resistance, 328
 - Anthelmintic resistance, 328
 - Antiprotozoal resistance, 333
 - Pesticide resistance, 334

6 The epidemiology of parasitic diseases, 336

- An increase in the numbers of infective stages, 336
 - Contamination of the environment, 336
 - Development and survival of infective stages, 337

- An alteration in host susceptibility, 338
 - Altered effects of an existing infection, 338
 - Altered susceptibility to the acquisition of new infections, 340
- The introduction of susceptible stock, 340
 - Absence of acquired immunity, 340
 - Absence of age immunity, 341
 - Longevity of infective stages, 341
 - Influence of genetic factors, 341
 - Strain of parasite, 341
- Introduction of infection into a clean environment, 341
 - Introduction of new stock, 341
 - Role of effluent, 341
 - Role of infected vectors, 342

7 Host resistance to parasitic diseases, 343

- Species resistance, 343
- Age resistance, 343
- Breed resistance, 343
- Acquired immunity to helminth infections, 344
 - Effect of the immune response, 344
 - Evasion of the host's immune response, 345
 - Cost of the immune response, 346
- Acquired immunity to protozoal infections, 346
- Acquired immunity to arthropod infections, 347
- The future of parasite vaccines, 347
 - Helminths, 347
 - Protozoa, 349
 - Ectoparasites, 351

Part 2: Host-parasite diseases**8 Parasites of cattle, 352**

- Endoparasites, 352
 - Parasites of the digestive system, 352
 - Parasites of the respiratory system, 379
 - Parasites of the liver, 383
 - Parasites of the pancreas, 388
 - Parasites of the circulatory system, 389
 - Parasites of the nervous system, 409
 - Parasites of the reproductive/urogenital system, 410
 - Parasites of the locomotory system, 413
 - Parasites of the connective tissue, 417
 - Parasites of the integument, 420
- Ectoparasites, 424
 - Flies, 424
 - Lice, 424
 - Mites, 427
- Cattle parasite checklist, 431

9 Parasites of sheep and goats, 436

- Endoparasites, 436
 - Parasites of the digestive system, 436
 - Parasites of the respiratory system, 474

- Parasites of the liver, 480
- Parasites of the pancreas, 489
- Parasites of the circulatory system, 489
- Parasites of the nervous system, 497
- Parasites of the reproductive/urogenital system, 498
- Parasites of the locomotory system, 500
- Parasites of the integument, 502
- Ectoparasites, 503
 - Lice, 503
 - Mites, 506
 - Fly strike (myiasis), 511
- Sheep parasite checklist, 516
- Goat parasite checklist, 520
- 10 Parasites of horses, 524**
 - Endoparasites, 524
 - Parasites of the digestive system, 524
 - Parasites of the respiratory system, 544
 - Parasites of the liver, 545
 - Parasites of the circulatory system, 545
 - Parasites of the nervous system, 552
 - Parasites of the reproductive/urogenital system, 554

Preface to the first edition

This book is intended for students of veterinary parasitology, for practising veterinarians and for others requiring information on some aspect of parasitic disease.

Originally intended as a modestly expanded version of the printed notes issued to our students in the third and fourth years of the course, the text, perhaps inevitably, has expanded. This was due to three factors. First, a gradual realization of the deficiencies in our notes; secondly, the necessity of including some of the comments normally imparted during the lecture course and thirdly, at the suggestion of the publishers, to the inclusion of certain aspects of parasitic infections not treated in any detail in our course.

We should perhaps repeat that the book is primarily intended for those who are directly involved in the diagnosis, treatment and control of parasitic diseases of domestic animals. The most important of these diseases have therefore been discussed in some detail, the less important dealt with more briefly and the uncommon either omitted or given a brief mention. Also, since details of classification are of limited value to the veterinarian we have deliberately kept these to the minimum sufficient to indicate the relationships between the various species. For a similar reason, taxonomic detail is only presented at the generic level and, occasionally, for certain parasites, at species level. We have also trod lightly on some other areas such as, for example, the identification of species of tropical ticks and the special significance and epidemiology of some parasites of regional importance. In these cases, we feel that instruction is best given by an expert aware of the significance of particular species in that region.

Throughout the text we have generally referred to drugs by their chemical, rather than proprietary, names because of the plethora of the latter throughout the world. Also, because formulations are often different, we have avoided stating doses; for these, reference should be made to the data sheets produced by the manufacturer. However, on occasions when a drug is recommended at an unusual dose, we have noted this in the text.

In the chapters at the end of the book we have attempted to review five aspects of veterinary parasitology, epidemiology, immunity, anthelmintics, ectoparasiticides and laboratory diagnosis. We hope that this broader perspective will be of value to students, and particularly to those dismayed by the many complexities of the subject.

There are no references in the text apart from those at the end of the chapter on diagnosis. This was decided with some regret and much relief on the grounds that it would have meant the inclusion, in a book primarily intended for undergraduates, of hundreds of references. We hope that those of our colleagues throughout the world who recognize the results of their work in the text will accept this by way of explanation and apology.

We would, however, like to acknowledge our indebtedness to the authors of several source books on veterinary parasitology whose work we have frequently consulted. These include *Medical and Veterinary Protozoology* by Adam, Paul & Zaman, *Veterinaermedizinische Parasitologie* by Boch & Supperer, Dunn's *Veterinary Helminthology*, Euzéby's *Les Maladies Vermineuses des Animaux Domestiques*, Georgi's *Parasitology for Veterinarians*, Reinecke's *Veterinary Helminthology*, Service's *A Guide to Medical Entomology* and Soulsby's *Helminths, Arthropods and Protozoa of Domesticated Animals*.

Any student seeking further information on specific topics should consult these or, alternatively, ask his tutor for a suitable review.

The ennui associated with repeated proof reading may occasionally (we hope, rarely) have led to some errors in the text. Notification of these would be welcomed by the authors. Finally we hope that the stresses endured by each of us in this collaborative venture will be more than offset by its value to readers.

Acknowledgements to the first edition

We would like to express our gratitude to the following individuals and organizations that assisted us in the preparation of this book.

First, to Drs R. Ashford and W. Beesley of Liverpool; Dr J. Bogan, Glasgow; Dr W. Campbell, Rahway, USA; Dr R. Dalglish, Brisbane; Dr L. Joyner, Weybridge, England; Dr T. Miller, Florida; Dr M. Murray, Nairobi; Dr R. Purnell, Sandwich, England; Dr S.M. Taylor, Belfast; Professor K. Vickerman, Glasgow. Each of these read and commented on sections of the text in which they are expert. Any errors in these areas are, however, solely the responsibility of the authors.

Secondly, to the following individuals and companies who kindly allowed us to use their photographs or material as illustrations or plates:

Dr E. Allonby, Nairobi (Plate I d, e, f); Dr K. Angus, Edinburgh (Fig. 167); Dr J. Arbuckle, Guildford, England (Fig. 61); Dr E. Batte, North Carolina, USA (Plate III f); Dr I. Carmichael, Johannesburg, S. Africa (Fig. 142); Dr L. Cramer, Sao Paulo (Fig. 126b); Crown Copyright, UK (Plate XIV b); Dr J. Dunsmore, Murdoch, W. Australia (Plate IV d); Professor J. Eckert, Zurich (Fig. 96); Glaxovet, Harefield, England (Plate II f); Dr I. Herbert, Bangor, Wales (Fig. 172); Dr A. Heydorn, W. Berlin (Figs 170, 171); Professor F. Hörning, Berne (Fig. 82; Plate V e); Dr B. Iovanitti, Balcarce, Argentina (Figs 22, 23); Dr D. Jacobs, London (Fig. 38); Drs D. Kelly and A. Longstaffe, Bristol (Figs 156, 157); The late Dr I. Lauder, Glasgow (Fig. 65, Plate XI c, e, XII b); Drs B. Lindemann and J. McCall, Georgia, USA (Fig. 67); Dr N. McEwan, Glasgow (Plate XI d, XII e); Dr G. Mitchell, Ayr, Scotland (Plate VI e); Professor M. Murray, Glasgow (Figs 68, 84, 152); Dr A. Nash, Glasgow (Fig. 138b, Plate XII c); Dr Julia Nicholls, Adelaide, Australia (Figs 6, 14c, d); Dr R. Purnell, Sandwich, England (Fig. 173, Plate VIII d, e, f); Professor H. Pirie, Glasgow (Fig. 40); Dr J. Reid, Brussels (Plate XII a); Dr Elaine

Rose, Houghton Poultry Research Station, Huntingdon, England (Figs 160, 163b, 164a, b); Professor I. Selman, Glasgow (Plate XI f); Dr D. Taylor, Glasgow (Plate XIV c); Dr M. Taylor, London (Fig. 85); Dr S. Taylor, Belfast (Plate II a); Dr H. Thompson, Glasgow (Fig. 92, Plate IV b, c, VI d); Dr R. Titchener, Ayr, Scotland (Fig. 113b, Plate VIII a); Dr A. Waddell, Brisbane, Australia (Fig. 66, Plate IV e); Wellcome Research Laboratories, Berkhamsted, England (Plate VIII c); Dr A. Wright, Bristol (Plate VI b, XI b, XII d, f). In this context we are also extremely grateful to Miss E. Urquhart, Wrexham, Wales who prepared many of the line drawings.

Thirdly, to the pharmaceutical companies of Crown Chemical, Kent, England; Hoechst UK, Bucks; Merck Sharp & Dohme, Herts; Pfizer, Kent; Schering, New Jersey; Syntex Agribusiness, California. Their generosity enabled us to present many of the photographs in colour, thus enhancing their value.

Finally, to those members of the Faculty of Veterinary Medicine, Glasgow, whose cooperation was essential in the production of this book. We would especially like to thank Kenneth Bairden, our chief technician, who prepared much of the material for photography, often at inordinately short notice; Archie Finnie and Allan May, of the Photographic Unit, who, almost uncomplainingly, undertook the extra work of photographing many specimens; our two departmental secretaries, Elizabeth Millar and Julie Nybo, without whose skill and attention to detail this book would certainly not have been written.

Preface and acknowledgements to the second edition

The first edition of this book was published in 1987 and the authors considered that a second edition is now necessary for several reasons.

First, the widespread use of drugs such as avermectins and milbemycons, which have had a significant effect on anthelmintic prophylaxis and control. At the time of the first edition only one, ivermectin, was marketed whereas at the present time there are now several such products, supplemented by a number of new, long-acting chemoprophylactic devices.

Secondly, in many countries the production of a number of older anthelmintics and insecticides has largely ceased or many are difficult to find.

Thirdly, several parasitic diseases have now been described, about which little was known at the time of the first edition. Notably these are neosporosis and Lyme disease. Also included is a short description of the nasal mite of dogs, *Pneumonyssus caninum*, kindly provided by Professor Arvid Uggla of the National Veterinary Institute and Swedish University of Agricultural Sciences, Uppsala, Sweden.

Fourthly, we have taken the opportunity of rewriting some parts of the text, which on reflection, were less clear than we had hoped. In many cases, this has been supplemented by new diagrams or photographs.

Another change in this edition is the adoption of the standardized nomenclature of animal parasitic diseases (SNOAPAD) proposed by an expert committee appointed by the World Association for the Advancement of Veterinary Parasitology (WAAVP) published in *Veterinary Parasitology* (1988) 29, 299–326. Although this may have a discomfoting effect on those who have used certain familiar terms for animal parasitic diseases for many years, it is designed to improve the clarity of scientific communication by the

general use of uniform terminology and should, in the long term, prove particularly beneficial in facilitating the retrieval of computerized data related to veterinary parasitology.

At the end of the book we have given a list of books and journals, which should be useful to anyone who wishes to pursue a specific subject in greater detail. This is confined to publications which are readily available in most libraries of universities and research institutes.

We wish to thank Drs Ken Bairden, Quintin McKellar and Jacqueline McKeand for helpful comments on the text, also Mr Stuart Brown who assisted in the preparation of some of the new illustrations and Una B. Shanks RSW who prepared all of the new drawings.

We should mention, with great regret, the death of our co-author Dr Angus M. Dunn, who died in 1991 before this review was started, but we are reasonably certain that he would have approved of all the alterations we have made.

At the start of this revision we had intended to include new sections on parasitic disease of both fish and laboratory animals. However, a subsequent review of the literature currently available on these two subjects indicated that both were adequately covered in existing publications and it seemed more sensible to include the titles of these in the list of suggested reading.

Finally we wish to express our appreciation of the reception accorded to the first edition by reviewers, colleagues and students; we hope this second edition will be equally well received.

F. W. Jennings

Preface and acknowledgements to the third edition

The third edition has been written to accommodate a wider readership which includes teachers and students in veterinary schools, research groups in universities and institutes, veterinarians in practice and in government service and others who are involved in aspects of parasitic disease. In producing the new edition of *Veterinary Parasitology* the authors had several aims.

The first was to preserve the spirit of the first and second editions, which had been compiled by eminent and respected veterinary parasitologists in their field and which provided a solid background on which to consolidate.

The second aim was to expand the sections on protozoa and ectoparasites and to incorporate a larger selection of parasites, which are of veterinary significance in other parts of the world. The book focuses mainly on core information relating to parasites of livestock and companion animals but new sections on parasites of poultry and gamebirds, laboratory animals, exotic pets, and 'farmed' species have been included. The majority of parasitic diseases are now covered in detail using a standardised format for each parasite to allow easy referencing and for comparison between species within a genus. Where appropriate, reference is made to human infections where there is natural transmission of parasitic disease between vertebrate animals and man (zoonoses).

The third aim was to present the information in a format which is compatible with the current parasitology teaching modules used within many university veterinary schools. This inevitably has had to be a compromise, as approaches to teaching veterinary parasitology differ throughout the world, but, by arranging the parasites under host species and their predilection site within the host and providing a comprehensive check list for each section and extensive cross-referencing, it is hoped that information on particular parasites can be easily located. Taxonomy of the main parasitic phyla and classes are provided within an introductory chapter along with generic descriptions and anatomical features of the parasite orders and families. Additional detailed sections are provided at the back of the book on veterinary antiparasitics, with a section on laboratory diagnosis, including numerous tables and identification charts. In keeping with previous editions a series of brief overviews of topics relevant to veterinary parasitology have been included to provide the non-expert with basic background information and to also highlight additional sources of reading.

The classification of parasites has been updated to reflect many of the systematic changes introduced, particularly where molecular genetics-based taxonomic re-organisation has been introduced. Throughout, synonyms have been provided reflecting older taxonomic nomenclature or where controversy remains. As with the previous edition, parasitic infections are described according to the Standardized Nomenclature of Animal Parasitic Diseases guidelines (SNOAPAD, 1988; *Veterinary Parasitology* 29, 299–326). In considering treatment of parasitic infections we have used the generic names of drugs to avoid listing the wide range of products which are currently marketed in different countries. Dose rates of drugs are not always stated as many vary from country to country, being influenced by the relevant regulatory authorities. In all cases, readers are advised to consult the manufacturer's data sheets for current information and local regulations.

The authors are extremely grateful to Professor Sir James Armour and Professor James Duncan for their interest and support and for reading through the drafts of the text and their constructive comments. Any errors in the book are solely the responsibility of the authors. In order to assist the reader and for clarification we took the decision to produce much of the book and illustrations in colour and we are most grateful for the generous financial support of the following pharmaceutical companies which made this possible: Fort Dodge Animal Health; Pfizer Animal Health; Merial Animal Health; Novartis Animal Health; Intervet UK Ltd.

Finally, the help and support of the following list of people is acknowledged in producing this textbook. Professor Quintin McKellar (previous scientific director) and Professor Julie Fitzpatrick (current scientific director) of the Moredun Research Institute provided support to Dr Coop allowing him full access to the library facilities following his retirement. Dr Frank Jackson for comments on the manuscript. Michelle Moore, Matthew Carroll and Caroline Chaffer provided invaluable assistance with setting up much of the initial file documentation required to develop the re-organised structure of the book. Ralph Marshall at the Veterinary Laboratories Agency provided information on coccidial species of camelids and gamebirds. The technical support of Shelagh Wall is gratefully acknowledged.

Professor Mike Taylor
Dr Bob Coop
Professor Richard Wall

Preface and acknowledgements to the fourth edition

This fourth edition has been written to provide detailed parasite descriptions and reference texts for teachers, research groups in universities and institutes, veterinarians in practice and in government service, and others involved in aspects of parasitic disease. In producing the new edition of *Veterinary Parasitology* the authors had the following aims and objectives.

The first was to preserve the spirit of the first two editions of the textbook *Veterinary Parasitology*, which had been compiled by eminent and respected veterinary parasitologists in their field and which provided a solid background on which to further consolidate.

The second aim was to greatly expand and revise the systematic sections on helminthology, protozoology and entomology and the descriptions of animal parasites which are of veterinary significance in many parts of the world. This edition focuses mainly on core information relating to parasites of livestock and companion animals but sections on parasites of poultry and gamebirds, laboratory animals, exotic pets and 'farmed' species are included. The majority of parasitic diseases are now covered in detail using standardised formats for each parasite to allow easy referencing and for comparison between species within a genus. Where appropriate, reference is made to human infections where there is natural transmission of parasitic disease between vertebrate animals and humans (zoonoses).

The third aim was to present the information in two formats which are considered compatible with the diversity of current parasitology teaching modules used within many universities and veterinary schools, both for teaching parasite systematics and for teaching of diseases on a host-organ basis. The latter is achieved by arranging the parasites under host species and their predilection sites. By providing both approaches, and because teaching of veterinary parasitology differs throughout the world, it is hoped that information on particular parasites can be easily located. Taxonomy of the main parasitic kingdoms, phyla, classes, orders and genera are now provided in much greater detail within the introductory chapters and subsections, along with detailed descriptions and anatomical features of the parasite orders, families and species. Additional detailed and updated sections are provided on veterinary antiparasitics, with an expanded section on laboratory diagnosis, including recent molecular developments and an increased number of tables and identification charts. In keeping with previous editions of the textbook, a series of brief overviews of topics relevant to veterinary parasitology have been included to provide the non-expert with basic background information and also to highlight additional sources of reading. An additional feature is the inclusion of a number of additional figures, diagrams and images of parasites.

The classification of parasites reflects many of the systematic changes, particularly where molecular genetics-based taxonomic reclassification has been introduced. Throughout, synonyms have

been provided reflecting older taxonomic nomenclature, or where controversy remains. As with the earlier textbook editions, parasitic infections are described according to the Standardised Nomenclature of Animal Parasitic Diseases guidelines (SNOAPAD, 1988; *Veterinary Parasitology* **29**, 299–326). In considering treatment of parasitic infections we have used the generic names of drugs to avoid listing the wide range of products that are currently marketed in different countries. Dose rates of drugs are not always stated as many vary from country to country, being influenced by the relevant regulatory authorities. In all cases, readers are advised to consult the manufacturer's data sheets for current information and local regulations.

The new edition retains the expertise of the three authors of the previous third edition.

Professor Mike Taylor is a veterinary graduate of Glasgow University Veterinary College, having studied under the authors of the first and second editions of the textbook *Veterinary Parasitology*, whose enthusiasm for their subject greatly influenced his interest in veterinary parasitology. After 6 years in general veterinary practice, a large part of his career was spent at the Central Veterinary Laboratory, Weybridge, later to become the Veterinary Laboratories Agency (VLA), where he worked on the epidemiology and control of parasitic helminths, protozoa and ectoparasites of domestic animals, and in particular parasite chemotherapy, parasite control and anthelmintic resistance. During this time he studied for a PhD at the Royal Veterinary College, London, under the expert guidance of Professor Dennis Jacobs. He has spent over 30 years in veterinary parasitology, published 20 book chapters and has over 250 scientific publications, as well as contributing extensively to the third and current editions of *Veterinary Parasitology*. He retired as Head of Veterinary Surveillance at the Central Science Laboratory York (later to become FERA) in 2011, but remains a visiting Professor of Parasitology at the Royal Veterinary College, London, an Emeritus Fellow of FERA, and now runs his own veterinary parasitology consultancy company. He is a Diplomate of the European College of Veterinary Parasitology, and a Diplomate of the European College of Small Ruminant Health and Management. He has been a Fellow of Edinburgh University, a former Editor-in-Chief of the *Journal Veterinary Parasitology*, and past president of the British Association for Veterinary Parasitology.

Dr Bob Coop graduated in biochemistry from the University of Liverpool and then undertook a PhD in large animal parasitology at the University of Wales, Bangor. He has spent over 35 years in veterinary parasitology research, initially working with lungworm infection in pigs and then on the epidemiology and pathogenesis of gastrointestinal nematode infection in small and large ruminants, and in particular the nutrition-parasite interaction and sustainable control strategies. He has been a Fellow of Edinburgh University

and a past president of the British Association for Veterinary Parasitology. Formerly as Head of the Division of Parasitology at the Moredun Research Institute, Edinburgh and now as a Fellow of the Moredun Foundation, he has considerable experience of knowledge transfer to end-user groups and veterinarians in practice. Dr Coop acknowledges full access to the Information Technology Services at the Moredun Research Institute.

Professor Richard Wall graduated in zoology from the University of Durham followed by a PhD in insect population ecology at the University of Liverpool. He is now Professor of Zoology at the University of Bristol, where he teaches and heads a research group studying a diverse range of arthropods, focusing particularly on ectoparasites of veterinary importance and insect colonisers of dung and carrion. His research ranges widely from fundamental studies of arthropod taxonomy and physiology, through to field population ecology and farm-level investigations of the application of sustainable control technologies.

The help and support of the following people is acknowledged in producing this edition. Dr Philip Skuce of the Moredun Research

Institute (MRI) wrote the section in Chapter 4 on molecular diagnostics for which the authors are extremely grateful. Professor James Duncan provided his collection of photographic slides from the Glasgow University Veterinary School, many of which appear as illustrations or figures, both in this and previous editions. Additional photographic material has been used from a collection of digital images gathered under the auspices of the British Association of Veterinary Parasitology over a period of 20 years. Several of the newer illustrations and figures included in this edition were reproduced from material by former colleagues from the Parasitology Department at the Central Veterinary Laboratory (CVL), Weybridge, which sadly now no longer exists. Acknowledgement is therefore made to the following: Dr Martin Gregory, Dr Len Joiner, Janet Catchpole, Chris Norton, Ralph and Jackie Marshall, Dr Mike Peirce, Dr Richard Cawthorne, Keith Hunt, Colin Hong, Barry Lancaster, Dr Charles Ollerenshaw, Gordon Graham, Dr Joe Donnelly, Paul Phipps, and Drs Alan Kirkwood, David Tarry and Peter Bates whose work and dedication inspired a generation of parasitologists in Britain and around the world. Finally, the authors are grateful to Merial for providing financial sponsorship for several of the figures appearing in this edition.

CHAPTER 1

Veterinary helminthology

PRINCIPLES OF CLASSIFICATION

When examined, living organisms can be seen to form natural groups with features in common. These similarities may be morphological, but increasingly may be based on DNA analysis. Groups of organisms are combined into biologically meaningful groups, usually attempting to represent evolutionary pathways. A group of this sort is called a **taxon**, and the study of this aspect of biology is called **taxonomy**. The study of the complex systems of interrelationship between living organisms is called **systematics**.

The taxa into which organisms may be placed are recognised by international agreement; the primary ones are **kingdom, phylum, class, order, family, genus** and **species**. The intervals between these are large, and some organisms cannot be allocated to them precisely, so intermediate taxa, prefixed appropriately, have been formed; examples of these are the **suborder** and the **superfamily**. As an example, the taxonomic status of one of the common abomasal parasites of ruminants may be expressed as shown below.

| | |
|-------------|---------------------|
| Kingdom | Animalia |
| Phylum | Nematoda |
| Class | Secernentea |
| Order | Strongylida |
| Suborder | Strongylina |
| Superfamily | Trichostrongyloidea |
| Family | Trichostrongylidae |
| Subfamily | Haemonchinae |
| Genus | <i>Haemonchus</i> |
| Species | <i>contortus</i> |

The names of taxa must follow a set of internationally agreed rules, but it is permissible to anglicise the endings, so that members of the superfamily Trichostrongyloidea in the example above may also be termed trichostrongylids.

The names of the genus and species are expressed in Latin form, the generic name having a capital letter, and they must be in grammatical agreement. It is customary to print Latin names in italics. Accents are not permitted. If an organism is named after a person, amendment may be necessary; the name of Müller, for example, has been altered in the genus *Muellerius*.

HELMINTHOLOGY

Parasitic helminths can affect humans, animals and plants, with estimated numbers of between 75,000 and 300,000 species. The higher taxa containing helminths of veterinary importance are:

Major

- Nematoda (roundworms)
- Platyhelminthes (flatworms)
 - Trematoda (Flukes)
 - Cestoda (Tapeworms)

Minor

- Acanthocephala (thorny-headed worms)

PHYLUM NEMATODA

The nematodes (Nematoda) are commonly called **roundworms** from their appearance in cross-section, and are parasitic or free-living. In the majority of nematodes the sexes are separate.

CLASS SECERNENTEA

The system of classification of nematodes of veterinary importance, which is based on current taxonomic literature, is given in Table 1.1. In this system, nematode genera and species in the class Secernentea are grouped into 16 **superfamilies** in which nematodes of veterinary importance occur. The superfamilies can be conveniently divided into **bursate** and **non-bursate** groups, the most typical features of which are summarised in Table 1.2.

STRUCTURE AND FUNCTION

Most nematodes have a cylindrical unsegmented form, tapering at either end, and the body is covered by a colourless, somewhat translucent, layer: the cuticle.

The tough cuticle is secreted by the underlying hypodermis, which projects into the body cavity forming two lateral cords, which carry the excretory canals, and a dorsal and ventral cord carrying the nerves (Fig. 1.1). The muscle cells, arranged longitudinally, lie between the hypodermis and the body cavity. The latter contains fluid at a high pressure, which maintains the turgidity and shape of the body (pseudocoelom). Locomotion is effected by undulating waves of muscle contraction and relaxation that alternate on the dorsal and ventral aspects of the worm. A circular muscle layer is absent in nematodes. Most of the internal organs are filamentous and suspended in the fluid-filled body cavity (Fig. 1.1).

The **digestive system** is tubular (Fig. 1.2a). The mouth, or stoma, of many nematodes is a simple opening, which may be surrounded by two or three lips, and leads directly into the oesophagus. Where

the mouth opening is large and well developed it is often surrounded by a leaf crown. In others, such as the strongyloids, it is large, and opens into a **buccal capsule**, which may contain blades or teeth. Such parasites, when feeding, draw a plug of mucosa into the buccal capsule, where it is broken down by the action of enzymes, which are secreted into the capsule from adjacent glands. Some of these worms may also secrete anticoagulant, and small vessels, ruptured in the digestion of the mucosal plug, may continue to bleed for some minutes after the worm has moved to a fresh site.

Those nematodes with very small buccal capsules, like the trichostrongyloids, or simple oral openings, like the ascaridoids, generally feed on mucosal fluid, products of host digestion and cell debris, while others, such as the oxyuroids, appear to scavenge on the contents of the lower gut. Worms living in the bloodstream or tissue spaces, such as the filarioids, feed exclusively on body fluids.

The **oesophagus** is usually muscular and pumps food into the intestine. It is of variable form (Fig. 1.3), and is a useful preliminary identification character for groups of worms. It may be **filariform**,

Table 1.2 Characteristic features of parasitic nematodes of veterinary importance.

| Superfamily | Typical features |
|--|---|
| Bursate nematodes | |
| Trichostrongyloidea <i>Trichostrongylus, Ostertagia, Dictyoacaulus, Haemonchus, etc.</i> | Buccal capsule small. Life cycle direct ; infection by L ₃ |
| Strongyloidea <i>Strongylus, Syngamus, etc.</i> | Buccal capsule well developed; leaf crowns and teeth usually present. Life cycle direct ; infection by L ₃ |
| Ancylostomatoidea <i>Ancylostoma, Uncinaria, etc.</i> | Buccal capsule well developed; leaf crowns and teeth usually present. Life cycle direct ; infection by L ₃ |
| Metastrongyloidea <i>Metastrongylus, Muellerius, Protostrongylus, etc.</i> | Buccal capsule small. Life cycle indirect ; infection by L ₃ in intermediate host |
| Non-bursate nematodes | |
| Rhabditoidea <i>Strongyloides, Rhabditis, etc.</i> | Very small worms; buccal capsule small. Free-living and parasitic generations. Life cycle direct ; infection by L ₃ |
| Ascaridoidea <i>Ascaris, Toxocara, Parascaris, etc.</i> | Large white worms. Life cycle direct ; infection by L ₂ in egg |
| Diectophymatoidea <i>Diectophyma, etc.</i> | Very large worms. Life cycle indirect ; infection by L ₃ in aquatic annelids |
| Oxyuroidea <i>Oxyuris, Skrjabinema, etc.</i> | Female has long pointed tail. Life cycle direct ; infection by L ₃ in egg |
| Spiuroidea <i>Spirocerca, Habronema, Thelazia, etc.</i> | Spiral tail in male. Life cycle indirect ; infection by L ₃ from insects |
| Filarioidea <i>Dirofilaria, Onchocerca, Parafilaria, etc.</i> | Long thin worms. Life cycle indirect ; infection by L ₃ from insects |
| Trichuroidea <i>Trichuris, Capillaria</i> | Whip-like or hair-like worms. Life cycle direct or indirect ; infection by L ₁ |
| Trichinelloidea <i>Trichinella, etc.</i> | |

simple and slightly thickened posteriorly, as in the bursate nematodes; **bulb-shaped**, with a large posterior swelling, as in the ascarioids; or **double bulb-shaped**, as in the oxyuroids. In some groups this wholly muscular form does not occur: the filarioids and spirooids have a **muscular-glandular** oesophagus which is muscular anteriorly, the posterior part being glandular; the **trichuroid** oesophagus has a capillary form, passing through a single column of cells, the whole being known as a stichosome. A **rhabditiform** oesophagus, with slight anterior and posterior swellings, is present in the preparasitic larvae of many nematodes, and in adult free-living nematodes.

Fig. 1.1 Transverse section of a generalised female nematode.

Fig. 1.2 Longitudinal sections of a generalised nematode. (a) Digestive, excretory and nervous system. (b) Reproductive system of a female nematode. (c) Reproductive system of a male nematode.

The **intestine** is a simple tube descending from the oesophagus whose lumen is enclosed by a single layer of epithelial cells or by a syncytium. The luminal surfaces possess microvilli, which increase the absorptive capacity of the cells. In female worms the intestine terminates in an anus, while in males there is a cloaca which functions as an anus, and into which opens the vas deferens and through which the copulatory spicules may be extruded.

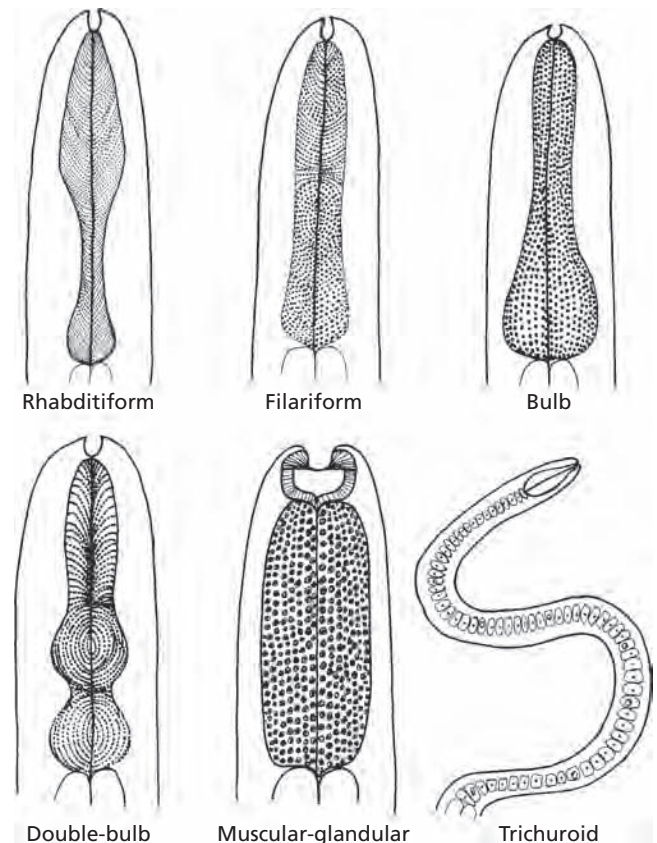

Fig. 1.3 The basic forms of oesophagus found in nematodes.

Fig. 1.4 Male trichostrongylid nematode bursa showing spicules and bursa.

The so-called ‘**excretory system**’ is very primitive, consisting of a canal within each lateral cord joining at the excretory pore in the oesophageal region.

The **reproductive systems** consist of filamentous tubes, which float in the body cavity. The **female organs** comprise ovary, oviduct and uterus, which may be paired (didelphic) or sometimes single (monodelphic), ending in a common short vagina, which opens at the vulva (Fig. 1.2b). The location of the vulva can be a useful aid in diagnosis, being at the anterior end (opisthodelphic), middle (amphidelphic) or the posterior end (prodelphic). At the junction of uterus and vagina in some species there is a short muscular organ, the ovejector, which regulates and assists in egg laying. A vulval flap may also be present. Nematodes can be oviparous, ovoviviparous or viviparous.

The **male organs** consist of a single continuous testis and a vas deferens terminating in a muscular ejaculatory duct into the cloaca (Fig. 1.2c). Accessory male organs are sometimes important in identification, especially of the trichostrongyloids, the two most important being the spicules and gubernaculum (Fig. 1.4). The **spicules** are chitinous organs, usually paired, which are inserted in the female genital opening during copulation. In some species they are absent (e.g. *Trichinella*) or only one spicule is present (e.g. *Trichuris*). The **gubernaculum**, also chitinous, is a small structure located in the dorsal wall, which acts as a guide for the spicules. When the guide is located in the ventral wall it is referred to as a **telamon**. With the two sexes in close apposition the amoeboid sperm are transferred from the cloaca of the male into the uterus of the female.

The **cuticle** may be modified to form various structures (Fig. 1.5), the more important of which include the following.

- **Leaf crowns** consisting of rows of papillae occurring as fringes round the rim of the buccal capsule (external leaf crowns) or just inside the rim (internal leaf crowns). They are especially prominent in certain nematodes of horses. Their function is not known, but it is suggested that they may be used to pin a patch of mucosa in position during feeding, or that they may prevent the entry of foreign matter into the buccal capsule when the worm has detached from the mucosa.

- **Cervical papillae** occur anteriorly in the oesophageal region, and **caudal papillae** posteriorly at the tail. They are spine-like or finger-like processes, and are usually diametrically placed. Their function may be sensory or supportive.
- **Cervical** and **caudal alae** are flattened wing-like expansions of the cuticle in the oesophageal and tail regions respectively.
- **Cephalic** and **cervical vesicles** are inflations of the cuticle around the mouth opening and in the oesophageal region.
- The **copulatory bursa**, which embraces the female during copulation, is important in the identification of certain male nematodes and is derived from much expanded caudal alae, which are supported by elongated caudal papillae called **bursal rays**. It consists of two lateral lobes and a single small dorsal lobe. It is particularly well developed in the strongylids.
- **Plaques** and **cordons** are plate-like and cord-like ornamentations present on the cuticle of many nematodes of the superfamily Spiruroidea.

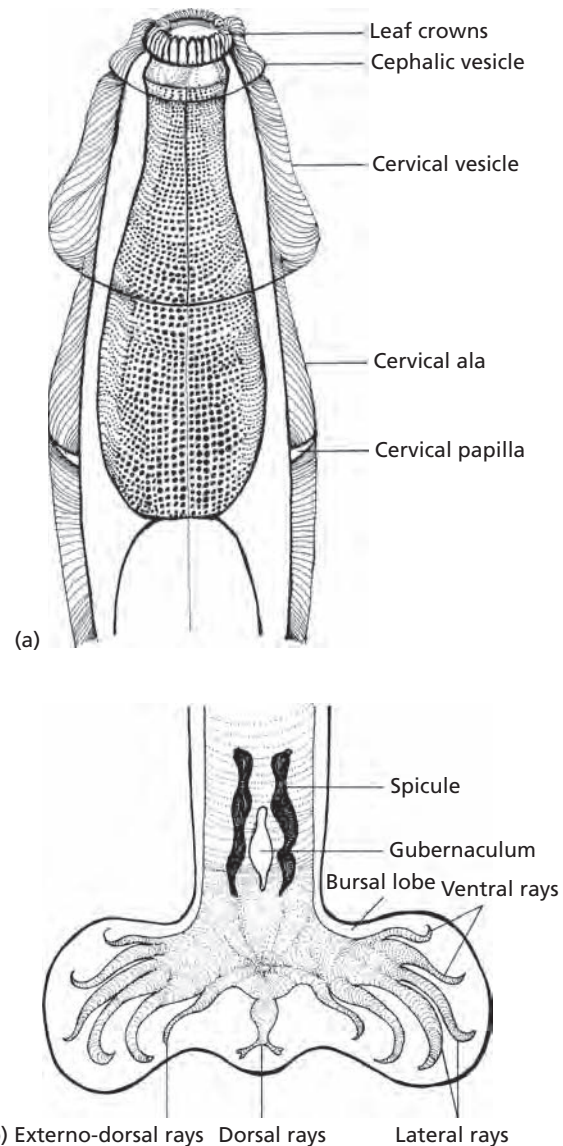

Fig. 1.5 Cuticular modifications of a generalised nematode: (a) anterior region; (b) posterior region of a male.

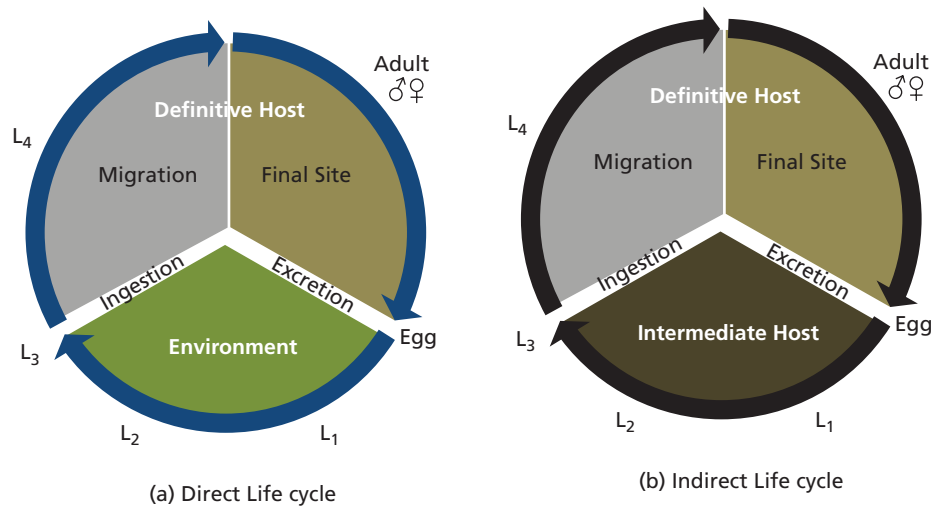

Fig. 1.6 Generalised nematode life cycles: (a) direct; (b) indirect.

BASIC NEMATODE LIFE CYCLE

In the Nematoda, the sexes are separate and the males are generally smaller than the females, which lay eggs or larvae. During development, a nematode moults at intervals, shedding its cuticle. In the complete life cycle there are four moults, the successive larval stages being designated L₁, L₂, L₃, L₄ and finally L₅, which is the immature adult.

One feature of the basic nematode life cycle is that immediate transfer of infection from one **final host** to another rarely occurs. Some development usually takes place either in the faecal pat or in a different species of animal, the **intermediate host**, before infection can take place.

In the common form of **direct** life cycle (Fig. 1.6a), the free-living larvae undergo two moults after hatching and infection is by ingestion of the free L₃ stage. There are some important exceptions however, infection sometimes being by larval penetration of the skin or by ingestion of the egg containing a larva.

In **indirect** life cycles (Fig. 1.6b), the first two moults usually take place in an intermediate host and infection of the final host is either by ingestion of the intermediate host or by inoculation of the L₃ when the intermediate host, such as a blood-sucking insect, feeds.

After infection, two further moults take place to produce the L₅ or immature adult parasite. Following copulation a further life cycle is initiated.

In the case of gastrointestinal parasites, development may take place entirely in the gut lumen or with only limited movement into the mucosa.

However, in many species, the larvae travel considerable distances through the body before settling in their final (predilection) site and this is the migratory form of life cycle. One of the most common routes is the **hepatic-tracheal**. This takes developing stages from the **gut** via the portal system to the **liver** then via the hepatic vein and posterior vena cava to the **heart** and from there via the pulmonary artery to the **lungs**. Larvae then travel via the bronchi, trachea and oesophagus to the **gut**. It should be emphasised that the above is a basic description of nematode life cycles and that there are many variations.

DEVELOPMENT OF THE PARASITE

Egg

Nematode eggs differ greatly in size and shape, and the shell is of variable thickness, usually consisting of three layers.

The inner membrane, which is thin, has lipid characteristics and is impermeable. A middle layer, which is tough and chitinous, gives rigidity and, when thick, imparts a yellowish colour to the egg. In many species this layer is interrupted at one or both ends with an operculum (lid) or plug. The third outer layer consists of protein, which is very thick and sticky in the ascaridoids and is important in the epidemiology of this superfamily.

In contrast, in some species the eggshell is very thin and may be merely present as a sheath around the larva.

The survival potential of the egg outside the body varies, but appears to be connected with the thickness of the shell, which protects the larva from desiccation. Thus parasites whose infective form is the larvated egg usually have very thick-shelled eggs which can survive for years on the ground.

Hatching

Depending on the species, eggs may hatch outside the body or after ingestion.

Outside the body, hatching is controlled partly by factors such as temperature and moisture and partly by the larva itself. In the process of hatching, the inner impermeable shell membrane is broken down by enzymes secreted by the larva and by its own movement. The larva is then able to take up water from the environment and enlarges to rupture the remaining layers and escape.

When the larvated egg is the infective form, the host initiates hatching after ingestion by providing stimuli for the larva, which then completes the process. It is important for each nematode species that hatching should occur in appropriate regions of the gut and hence the stimuli will differ, although it appears that dissolved carbon dioxide is a constant essential.

Larval development and survival

Three of the important superfamilies, the trichostrongyloids, the strongyloids and the rhabditoids, have a completely free-living pre-parasitic phase. The first two larval stages usually feed on bacteria, but the L₃, sealed off from the environment by the retained cuticle of the L₂, cannot feed and must survive on the stored nutrients acquired in the early stages. Growth of the larva is interrupted during moulting by periods of lethargus in which it neither feeds nor moves.

The cuticle of the L₂ is retained as a sheath around the L₃; this is important in larval survival with a protective role analogous to that of the eggshell in egg-infective groups.

The two most important components of the external environment are temperature and humidity. The optimal temperature for the development of the maximum number of larvae in the shortest feasible time is generally in the range 18–26°C. At higher temperatures, development is faster and the larvae are hyperactive, thus depleting their lipid reserves. The mortality rate then rises, so that few will survive to L₃. As the temperature falls the process slows, and below 10°C the development from egg to L₃ usually cannot take place. Below 5°C movement and metabolism of L₃ is minimal, which in many species favours survival.

The optimal humidity is 100%, although some development can occur down to 80% relative humidity. It should be noted that even in dry weather where the ambient humidity is low, the microclimate in faeces or at the soil surface may be sufficiently humid to permit continuing larval development.

In the trichostrongyloids and strongyloids, the embryonated egg and the ensheathed L₃ are best equipped to survive in adverse conditions such as freezing or desiccation; in contrast, the L₁ and L₂ are particularly vulnerable. Although desiccation is generally considered to be the most lethal influence in larval survival, there is increasing evidence that by entering a state of anhydrobiosis, certain larvae can survive severe desiccation.

On the ground most larvae are active, although they require a film of water for movement and are stimulated by light and temperature. It is now thought that larval movement is mostly random and encounter with grass blades accidental.

Infection

As noted previously, infection may be by ingestion of the free-living L₃, and this occurs in the majority of trichostrongyloid and strongyloid nematodes. In these, the L₃ sheds the retained sheath of the L₂ within the alimentary tract of the host, the stimulus for exsheathment being provided by the host in a manner similar to the hatching stimulus required by egg-infective nematodes. In response to this stimulus the larva releases its own exsheathing fluid, containing an enzyme, leucine aminopeptidase, which dissolves the sheath from within, either at a narrow collar anteriorly so that a cap detaches, or by splitting the sheath longitudinally. The larva can then wriggle free of the sheath.

As in the pre-parasitic stage, growth of the larva during parasitic development is interrupted by two moults, each of these occurring during a short period of lethargus.

The time taken for development from infection until mature adult parasites are producing eggs or larvae is known as the **pre-patent period** and this is of known duration for each nematode species.

METABOLISM

The main food reserve of pre-parasitic nematode larvae, whether inside the eggshell or free-living, is lipid, which may be seen as droplets in the lumen of the intestine. The infectivity of these stages is often related to the amount of lipid present; larvae which have depleted their reserves are not as infective as those which still retain quantities of lipid.

Apart from these reserves, the free-living first- and second-stage larvae of most nematodes feed on bacteria. However, once they reach the infective third stage, they are sealed in the retained cuticle of the second stage, cannot feed and are completely dependent on their stored reserves.

In contrast, the adult parasite stores its energy as glycogen, mainly in the lateral cords and muscles, and this may constitute 20% of the dry weight of the worm.

Free-living and developing stages of nematodes usually have an aerobic metabolism, whereas adult nematodes can metabolise carbohydrate by both glycolysis (anaerobic) and oxidative decarboxylation (aerobic). However, in the latter, pathways may operate which are not present in the host and it is at this level that some antiparasitic drugs operate.

The oxidation of carbohydrates requires the presence of an electron transport system, which in most nematodes can operate aerobically down to oxygen tensions of 5.0 mmHg or less. Since the oxygen tension at the mucosal surface of the intestine is around 20 mmHg, nematodes in close proximity to the mucosa normally have sufficient oxygen for aerobic metabolism. Otherwise, if the nematode is temporarily or permanently some distance from the mucosal surface, energy metabolism is probably largely anaerobic.

As well as the conventional cytochrome and flavoprotein electron transport system, many nematodes have 'haemoglobin' in their body fluids which gives them a red pigmentation. This nematode haemoglobin is chemically similar to myoglobin and has the highest affinity for oxygen of any known animal haemoglobin. The main function of nematode haemoglobin is thought to be to transport oxygen, acquired by diffusion through the cuticle or gut, into the tissues; blood-sucking worms presumably ingest a considerable amount of oxygenated nutrients in their diet.

The end products of the metabolism of carbohydrates, fats or proteins are excreted through the anus or cloaca, or by diffusion through the body wall. Ammonia, the terminal product of protein metabolism, must be excreted rapidly and diluted to non-toxic levels in the surrounding fluids. During periods of anaerobic carbohydrate metabolism, the worms may also excrete pyruvic acid rather than retaining it for future oxidation when aerobic metabolism is possible.

The 'excretory system' terminating in the excretory pore is almost certainly not concerned with excretion, but rather with osmoregulation and salt balance.

Two phenomena which affect the normal parasitic life cycle of nematodes and which are of considerable biological and epidemiological importance are **arrested larval development** and the **periparturient rise** in faecal egg counts.

ARRESTED LARVAL DEVELOPMENT

(Synonyms: inhibited larval development, hypobiosis)

This phenomenon may be defined as the temporary cessation in development of a nematode at a precise point in its parasitic development. It is usually a facultative characteristic and affects only a

proportion of the worm population. Some strains of nematodes have a high propensity for arrested development while in others this is low. The stage at which larvae become arrested varies between species of nematodes; for example, L₃ stage in *Trichostrongylus*, Cyathostominae, and *Ancylostoma*, L₄ stage in *Ostertagia*, *Teladorsagia*, *Haemonchus*, and *Obeliscoides*, or immature adults as in *Dictyocaulus*.

Conclusive evidence for the occurrence of arrested larval development can only be obtained by examination of the worm population in the host. It is usually recognised by the presence of large numbers of larvae at the same stage of development in animals withheld from infection for a period longer than that required to reach that particular larval stage.

The nature of the stimulus for arrested development and for the subsequent maturation of the larvae is still a matter of debate. Although there are apparently different circumstances which initiate arrested larval development, most commonly the stimulus is an environmental one received by the free-living infective stages prior to ingestion by the host. It may be seen as a ruse by the parasite to avoid adverse climatic conditions for its progeny by remaining sexually immature in the host until more favourable conditions return. The name commonly applied to this seasonal arrestment is **hypobiosis**. Thus the accumulation of arrested larvae often coincides with the onset of cold autumn/winter conditions in the northern hemisphere, or very dry conditions in the subtropics or tropics. In contrast, the maturation of these larvae coincides with the return of environmental conditions suitable to their free-living development, although it is not clear what triggers the signal to mature and how it is transmitted.

The degree of adaptation to these seasonal stimuli and therefore the proportion of larvae which do become arrested seem to be a heritable trait and is affected by various factors, including grazing systems and the degree of adversity in the environment. For example, in Canada where the winters are severe, most trichostrongyloid larvae ingested in late autumn or winter become arrested, whereas in southern Britain with moderate winters, about 50–60% are arrested. In the humid tropics where free-living larval development is possible all the year round, relatively few larvae become arrested.

However, arrested development may also occur as a result of both acquired and age immunity in the host and, although the proportions of larvae arrested are not usually so high as in hypobiosis, they can play an important part in the epidemiology of nematode infections. Maturation of these arrested larvae seems to be linked with the breeding cycle of the host and occurs at or around parturition.

The epidemiological importance of arrested larval development from whatever cause is that, first, it ensures the survival of the nematode during periods of adversity and, second, the subsequent maturation of arrested larvae increases the contamination of the environment and can sometimes result in clinical disease.

PERIPARTURIENT RISE IN FAECAL EGG COUNTS

(Synonyms: postparturient rise, spring rise)

Periparturient rise (PPR) refers to an increase in the numbers of nematode eggs in the faeces of animals around parturition. This phenomenon is most marked in ewes, goats and sows and recent data support the hypothesis that there is competition for nutrients between the immune system, the rapidly growing fetus in late pregnancy and the udder during lactation, particularly metabolisable

protein. This relaxation of immunity can be largely restored by supplementation with rumen-undegradable protein and is also influenced by the body protein status of the ewe.

The source of the PPR is threefold:

- 1 Maturation of larvae arrested due to host immunity.
- 2 An increased establishment of infections acquired from the pastures and a reduced turnover of existing adult infections.
- 3 An increased fecundity of existing adult worm populations.

Contemporaneously, but not associated with the relaxation of host immunity, the PPR may be augmented by the maturation of hypobiotic larvae.

The importance of the PPR is that it occurs at a time when the numbers of new susceptible hosts are increasing and so ensures the survival and propagation of the worm species. Depending on the magnitude of infection, it may also cause a loss of production in lactating animals and, by contamination of the environment, lead to clinical disease in susceptible young stock.

NEMATODE SUPERFAMILIES

SUPERFAMILY TRICHOSTRONGYLOIDEA

The trichostrongyloids are small, often hair-like, worms in the bursate group, which, with the exception of the lungworm *Dictyocaulus*, parasitise the alimentary tract of animals and birds. Structurally they have few cuticular appendages and the buccal capsule is vestigial and possesses no leaf crowns. Teeth are usually absent. The males have a well developed bursa with large lateral lobes and two spicules, the configuration of which is used for species differentiation. The life cycle is direct and usually non-migratory and the ensheathed L₃ is the infective stage.

The trichostrongylids are responsible for considerable mortality and widespread morbidity, especially in ruminants. The most important alimentary genera are *Ostertagia* (and other members of the subfamily Ostertaginae, *Teladorsagia*, *Spiculoptera*, *Apteria*, *Camelostromylus*), *Haemonchus*, *Trichostrongylus*, *Cooperia*, *Nematodirus*, *Hyostrongylus*, *Marshallagia* and *Mecistocirrus*. *Dictyocaulus* is an important genus affecting the respiratory tract of ruminants and horses.

Other genera of lesser importance are *Graphidium*, *Obeliscoides*, *Ollulanus*, *Libyostrongylus*, *Graphinema*, *Impalaia*, *Ornithostrongylus*, *Amidostomum*, *Epomidiostomum*, *Nematodirella*, *Lamanema*, *Nippostrongylus* and *Nematospirides*.

FAMILY TRICHOSTRONGYLIDAE

Trichostrongylus

Adult worms are small, slightly reddish/brown in colour, slender and hair-like, usually less than 7.0 mm long (Fig 1.7) and difficult to see with the naked eye. The worms have no obvious buccal capsule and cephalic inflations are absent. A most useful generic character is the distinct excretory notch in the oesophageal region (Fig. 1.8). The male bursa has long lateral lobes, while the dorsal lobe is not well defined with a slender dorsal ray, which is cleft near its tip into two branches. The ventro-ventral ray is well separated from the other rays. The spicules are thick and unbranched and a gubernaculum is present. Species identification is based on the shape and size of the spicules (Table 1.3). In the female, the tail is bluntly tapered

Fig. 1.7 Adult *Trichostrongylus* worms.

Fig. 1.8 Characteristic excretory notch in the oesophageal region of *Trichostrongylus*.

Table 1.3 Identification of *Trichostrongylus* spp. based on male spicule morphology.

| Species | Spicules: description | Spicules: morphology |
|---------------------------|--|----------------------|
| <i>T. axei</i> | Spicules are dissimilar and unequal in length (the right being shorter than the left) | (a) |
| <i>T. colubriformis</i> | Thick, brown, unbranched, of equal length and terminate in a barb-like tip | (b) |
| <i>T. vitrinus</i> | Thick, unbranched, of equal length and end in a point | (c) |
| <i>T. longispicularis</i> | The spicules are stout, brown, unbranched, slightly unequal in length and terminate in a tapering blunt tip that has a small semi-transparent protrusion | (d) |
| <i>T. rugatus</i> | Spicules are unequal and dissimilar, bearing transverse ridges near the tip | (e) |
| <i>T. falculatus</i> | Spicules sub-equal – 100 µm long | (f) |
| <i>T. capricola</i> | Spicules are equal in length. Thinner distally than anteriorly and terminate in a rounded tip | (g) |
| <i>T. retortaeformis</i> | Spicules are stout, unequal in length and terminate in a barb-like tip | (h) |

Fig. 1.9 Tail of adult female *Trichostrongylus*.

(Fig. 1.9) and there is no vulval flap and the vulva opens a short distance from the middle of the body. The females possess double ovejectors.

Life cycle: This is direct and the preparasitic phase is typically trichostrongyloid, eggs developing to the infective L₃ in about 7–10 days under optimal conditions. Following ingestion and exsheathment, larvae penetrate the mucosa of the small intestine (Fig. 1.10) and after two moults the fifth-stage worms are present under the intestinal epithelium around 2 weeks after initial infection. The prepatent period is generally 2–3 weeks.

Trichostrongylus species

| Species | Hosts | Site |
|--|--|------------------------------------|
| <i>Trichostrongylus axei</i> (syn. <i>Trichostrongylus extenuatus</i>) | Cattle, sheep, goat, deer, horse, pig | Abomasum or stomach |
| <i>Trichostrongylus colubriformis</i> | Cattle, sheep, goat, camel, rabbit, pig, dog, human | Duodenum, anterior small intestine |
| <i>Trichostrongylus vitrinus</i> | Sheep, goat, camel, deer, rabbit | Duodenum, small intestine |
| <i>Trichostrongylus capricola</i> | Sheep, goat | Small intestine |
| <i>Trichostrongylus falculatus</i> | Sheep, goat, antelope | Small intestine |
| <i>Trichostrongylus longispicularis</i> | Sheep, cattle, goat, camel, deer, llama | Small intestine |
| <i>Trichostrongylus probolurus</i> | Sheep, goat, camel, occasionally human | Stomach, small intestine |
| <i>Trichostrongylus rugatus</i> | Sheep, goat | Small intestine |
| <i>Trichostrongylus retortaeformis</i> | Rabbit, hare | Small intestine |
| <i>Trichostrongylus calcaratus</i> | Rabbit, hare | Small intestine |
| <i>Trichostrongylus affinis</i> | Rabbit, sheep, occasionally human | Small intestine |
| <i>Trichostrongylus tenuis</i> | Gamebirds (grouse, partridge, pheasant), chicken, duck, goose, turkey, emu | Small intestine, caecae |

Trichostrongylus axei

Synonym: *Trichostrongylus extenuatus*

Common name: Stomach hairworm

Description, gross: Males measure around 3–6 mm and females 4–8 mm in length. The male spicules are dissimilar and unequal

Fig. 1.10 Developing *Trichostrongylus vitrinus* in the small intestinal mucosa.

Fig. 1.11 Copulatory bursa and spicule of *Trichostrongylus axei*.

in length, the right being shorter than the left (Table 1.3a and Fig. 1.11).

Trichostrongylus colubriformis

Synonym: *Trichostrongylus instabilis*

Common name: Black scour or bankrupt worm

Description: Males measure around 4.0–5.5 mm and females 5.5–7.5 mm in length. The spicules are thick, brown, unbranched, of equal length and terminate in a barb-like tip (Table 1.3b and Fig. 1.12). The female has double ovejectors.

Fig. 1.12 Copulatory bursa and spicule of *Trichostrongylus colubriformis*.

Fig. 1.13 Copulatory bursa and spicule of *Trichostrongylus vitrinus*.

Trichostrongylus vitrinus

Common name: Black scour worm

Description: Males measure around 4–6 mm and females 5–8 mm in length. The spicules are thick, unbranched, of equal length and end in a point (Table 1.3c and Fig. 1.13).

Trichostrongylus capricola

Description: Males measure around 4–5 mm and females 6–7 mm in length. The male spicules are of equal length, thicker anteriorly than distally and end in a rounded tip (Table 1.3g).

Trichostrongylus falculatus

Description: Males measure around 4.5–5.5 mm. The spicules are thick, brown, of almost equal length with a sickle-shaped offshoot (Table 1.3f). The gubernaculum is bent anteriorly at right angles.

Trichostrongylus longispicularis

Description: Males are around 5.5 mm in length. The spicules are stout, brown, unbranched, and slightly unequal in length terminating in a tapering blunt tip that has a small semi-transparent membranous protrusion (Table 1.3d).

Trichostrongylus probolurus

Description: Males are 4.5–6.5 mm and females 6–7.5 mm in length. The spicules are large and of equal size with two triangular projections.

Trichostrongylus rugatus

Description: Males are 4.5–5.5 mm and females 4.5–7.0 mm in length. The spicules differ in size and dimensions and have a complex form with transverse ridges near the tip of the spicule (Table 1.3e).

Trichostrongylus retortaeformis

Description: Males measure around 5.5–7 mm and females 7–9 mm in length. The spicules are short, large and curved with two thin offshoots (Table 1.3h).

Trichostrongylus calcaratus

Description: The adults are small, white and hair-like, usually less than 7.0 mm long. Male worms have an asymmetrical dorsal ray and two short nearly equal spicules.

Trichostrongylus affinus

Description: Males measure 5–7.5 mm and females 8.5–9 mm in length. The male spicules are short, broad, and equal in length, bent ventrally and taper distally into two blunt hooks.

Trichostrongylus tenuis

Description: Males measure around 5.0–6.5 mm and females 7–9 mm in length. The spicules are curved distally and possess an auricular offshoot anteriorly.

Life cycle: The prepatent period is short (7–10 days).

Marshallagia

Similar to *Ostertagia* spp. and can be differentiated by its greater length (males 10–13 mm; females 15–20 mm).

Life cycle: The life cycle is similar to *Ostertagia* except that L₂ can hatch from the egg. Following ingestion, larvae burrow into the abomasal mucosa and form small greyish white nodules, which may contain several developing parasites. The young L₅ emerge from the nodules around day 16 post infection and egg-laying is usually apparent by 3 weeks. Arrested development of larvae can occur.

Marshallagia species

| Species | Hosts | Site |
|-------------------------------|--------------------------|----------|
| <i>Marshallagia marshalli</i> | Sheep, goat, deer, camel | Abomasum |

Marshallagia marshalli

Synonym: *Ostertagia tricuspis*, *Ostertagia marshalli*

Description: The male bursa has a long thin dorsal ray, which bifurcates near the posterior extremity (Fig. 1.14). The end of the yellowish-brown spicule is divided into three small processes (Fig. 1.15). The ellipsoidal eggs are much larger than other trichostrongyloid species (>150 µm) and resemble those of *Nematodirus battus* (see Fig. 4.3).

Hyostrogylus

Slender reddish worms when fresh, with males measuring around 5–7 mm and females 6–10 mm in length (Fig. 1.16). The body cuticle is both transversely and longitudinally striated with 40–45 longitudinal striations.

Life cycle: The free-living and parasitic stages are similar to those of *Ostertagia* in cattle; infection is through oral ingestion of L₃. The pre-patent period is about 3 weeks. Hypobiosis of L₄ may occur following repeated infection, or be induced by seasonal changes, and is often seen in older animals. In sows these hypobiotic larvae may resume their development during the periparturient relaxation of immunity and/or early lactation, leading to an increase in the faecal egg count.

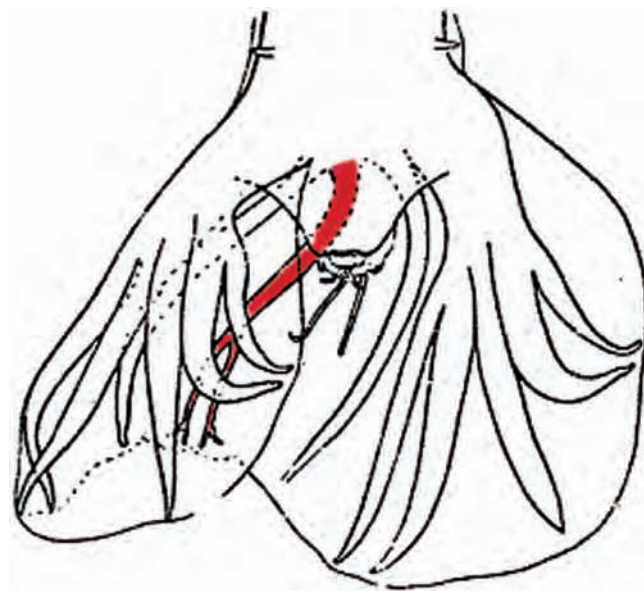

Fig. 1.14 Copulatory bursa of *Marshallagia marshalli* highlighting long thin bifurcating dorsal ray. (Redrawn from Ransom, 1907.)

Fig. 1.15 Spicules of *Marshallagia marshalli*. (Redrawn from Ransom, 1907.)

Fig. 1.16 Adult worms of *Hyostrogylus rubidus*.

Hyostrogylus species

| Species | Hosts | Site |
|-----------------------------|-------|---------|
| <i>Hyostrogylus rubidus</i> | Pig | Stomach |

Hyostrogylus rubidus

Description: A small cephalic vesicle is present. The bursa of the male is well developed and the dorsal lobe is small. There is a well-developed narrow telamen and the spicules are equal, short, thinning distally and bifurcate into two branches. It is usually the only bursate nematode located in the pig stomach.

Mecistocirrus

Worms of this genus are similar in appearance to *Haemonchus contortus*, except that in the female the slit-shaped flapless vulva is located close to the anus. The males measure up to around 30 mm and the females 42 mm in length. The cuticle contains many longitudinal ridges and the paired cervical papillae are readily apparent. The small buccal capsule is armed with a small lancet. In the female the ovaries are spirally coiled round the intestine, similar to *Haemonchus*. The male spicules are thin and long and in the bursa the dorsal ray is located symmetrically.

Life cycle: This is direct and similar to that of *Haemonchus*. The prepatent period is longer than in *Haemonchus*, being 60–80 days, partly the result of the longer duration of the fourth stage in the abomasal mucosa.

Mecistocirrus species

| Species | Hosts | Site |
|--------------------------------|-----------------------------------|----------|
| <i>Mecistocirrus digitatus</i> | Cattle, buffalo, sheep, goat, pig | Abomasum |

Mecistocirrus digitatus

Description: The spicules are long and narrow and fused together for the majority of their length and the tips are surrounded by a spindle-shaped tube. In the female the vulva is positioned near the tip of the tail and there is no vulval flap.

Graphidium

Stomach worms of lagomorphs found throughout Europe.

Life cycle: The life cycle is direct. Infection is by ingestion of infective larvae, which develop to the adult stage in the stomach in about 12 days.

Graphidium species

| Species | Hosts | Site |
|-----------------------------|--------------|--------------------------|
| <i>Graphidium strigosum</i> | Rabbit, hare | Stomach, small intestine |

Graphidium strigosum

Description: Adults are reddish worms when fresh. The male is 8–16 mm and the female 11–20 mm in length. The cuticle possesses 40–60 longitudinal lines and thin transverse striations. The lateral lobes of the bursa are large and the dorsal lobe small. The long slender spicules terminate in several branched points.

Obeliscoides

This genus contains several species of worms found in a number of rabbit species in the USA.

Life cycle: The life cycle is direct. Infection is by ingestion of infective larvae, which develop to the adult stage in the stomach in about 19 days.

Obeliscoides species

| Species | Hosts | Site |
|------------------------------|--|---------|
| <i>Obeliscoides cuniculi</i> | Rabbit, hare. Occasionally white-tailed deer | Stomach |

Obeliscoides cuniculi

Description: Adults are red-brownish in colour and males measure 10–16 mm and the females 15–18 mm in length. The brown spicules are bifurcated at their distal tips and terminate in a hook. The female worm tapers in the distal 20% of the body.

Libyostrongylus

Parasites of ratites (ostrich) commonly referred to as ‘wireworms’ found in the proventriculus and gizzard.

Life cycle: The life cycle is typically strongyle. Following ingestion, infective larvae burrow into the proventricular glands and under the kaolin layer of both the proventriculus and gizzard where they develop into adult worms 4–5 weeks later. Eggs which contain fully developed larvae are very resistant to desiccation and can survive a couple of years.

Libyostrongylus species

| Species | Hosts | Site |
|----------------------------------|---------|-------------------------|
| <i>Libyostrongylus douglassi</i> | Ostrich | Proventriculus, gizzard |
| <i>Libyostrongylus dentatus</i> | Ostrich | Proventriculus, gizzard |

Libyostrongylus douglassi

Description: Small yellowish-red nematodes, males 4–6 mm and females 5–6 mm in length. The male bursa is well developed; the dorsal ray is long and split in its distal half forming three small branches either side. The spicules each terminate in a large and small spine.

Libyostrongylus dentatus

Description: Males worms are 6–8 mm and females 10–12 mm in length. There is a prominent dorsal, oesophageal tooth. The male has a large bursa; the dorsal ray is long and bifurcated extending into a rounded lobe of the bursal membrane. The spicules have a dorsal process arising two-thirds from the anterior and the main shaft ending in a rounded point capped by a hyaline sheath.

Graphinema

Graphinema species

| Species | Hosts | Site |
|-----------------------------|---------------|----------|
| <i>Graphinema aucheniae</i> | Llama, vicuna | Abomasum |

Graphinema aucheniae

Description: Male worms measure 5.5–8.0 mm and females 9–12 mm in length. These worms have a small buccal capsule, a

claviform oesophagus and cervical papillae. The male bursa has a small antero-ventral ray and a widely divergent posteroventral ray. The dorsal ray bifurcates near the distal tip, with each branch dividing distally. The spicules are long and pointed.

Life cycle: Similar to that of other trichostrongyles.

Impalaia

Impalaia species

| Species | Hosts | Site |
|-----------------------------|-------|----------|
| <i>Impalaia tuberculata</i> | Camel | Abomasum |
| <i>Impalaia nudicollis</i> | Camel | Abomasum |

Impalaia tuberculata

Description: Males are 7–9 mm and females 14–18 mm long. The cervical cuticle is studded with papillae. Spicules are equal in length, slender and with a fine pointed end.

Impalaia nudicollis

Description: Males are 7.5–8.2 mm and females 14.8–16.7 mm long. Males have long spicules and a long gubernaculum.

SUBFAMILY OSTERTAGINAE

Species within the subfamily Ostertaginae are considered together as they form a large and complex group, the taxonomy of which has not been fully elucidated. Some species names are considered synonymous and species polymorphism is commonly reported. The adults are slender reddish-brown worms up to 1.0 cm long, occurring on the surface of the abomasal mucosa and are only visible on close inspection (Fig. 1.17). They possess a short buccal cavity and a very small pair of cervical papillae. The short spicules are brown in colour and terminate in two or three processes, depending on the species. In the female the vulva can be covered with a flap or this may be absent and the tip of the tail is annulated. The larval stages

Fig. 1.17 *Ostertagia ostertagi* on the abomasal mucosa.

occur in the gastric glands and can only be seen microscopically following processing of the gastric mucosa. Species differentiation is generally based on the structure of the male spicules. These worms occur in cattle, sheep and other ruminants.

Life cycle: Eggs are passed in the faeces and, under optimal conditions, develop within the faecal pat to the infective third stage within 2 weeks. When moist conditions prevail, the L₃ migrate from the faeces on to the herbage. After ingestion, the L₃ exsheaths in the rumen and further development takes place in the lumen of an abomasal gland. Two parasitic moults occur before the L₅ emerges from the gland around 18 days after infection to become sexually mature on the mucosal surface. The entire parasitic life cycle usually takes 3 weeks, but under certain circumstances many of the ingested L₃ become arrested in development at the early fourth larval stage (EL₄) for periods of up to 6 months (also referred to as hypobiosis).

Ostertagia ostertagi

Morph species: *Ostertagia* (syn. *Skrjabinagia*) *lyrata*

Description: Adults are slender reddish-brown worms with a short buccal cavity. Males measure 6–8 mm and females 8–11 mm in length. The cuticle in the anterior region is striated transversely whereas the rest of the body is unstriated and bears around 30 longitudinal ridges.

- *Ostertagia ostertagi*. The spicules are divided in the posterior region where two thin lateral branches arise from the main stem (Table 1.4a). The bursa is small and the accessory bursal membrane is supported by two divergent rays (Fig. 1.18). In the female, the vulva is sited about 1.5 mm from the posterior and is covered with a flap (Fig. 1.19).
- *Ostertagia lyrata*. The spicules are stout and divided into three branches posteriorly. The main branch is solid and ends in a shoe-like expansion. One lateral branch is thick and massive, terminating in a hat-like expansion; the other is small and pointed (Table 1.4b and Fig. 1.20). The gubernaculum is spindle-shaped.

Ostertagia species (subfamily Ostertaginae)

| Species | Hosts | Site |
|---|---|----------|
| <i>Ostertagia ostertagi</i> <i>Ostertagia</i> (syn. <i>Skrjabinagia</i>) <i>lyrata</i> | Cattle, deer, rarely goat | Abomasum |
| <i>Ostertagia leptospicularis</i> (syn. <i>Ostertagia crimensis</i>) <i>Skrjabinagia</i> (<i>Ostertagia</i>) <i>kolchida</i> (syn. <i>Grosspiculagia podjapolskyi</i>) | Deer, cattle, sheep and goat | Abomasum |
| <i>Teladorsagia circumcincta</i> <i>Ostertagia trifurcata</i> <i>Teladorsagia davtianii</i> | Sheep, goat, deer, camel, llama | Abomasum |
| <i>Spiculoptera spiculoptera</i> (syn. <i>Apteragia spiculoptera</i> , <i>Rinadia spiculoptera</i> , <i>Mazamostrongylus spiculoptera</i>) | Deer (red deer, fallow deer, roe deer), cattle, sheep, goat | Abomasum |
| <i>Spiculoptera asymmetrica</i> (syn. <i>Ostertagia asymmetrica</i> , <i>Apteragia asymmetrica</i> , <i>Rinadia asymmetrica</i> , <i>Mazamostrongylus asymmetrica</i>) | Deer (roe deer, sika deer, fallow deer) | Abomasum |
| <i>Apteragia quadrispiculata</i> | Deer (roe deer, sika deer, fallow deer) | Abomasum |
| <i>Spiculoptera</i> (<i>Apteragia</i>) <i>bohmi</i> <i>Spiculoptera</i> (<i>Rinadia</i>) <i>mathevossiani</i> | Mouflon, deer (fallow deer, roe deer) | Abomasum |
| <i>Spiculoptera peruvianus</i> | Llama, vicuna | Abomasum |

Table 1.4 Identification of Ostertaginae based on male spicule morphology.

| Species | Spicules: description | Spicules: morphology |
|-----------------------------------|---|---|
| <i>Ostertagia ostertagi</i> | The spicules are of equal length and shape, tapering towards the distal end into three processes | (a)  |
| <i>Ostertagia lyrata</i> | The spicules are stout and divided into three branches posteriorly. The main branch is solid and ends in a shoe-like expansion. One lateral branch is thick and massive terminating in a hat-like expansion; the other is small and pointed | (b)  |
| <i>Ostertagia leptospicularis</i> | The spicules are slender, of equal length and shape tapering towards the distal end into three processes, with the two lateral branches extremely fine and pointed | (c)  |
| <i>Skryabinagia kolchida</i> | The spicules are of equal length and shape tapering towards the distal end into three branches terminating in an 'ice-skate' like structure. The medial branch is the shortest and truncated | (d)  |
| <i>Teladorsagia circumcincta</i> | Spicules are variable in length but normally long and thin. The posterior end is split into two branches of equal length. A third short offshoot, not readily seen, arises in front of the bifurcation | (e)  |
| <i>Ostertagia trifurcata</i> | Spicules are short and broad; the posterior end is divided into three processes, one long and thick with a truncated end, and two short slender branches each tapering to a point | (f)  |
| <i>Spiculoptera spiculoptera</i> | The spicules are of equal length, bifurcating distally where it contains a cavity and distally ending in a fan-shaped expansion | (g)  |
| <i>Spiculoptera bohmi</i> | Spicules of equal size but asymmetrical. The right spicule divides into into three branches and the left spicule into two branches | (h)  |

Fig. 1.20 Male bursa and spicules of *Ostertagia lyrata*.

Fig. 1.21 Male bursa and spicules of *Ostertagia leptospicularis*.

Ostertagia leptospicularis

Synonym: *Ostertagia crimensis*

Morph species: *Skrjabinagia (Ostertagia) kolchida* (syn. *Grosspiculagia podjapolskyi*)

Description: Adults are slender reddish-brown worms with a short buccal cavity. Males measure 6–8 mm and females 8–9 mm in length. Distinguished from other ostertagian species by the length of the oesophagus, which is longer (0.7 mm compared with approximately 0.6 mm in other species). In cattle, the worms are thinner than *O. ostertagi* and male worms are differentiated on spicule morphology.

- *Ostertagia leptospicularis*. The spicules are of equal length and shape, tapering towards the distal end into three processes (Table 1.4c and Fig. 1.21). The gubernaculum is racket-shaped.
- *Skrjabinagia kolchida*. The spicules are of equal length and shape, tapering towards the distal end into three branches terminating in a shoe-like structure (Table 1.4d and Fig. 1.22). The medial branch is the shortest and truncated. The gubernaculum is longer than in *O. leptospicularis* and twisted.

Teladorsagia circumcincta

Synonym: *Ostertagia circumcincta*

Morph species: *Ostertagia trifurcata*, *Teladorsagia davtiani*

Description: Adults are slender reddish-brown worms with a short buccal cavity. Males measure 6–8 mm and females 8–10 mm.

- *Teladorsagia circumcincta*. The lateral lobes of the bursa are well developed but the dorsal lobe is small; a telamon is present in the genital cone; the accessory bursal membrane is small, and supported by two divergent rays (Fig. 1.23). Spicules are variable in length but normally long and thin (Table 1.4e and Fig. 1.24a). The posterior end is split into two branches of equal length. A third short offshoot,

Fig. 1.22 Male bursa and spicules of *Skrjabinagia kolchida*.

not readily seen, arises in front of the bifurcation. The gubernaculum is racket-shaped. In the female, the vulva is usually covered with a large flap and opens near the posterior of the body.

- *Ostertagia trifurcata*. The bursa is longer than in *T. circumcincta*. The lateral lobes of the bursa are well developed, and the dorsal lobe is small (Fig. 1.25). A well-developed telamon is present in the genital cone. The accessory bursal membrane is modified to form Sjöberg's organ supported by two rays. The spicules are

Fig. 1.23 Male bursa and spicules of *Teladorsagia circumcincta*.

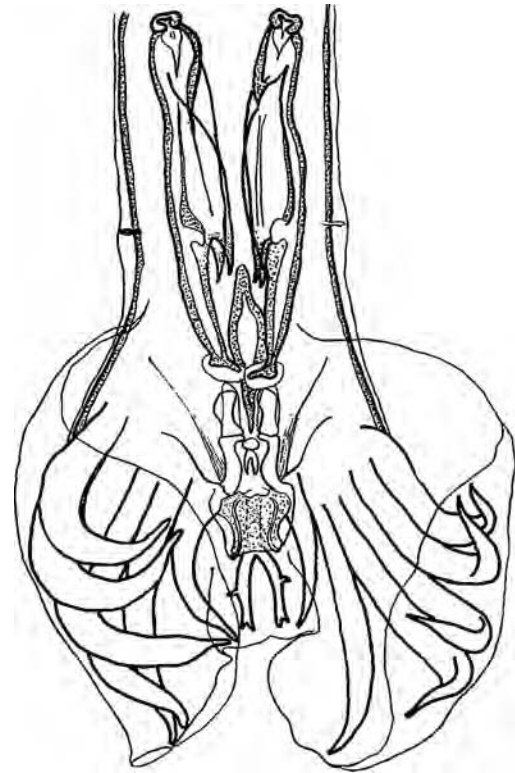

Fig. 1.25 Male bursa and spicules of *Ostertagia trifurcata*.

Fig. 1.24 Comparison of spicules of (a) *Teladorsagia circumcincta* and (b) *Ostertagia trifurcata*. Those of *T. circumcincta* are long and thin whereas *O. trifurcata* spicules are short and broad.

short and broad (Table 1.4f and Fig. 1.25) with the posterior ends divided into three processes, one long and thick with a truncated end, and two short slender branches each tapering to a point. The gubernaculum is somewhat spindle-shaped.

- *Teladorsagia davtiani*. This morph species is similar in appearance to *O. trifurcata*. The accessory bursal membrane is modified to form Sjöberg's organ and resembles a pair of sessile papillae on the posterior extremity of the genital cone (Fig. 1.26).

Spiculoptera spiculoptera

Synonyms: *Apteragia spiculoptera*, *Rinadia spiculoptera*, *Mazamostrongylus spiculoptera*

Description: The spicules are of equal length, bifurcating distally where it contains a cavity, and distally ending in a fan-shaped expansion (Table 1.4g). The gubernaculum is absent.

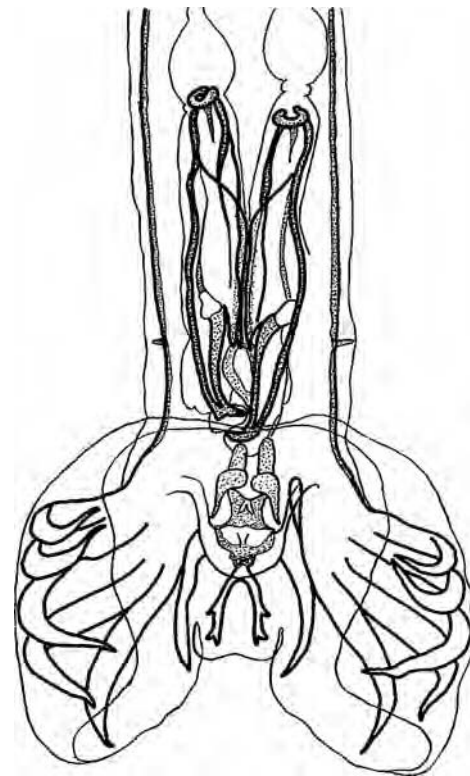

Fig. 1.26 Male bursa and spicules of *Teladorsagia davtiani*.

Spiculopteragia asymmetrica

Synonyms: *Ostertagia asymmetrica*, *Apteragia asymmetrica*, *Rinadia asymmetrica*, *Mazamostrongylus asymmetrica*

Description: Males measure 4.5–6 mm. Spicules are distally asymmetrical and pointed, with a T-shaped offshoot near the distal end of the right spicule. The gubernaculum is small and boat-shaped.

Apteragia quadrispiculata

Description: Males measure 6–8.5 mm. Spicules possess four branches distally.

Spiculopteragia bohmi

Synonym: *Apteragia bohmi*, *Rinadia bohmi*, *Mazamostrongylus bohmi*, *Ostertagia bohmi*

Morph species: *Spiculopteragia (Rinadia) mathevossiani*

Description: Males measure 6–7 mm.

- *Spiculopteragia bohmi*. Spicules of equal size but asymmetrical. The right spicule divides into three branches and the left spicule into two branches (Table 1.4h). The gubernaculum is absent.
- *Spiculopteragia mathevossiani*. The spicules have asymmetrical distal thirds each ending in three branches. The gubernaculum is absent.

Spiculopteragia peruvianus

Description: Males measure 6.5–8.0 mm and females 8.5–10 mm in length.

Camelostrongylus

Camelostrongylus species

| Species | Hosts | Site |
|------------------------------------|--------------------|---------------------------|
| <i>Camelostrongylus mentulatus</i> | Camel, sheep, goat | Abomasum, small intestine |

Camelostrongylus mentulatus

Synonym: *Ostertagia mentulatus*

Description: Males measure 6.5–7.5 mm. The spicules are long and narrow, bifurcating into pincer-like ends with one end shorter, and the longer end forming a hammer-like hook (Fig 1.27).

SUBFAMILY HAEMONCHINAE

Haemonchus

The adults are easily identified because of their specific location in the abomasum and their large size (2.0–3.0 cm). In fresh female specimens, the white ovaries winding spirally around the

Fig. 1.27 Male bursa and spicule of *Camelostrongylus mentulatus*. (Redrawn from Skrjabin *et al.*, 1954.)

Fig. 1.28 Adult male and female worms of *Haemonchus contortus* on the abomasal mucosa.

blood-filled intestine produce a ‘barber’s pole’ appearance (Fig 1.28). The buccal cavity is small and contains a small lancet-like tooth. The anterior body possesses prominent cervical papillae. The vulva is usually protected by a cuticular flap which can have a range of shapes. In the male the lateral lobes of the bursa are large, whereas the dorsal ray is small and asymmetrical.

Life cycle: This is direct and the preparasitic phase is typically trichostrongyloid. The females are prolific egg layers. The eggs hatch to L₁ on the pasture and may develop to L₃ in as short a period as 5 days but development may be delayed for weeks or months under cool conditions. After ingestion, and exsheathment in the rumen, the larvae moult twice in close apposition to the gastric glands. Just before the final moult they develop the piercing lancet which enables them to obtain blood from the mucosal vessels. As adults they move freely on the surface of the mucosa. The prepatent period is 2–3 weeks in sheep and 4 weeks in cattle.

Haemonchus species

| Species | Hosts | Site |
|---|--|----------|
| <i>Haemonchus contortus</i> (syn. <i>Haemonchus placei</i>) | Sheep, goat, cattle, deer, camel, llama | Abomasum |
| <i>Haemonchus similis</i> | Cattle, deer | Abomasum |
| <i>Haemonchus longistipes</i> | Camel, sheep | Abomasum |

Haemonchus contortus

Synonym: *Haemonchus placei*

Description: Males are about 10–22 mm and females 20–30 mm in length. The male has an asymmetrical dorsal lobe and barbed spicules (Fig. 1.29a); the female usually has a prominent vulval flap. In both sexes there are cervical papillae (Fig. 1.29b) and a tiny lancet inside the buccal capsule.

Notes: Until recently the sheep species was *H. contortus* and the cattle species *H. placei*. However, there is now increasing evidence that these are the single species *H. contortus* with only strain adaptations for cattle and sheep.

Fig. 1.29 (a) Barbed spicules and bursa of a mature *Haemonchus contortus* male worm. (b) Anterior of *H. contortus* showing the position of the cervical papillae.

Haemonchus similis

Description: The adults are 2.0–3.0 cm and reddish in colour. The male has an asymmetrical dorsal lobe and barbed spicules, differing from *H. contortus* in that the terminal processes of the dorsal ray are longer and the spicules shorter.

Haemonchus longistipes

Description: Adults are about 1–3 cm in size. The spicules are thin with small lateral processes at the distal ends and are much longer than in the other species.

FAMILY COOPERIDAE**Cooperia**

Relatively small worms (usually less than 9 mm long), which appear pinkish-white when fresh. The main generic features are the small cephalic vesicle and the marked transverse cuticular striations in the oesophageal region (Fig. 1.30). The body possesses longitudinal ridges. The male bursa is relatively large compared to the size of the body. It has a small dorsal lobe, and the brown-coloured spicules are short and stout with distinct wing-like expansions in the middle region, which often bear transverse ridged striations (except in *C. surnabada*) (see Table 1.5). There is no gubernaculum. The females have a long tapering tail and the vulva may be covered by a vulval flap and is located posterior to the middle of the body.

Life cycle: The life cycle is direct and typical of the superfamily. Ingested L₃ exsheath, migrate into the intestinal crypts for two moults and then the adults develop on the surface of the intestinal mucosa. The prepatent period is 2–3 weeks. The bionomic requirements of the free-living stages are similar to those of *Teladorsagia*.

Fig. 1.30 Anterior of *Cooperia* spp showing the cephalic vesicle and cuticular striations.

Table 1.5 Identification of *Cooperia* spp. based on male spicule morphology.

| Species | Spicules: description | Spicules: morphology |
|---------------------------|---|--|
| <i>Cooperia oncophora</i> | Spicules are 240–300 µm long and have a longitudinal line pattern with the distal end rounded and bearing cuticular formations | (a)  |
| <i>Cooperia curticei</i> | Spicules are equal in length (135–145 µm) and have a central protruberance with a transverse striation and end in a rounded 'disc-like' structure | (b)  |
| <i>Cooperia surnabada</i> | The spicules are 270 µm long and thin with a posterior bifurcation into an external branch with small conical appendage; and an internal branch that is shorter and pointed | (c)  |
| <i>Cooperia punctata</i> | Spicules are short (120–150 µm) and bear a large protruberance at the distal half, tapering to a slightly blunted point | (d)  |
| <i>Cooperia pectinata</i> | Spicules are 240–280 µm long with a large protruberance centrally, and are bent ventrally, with a wrinkled inner surface | (e)  |

Cooperia species

| Species | Hosts | Site |
|--|---|-----------------|
| <i>Cooperia oncophora</i> | Cattle, sheep, goat, deer, camel | Small intestine |
| <i>Cooperia curticei</i> | Sheep, goat, deer (red deer, fallow deer) | Small intestine |
| <i>Cooperia punctata</i> | Cattle, deer, rarely sheep | Small intestine |
| <i>Cooperia pectinata</i> | Cattle, deer, rarely sheep | Small intestine |
| <i>Cooperia surnabada</i> (syn. <i>Cooperia mcmasteri</i>) | Cattle, sheep, goat, camel | Small intestine |

Cooperia oncophora

Description: In size, *C. oncophora* is similar to *Ostertagia* but with a large bursa. Males measure around 5.5–9 mm and females 6–8 mm in length. Spicules have a longitudinal line pattern with the distal end rounded and bearing cuticular formations (Table 1.5a).

Cooperia curticei

Description: *Cooperia curticei* is moderately small with a large bursa. Males measure around 4.5–6.0 mm and females 6.0–8.0 mm in length. The most notable feature is the 'watch spring-like' posture. Spicules are equal in length and have a central protruberance with a transverse striation and end in a rounded 'disc-like' structure (Table 1.5b).

Cooperia surnabada

Synonym: *Cooperia mcmasteri*

Description: The males measure around 7 mm and the females 8 mm in length. The appearance is very similar to *C. oncophora*, although the bursa is larger and the bursal rays tend to be thinner. The spicules are thinner with a posterior bifurcation into an external branch with a small conical appendage; and an internal branch that is shorter and pointed (Table 1.5c).

Cooperia punctata

Description: Males measure around 4.5–6.0 mm and females 6–8 mm in length. Spicules are short and bear a large protruberance at the distal half, tapering to a slightly blunted point (Table 1.5d).

Cooperia pectinata

Description: Males measure around 7–8 mm and females 7.5–10 mm in length. Spicules bear a protruberance centrally and are bent ventrally, with a wrinkled inner surface (Table 1.5e).

FAMILY ORNITHOSTRONGYLIDAE
Ornithostromylus

The adult worms, which measure up to 2.5 cm, are bloodsuckers, have a reddish colour and can be seen by the naked eye.

Life cycle: The life cycle is direct and typically trichostrongyle.

***Ornithostromylus* species**

| Species | Hosts | Site |
|--|--------------|---------------------------------------|
| <i>Ornithostromylus quadriradiatus</i> | Pigeon, dove | Crop, proventriculus, small intestine |

Ornithostromylus quadriradiatus

Description: Males measure 9–12 mm and females 18–24 mm in length. The cuticle of the head is slightly inflated and the body bears longitudinal cuticular ridges. In the male bursa, the ventral rays are close together and the dorsal ray is short and the telamon is cross-like in appearance. Spicules terminate in three pointed processes. The female tail is truncated and terminates in a small spine.

FAMILY AMIDOSTOMIDAE
Amidostomum

The slender adult worms, bright red in colour when fresh and up to 2.5 cm in length, are easily recognised at necropsy where they predominate in the horny lining of the gizzard (Fig. 1.31). These worms have a shallow buccal cavity and do not possess leaf crowns. Three longitudinal ridges/plates line the oesophagus.

Life cycle: Direct and similar to other strongyles. Infection is via ingestion of L₃, or through skin penetration. Eggs passed in the faeces

Fig. 1.31 Adult worms of *Amidostomum anseris*.

are already embryonated and develop to the L₃ in the egg. Ingested larvae penetrate the submucosa of the gizzard. Patency is around 2–3 weeks in geese.

Amidostomum species

| Species | Hosts | Site |
|--|-------------|---------|
| <i>Amidostomum anseris</i> (syn. <i>Amidostomum nodulosum</i>) | Goose, duck | Gizzard |
| <i>Amidostomum acutum</i> (syn. <i>Amidostomum skrjabini</i>) | Duck | Gizzard |

Amidostomum anseris

Synonym: *Amidostomum nodulosum*

Description: Males measure about 10–17 mm and female worms 15–25 mm in length. Worms are characterised by a shallow buccal capsule with three pointed teeth in the base, the middle tooth being the largest. The male spicules are of equal length and are divided into two branches at the distal end.

Amidostomum acutum

Synonym: *Amidostomum skrjabini*

Description: Characterised by a shallow buccal capsule with one pointed tooth. The spicules have two to three branches at the distal end.

Epomidiostomum

These worms are similar to *Amidostomum* but smaller.

Epomidiostomum species

| Species | Hosts | Site |
|---|-------------------|---------------------|
| <i>Epomidiostomum uncinatum</i> (syn. <i>Epomidiostomum anatinum</i> , <i>Strongylus uncinatus</i> , <i>Amidostomum anatinum</i>) | Duck | Gizzard |
| <i>Epomidiostomum orispinum</i> (syn. <i>Strongylus anseris</i> , <i>Strongylus orispinum</i>) | Duck, goose, swan | Gizzard, oesophagus |
| <i>Epomidiostomum skrjabini</i> | Goose | Gizzard |

Epomidiostomum uncinatum

Synonyms: *Epomidiostomum anatinum*, *Strongylus uncinatus*, *Amidostomum anatinum*

Description: Males measure about 10 mm and females 15 mm in length. Teeth are absent from the rudimentary buccal capsule. The cuticle bears distinct thickenings, 'epaulettes', at the anterior end and tooth-like projections form a fringe around the mouth. The posterior of the female is rounded and has a small button-shaped tip. Three branches occur on each spicule.

Epomidiostomum orispinum

Synonyms: *Strongylus anseris*, *Strongylus orispinum*

Description: Males measure around 11 mm and females 16 mm in length. The anterior of the worm possesses four posteriorly pointing offshoots and lateral festoons bearing a pair of papillae. Spicules are equal with three shafts pointing distally. The body of the female tapers abruptly, towards the digitate tail.

Epomidiostomum skrjabini

Description: The size of the males and females is similar to that of *E. orispinum*. The head of the worm possesses a cuticular prominence which is armed with four symmetrical, lateral-pointing spines. There are also two epaulette formations. The mouth is surrounded by four small spines. The bursa has three lobes, the central lobe being poorly developed. Spicules are equal and the posterior ends are split into three sharp-tipped branches. The anterior ends are blunt. The female tail terminates in a finger-like appendage, which is bent ventrally.

FAMILY MOLINEIDAE

Nematodirus

Adult worms are whitish, slender, and relatively long, with the anterior thinner than the posterior region. They may appear slightly coiled. Adult males are 10–15 mm and females 15–24 mm in length. A small, but distinct, cephalic vesicle is present (Fig 1.32) and the cuticle possesses about 14–18 longitudinal ridges. The male bursa has elongate lateral lobes and the spicules are long and slender; the tips of the spicules are fused together and terminate in a small expansion, which varies in shape and is a useful feature for species differentiation (Table 1.6). The ventral rays are parallel and are situated close together. The female worm has a short tail with a slender terminal appendage. The eggs are large and readily distinguishable from other trichostrongylid species.

Life cycle: The preparasitic phase is almost unique in the trichostrongyloids in that development to the L₃ stage takes place within the eggshell. Species differences occur regarding the critical hatching requirements.

Nematodirus species

| Species | Hosts | Site |
|---------------------------------|----------------------------------|-----------------|
| <i>Nematodirus battus</i> | Sheep, goat, occasionally cattle | Small intestine |
| <i>Nematodirus filicollis</i> | Sheep, goat, occasionally deer | Small intestine |
| <i>Nematodirus spathiger</i> | Sheep, goat, cattle | Small intestine |
| <i>Nematodirus helvetianus</i> | Cattle, occasionally sheep, goat | Small intestine |
| <i>Nematodirus abnormalis</i> | Camel, sheep, goat | Small intestine |
| <i>Nematodirus mauritanicus</i> | Camel | Small intestine |
| <i>Nematodirus lamae</i> | Llama, alpaca, vicuna | Small intestine |
| <i>Nematodirus leporis</i> | Rabbit | Small intestine |

Fig. 1.32 Anterior of *Nematodirus battus* illustrating the small cephalic vesicle.

Table 1.6 Identification of *Nematodirus* species based on male spicule morphology.

| Species | Spicules: description | Spicules: morphology |
|--------------------------------|---|---|
| <i>Nematodirus battus</i> | The spicules are long and slender and the tips are fused into a small, flattened oval-shaped projection | (a)  |
| <i>Nematodirus filicollis</i> | The spicules are long and slender with fused tips and terminate in a narrow pointed swelling | (b)  |
| <i>Nematodirus spathiger</i> | The spicules are long and slender with fused tips and terminate in a spoon-shaped tip | (c)  |
| <i>Nematodirus helvetianus</i> | The long slender spicules terminate in a fused point with the surrounding membrane being lanceolate | (d)  |
| <i>Nematodirus abnormalis</i> | The spicules are asymmetrical with the distal ends bent to form an asymmetrical lancet | (e)  |

Nematodirus battus

Description: Males measure about 10–16 mm and females 15–25 mm in length and are characterised by having only one set of divergent rays in each bursal lobe (Fig. 1.33) and the tips of the spicules are fused into a small, flattened, oval-shaped projection (Table 1.6a). The female worm has a long conical tail, which tapers to a point. The large egg is brownish with parallel sides.

Life cycle: Development to the L₃ takes place within the eggshell. Hatching of most eggs requires a prolonged period of chill followed by a mean day/night temperature of more than 10°C, conditions which occur in late spring in the northern hemisphere. Hence most of the eggs from one season's grazing remain unhatched on the ground during the winter and usually only one generation is possible each year for the bulk of this species. However, some *N. battus* eggs deposited in the spring are capable of hatching in the autumn of the same year, resulting in significant numbers of L₃ on the pasture at this time. The ingested L₃ penetrate the mucosa of the small intestine and moult to the L₄ stage around the fourth day. After moulting to the L₅ the parasites inhabit the lumen, sometimes superficially coiled around villi. The prepatent period is 14–16 days.

Nematodirus filicollis

Description: The male has two sets of parallel rays in each of the main bursal lobes (Fig. 1.34). The spicules are long and slender with fused tips and terminate in a narrow pointed swelling (Table 1.6b). The female has a truncate blunt tail with a small spine (similar to *N. spathiger*), and the egg is large, ovoid, thin-shelled and colourless and twice the size of the typical trichostrongyle egg.

Life cycle: Development to the L₃ takes place within the eggshell. *Nematodirus filicollis* does not have the same critical hatching requirements as *N. battus*. Hatching occurs over a more prolonged

Fig. 1.33 Male bursa and spicules of *Nematodirus battus* with single sets of parallel rays in the dorsal lobes.

Fig. 1.34 Male bursa and spicules of *Nematodirus filicollis* with two sets of parallel rays in the dorsal lobes.

period and so larvae often appear on the pasture within 2–3 months of the eggs being excreted in the faeces. The parasitic phase within the host is similar to that of *N. battus*. The prepatent period is 2–3 weeks.

Nematodirus spathiger

Description: Males are around 10–15 mm and the females 15–25 mm in length. The male has two sets of parallel rays in each of the main bursal lobes. The spicules are long and slender with fused tips and terminate in a spoon-shaped tip (Table 1.6c). The female has a truncate blunt tail with a small spine (similar to *N. filicollis*), and the egg is large, ovoid, thin-shelled and colourless and twice the size of the typical trichostrongyle egg.

Life cycle: As for *N. filicollis*.

Nematodirus helvetianus

Description: Adult males measure around 11–16 mm and females 17–24 mm in length. The male has two sets of parallel rays in each of the main bursal lobes and the dorsal lobe is not separated from the lateral lobe. The long slender spicules terminate in a fused point, with the surrounding membrane being lanceolate (Table 1.6d). The female has a truncate tail with a small spine, and the egg is large, ovoid and colourless and twice the size of the typical trichostrongyle egg.

Life cycle: *Nematodirus helvetianus* does not have the same critical hatching requirements as *N. battus* and so the larvae often appear on the pasture within 2–3 weeks of the eggs being excreted in the faeces. More than one annual generation is therefore possible. The parasitic phase within the host is similar to that of *N. battus*. The prepatent period is around 3 weeks.

Nematodirus abnormalis

Description: Adult males measure around 11–17 mm and females 18–25 mm. The spicules are asymmetrical with the distal ends bent to form an asymmetrical lancet (Table 1.6e).

Nematodirus mauritanicus

Description: Adult females are 21–24 mm and males 13–15 mm long. Male spicules are joined for part of their length with the tips enclosed in a thin lanceolate membrane.

Nematodirus lamae

Description: These are small worms, females 14–20 mm, males 10–13 mm long. Male worms have a deeply emarginated dorsal lobe with two distinct lobules, and long spicules with the distal end enlarged and terminating in two distinct bifurcated medioventral processes.

Nematodirus leporis

Description: Male worms are 8–15 mm and female worms 16–20 mm in length. The bursa has rounded lobes with parallel posterolateral and mediolateral bursal rays and the spicules are long.

Nematodirella

The anterior of the worm is narrow and is similar to *Nematodirus*. Male spicules are extremely long and thin.

Nematodirella species

| Species | Hosts | Site |
|---|---------------------------------|-----------------|
| <i>Nematodirella dromedarii</i> | Camel (dromedary) | Small intestine |
| <i>Nematodirella cameli</i> | Camel (Bactrian), elk, reindeer | Small intestine |
| <i>Nematodirella alcides</i> (syn. <i>Nematodirus longispiculata</i> , <i>Nematodirella longissimespiculata</i>) | Elk | Small intestine |

Nematodirella dromedarii

Description: Males are 10–15 mm and females 10–30 mm in size. The very long spicules can measure up to half the body length and are equal in size (Fig. 1.35).

Nematodirella cameli

Description: Males are 16–17 mm and females 21–25 mm in size. In the males, the spicules are asymmetrical, thin and extremely long, adjoining each other closely over their entire length forming rounded swellings distally from which branch off spine-shaped distal extremities.

Nematodirella alcides

Synonym: *Nematodirus longispiculata*, *Nematodirella longissimespiculata*

Fig. 1.35 *Nematodirella dromedarii* showing the very long male spicules.

Description: Males are 15–17 mm and females 23–25 mm in size. The spicules are long, thin and filiform with a spear-like tip.

Lamanema

Lamanema species

| Species | Hosts | Site |
|--------------------------|----------------|-----------------|
| <i>Lamanema chavezii</i> | Alpaca, vicuna | Small intestine |

Lamanema chavezii

Description: Small worms, females measuring 14–18 mm and males 9–11 mm long. There is a shallow buccal capsule with dorsal tooth and two small lateroventral teeth at the base. In the male, the lateral lobes are large, dorsal lobe is small, and there are short spicules and a large gubernaculum.

Life cycle: Ingested infective larvae penetrate the intestinal mucosa and migrate to the liver and the lungs. Maturation is completed by migration of the worms back to the intestine via the trachea.

Ollulanus

These are very minute worms. Males are 0.7–0.8 mm and females 0.8–1 mm long. The buccal cavity is small. Microscopic identification is by the presence of the spiral coil of the head.

Life cycle: The worms are viviparous, the larvae developing to the L₃ stage in the uterus of the females. Autoinfection can occur, the shed L₃ developing into adult worms on the gastric mucosa in around 4–5 weeks. The whole life cycle may be completed endogenously and transmission, at least in the cat, is thought to be via ingestion of vomit containing the L₃. The worms live under a layer of mucus in the stomach wall and the anterior end of the worm is often located within the gastric crypts.

Ollulanus species

| Species | Hosts | Site |
|----------------------------|---------------------------------|---------|
| <i>Ollulanus tricuspis</i> | Cat, wild felids, pig, dog, fox | Stomach |

Ollulanus tricuspis

Description: The male bursa is well developed and the spicules are stout and each is split into two for a considerable portion of their length. The female has a tail, which terminates in three or four short cusps. The vulva is in the posterior part of the body and there is only one uterus and ovary.

FAMILY HELLIGMONELLIDAE

Nippostrongylus

Nippostrongylus species

| Species | Hosts | Site |
|--|--|-----------------|
| <i>Nippostrongylus brasiliensis</i> (syn. <i>Nippostrongylus muris</i> , <i>Heligmosomum muris</i>) | Rat, mouse, hamster, gerbil, rabbit, chinchilla | Small intestine |

Nippostrongylus brasiliensis

Synonyms: *Nippostrongylus muris*, *Heligmosomum muris*

Description: Adults are filiform and reddish in colour; males measure 2.1–4.5 mm and females 2.5–6 mm.

Life cycle: The life cycle is direct and typically trichostrongyloid. Infection is usually percutaneous and larvae migrate via the lungs. Worms are adult by around 5 days post infection and are usually short-lived. The prepatent period is 5–6 days.

Nematospiroides

Nematospiroides species

| Species | Hosts | Site |
|---|------------|-----------------|
| <i>Nematospiroides dubius</i> (syn. <i>Heligmosomoides polygyrus</i>) | Rat, mouse | Small intestine |

Nematospiroides dubius

Description: Adults are long red worms measuring 0.6–1.3 cm in length, with a coiled tail and a cephalic vesicle.

Life cycle: Typically trichostrongyloid with infection via the L₃. The prepatent period is 9 days and patency may last for up to 8 months.

FAMILY DICTYOCAULIDAE

Dictyocaulus

The adults are slender thread-like worms, white/light grey in colour and up to 8.0–10 cm in length. Their location in the trachea and bronchi and their size are diagnostic. The buccal capsule and the bursa are small. The brown spicules are short and often have a

Fig. 1.36 First-stage larvae of *Dictyocaulus viviparus*.

slightly granular appearance. There is some debate over the species taxonomy in deer.

Life cycle: The female worms are ovoviviparous, producing eggs containing fully developed larvae, which hatch almost immediately. The L₁ migrate up the trachea, are swallowed and pass out in the faeces. The larvae are unique in that they are present in fresh faeces, are characteristically sluggish, and their intestinal cells are filled with dark-brown food granules (Fig. 1.36). In consequence, the preparasitic stages do not need to feed. Under optimal conditions the L₃ stage is reached within 5 days, but usually takes longer in the field. The L₃ leave the faecal pat to reach the herbage either by their own motility or through the agency of the ubiquitous fungus *Pilobolus*. After ingestion, the L₃ penetrate the intestinal mucosa and pass to the mesenteric lymph nodes where they moult. The L₄ then travel via the lymph and blood to the lungs, and break out of the capillaries into the alveoli about 1 week after infection. The final moult occurs in the bronchioles a few days later and the young adults then move up the bronchi and mature.

Dictyocaulus species

| Species | Hosts | Site |
|---|--|----------------|
| <i>Dictyocaulus viviparus</i> | Cattle, buffalo, deer, camel | Trachea, lungs |
| <i>Dictyocaulus filaria</i> | Sheep, goat, camelids | Trachea, lungs |
| <i>Dictyocaulus arnfieldi</i> | Horse, donkey, zebra | Trachea, lungs |
| <i>Dictyocaulus eckerti</i> (syn. <i>Dictyocaulus noerneri</i>) | Deer (roe deer, fallow deer, red deer), cattle | Trachea, lungs |
| <i>Dictyocaulus capreolus</i> | Deer (roe deer, moose) | Trachea, lungs |

Dictyocaulus viviparus

Description: The adults are slender thread-like worms; males measure around 4.0–5.5 cm and females 6–8 cm in length. The buccal ring is triangular in shape. They are very similar to *D. filaria* but the posterolateral and mediolateral rays are entirely fused together.

Life cycle: The prepatent period is around 3–4 weeks in cattle. The prepatent period in red deer is 20–24 days.

Dictyocaulus filaria

Description: The worms are white with the intestine visible as a dark band. Males measure around 4–8 cm and the females 6–10 cm

in length. In the bursa the posterolateral and the mediolateral rays are fused together, except at their extremities. The dark-brown spicules are stout and shaped like a boot. The vulva is located just posterior to the middle of the worm.

Life cycle: The prepatent period is about 4–5 weeks.

Dictyocaulus arnfieldi

Description: The adults are slender, thread-like and whitish in colour, the adult males measuring around 3.5 cm and the females 6.5 cm in length. Male worms have a small non-lobulated bursa with short rays, with the mediolateral and posterolateral rays fused for half their length. The spicules are short, of equal length and slightly curved.

Life cycle: The detailed life cycle is not fully known, but is considered to be similar to that of the bovine lungworm, *D. viviparus*, except in the following respects. The adult worms are most often found in the small bronchi and their thin-shelled eggs, containing the first-stage larvae, are coughed up before they are swallowed, passed in the faeces and then hatch soon after being deposited. The prepatent period is around 2–3 months. Patent infections are common in donkeys of all ages, but in horses generally only occur in foals and yearlings. In older horses the adult lungworms rarely attain sexual maturity.

Dictyocaulus eckerti

Synonym: *Dictyocaulus noerneri*

Description: Similar to *D. viviparus* but the mouth opening is elongate and the buccal ring is kidney-shaped.

Dictyocaulus capreolus

Description: Distinguished from *D. eckerti* on the basis of the morphology of the buccal capsule and the bursa.

SUPERFAMILY STRONGYLOIDEA

There are several important parasites of domestic mammals and birds in this superfamily of bursate nematodes. Most are characterised by a large buccal capsule, which often contains teeth or cutting plates, and in some there are prominent leaf crowns surrounding the mouth opening. The bursa of males is well developed and a gubernaculum or telamon is usually present. The spicules are usually of equal length. The adults occur on mucosal surfaces of the gastrointestinal and respiratory tracts and feeding is generally by the ingestion of plugs of mucosa.

With the exception of three genera, *Syngamus*, *Mammomonogamus* and *Cyathostoma*, which are parasitic in the trachea and major bronchi, and *Stephanurus* found in the perirenal area, all other genera of veterinary importance in this superfamily are found in the intestine and can be conveniently divided into two groups, the **strongyles** and **hookworms**.

The strongyles are parasitic in the large intestine and the important genera are *Strongylus*, *Triodontophorus* ('large strongyles' of

horses), *Chabertia* and *Oesophagostomum*. Also in this group of small strongyles are the genera *Poteriostomum*, *Craterostomum* and *Oesophagodontus*.

The cyathostomins (cyathostomes or trichonemes) or 'small strongyles' of horses (subfamily Cyathostominae) include the genera *Cyathostomum*, *Cylicocyclus*, *Cylicodontophorus* and *Cylicostephanus* (formerly the single genus *Trichonema*).

Syngamus and *Cyathostoma* are important parasites of the respiratory tract of birds. *Mammomonogamus* are parasites of the respiratory tract of cattle, sheep and goats.

FAMILY STRONGYLIDAE

SUBFAMILY STRONGYLINAE

Strongylus

Members of this genus live in the large intestine of horses and donkeys. These are robust dark-red worms which are easily seen against the intestinal mucosa (Fig. 1.37). The well-developed deep buccal capsule of the adult parasite is prominent as is the bursa of the male. The anterior margin of the buccal capsule usually bears leaf-like cuticular structures (leaf crowns or corona radiata). Species differentiation is based on size and the presence and shape of the teeth in the base of the buccal capsule.

Strongylus species

| Species | Hosts | Site |
|--|---------------|-----------------|
| <i>Strongylus edentatus</i> (syn. <i>Alfortia edentatus</i>) | Horse, donkey | Large intestine |
| <i>Strongylus equinus</i> | Horse, donkey | Large intestine |
| <i>Strongylus vulgaris</i> (syn. <i>Delafondia vulgaris</i>) | Horse, donkey | Large intestine |

Fig. 1.37 *Strongylus* spp. Adult worms (large strongyles) on the intestinal mucosa with smaller cyathostomins (small strongyles) also present.

Strongylus edentatus

Description: Male worms are 2.3–2.8 cm and females 3.3–4.4 cm in size. The truncate head end is wider than the rest of the body. The buccal capsule is wider anteriorly than at the middle and teeth are absent (Fig. 1.38a).

Life cycle: Eggs, which resemble those of the trichostrongyles, are passed in the faeces and development from egg to the L₃ under summer conditions in temperate climates requires approximately 2 weeks. Infection is by ingestion of the L₃. Subsequently, parasitic larval development of the three species of *Strongylus* differs and will be dealt with separately.

After penetration of the intestinal mucosa L₃ travel via the portal system, and reach the liver parenchyma within a few days. About

(a)

(b)

(c)

Fig. 1.38 (a) Anterior of *Strongylus edentatus* showing the cup-shaped buccal capsule, which is devoid of teeth. (b) Anterior of *Strongylus equinus* showing oval buccal capsule with a large dorsal tooth and smaller subventral conical teeth. (c) Anterior of *Strongylus vulgaris* showing ear-shaped rounded teeth at the base of the buccal capsule.

2 weeks later the moult to L_4 takes place; further migration then occurs in the liver and, by 6–8 weeks post infection, larvae can be found subperitoneally around the hepatorenal ligament. The larvae then travel under the peritoneum to many sites, with a predilection for the flanks and hepatic ligaments. The final moult occurs after 4 months and each L_5 then migrates, still subperitoneally, to the wall of the large intestine where a large purulent nodule is formed, which subsequently ruptures with release of the young adult parasite into the lumen. The prepatent period is usually about 10–12 months and is the longest of the strongyles.

Strongylus equinus

Description: These sturdy worms (about 2 mm thick) are usually coloured dark grey. Males are 2.6–3.5 cm and females 3.8–4.7 cm in size. The head end is not demarcated from the rest of the body. The deep buccal capsule is oval and possesses both external and internal leaf crowns. The base of the buccal capsule is armed with a large dorsal tooth with a bifid tip and also two smaller subventral teeth (Fig. 1.38b). The dorsal oesophageal gland connects to the buccal capsule through several pores located in the dorsal gutter. This thickened ridge is formed by the wall of the buccal capsule. The male has two slender spicules of similar appearance.

Life cycle: The adult parasites live in the caecum and colon. The free-living phase is as described for *S. edentatus*. Of the three *Strongylus* species, least is known of the larval migration of *S. equinus*. It appears that the L_3 lose their sheaths while penetrating the wall of the caecum and ventral colon and within 1 week provoke the formation of nodules in the muscular and subserosal layers of the intestine. The moult to L_4 occurs within these nodules and the larvae then travel across the peritoneal cavity to the liver where they migrate within the parenchyma for 6 weeks or more. After this time, L_4 and L_5 have been found in and around the pancreas before their appearance in the large intestinal lumen. The prepatent period is 8–9 months.

Strongylus vulgaris

Description: Adults of this species are shorter and thinner than the other two *Strongylus* species, with males 14–16 mm and females 20–24 mm in size. The head end is not marked off from the rest of the body. The buccal capsule is oval in outline and contains two ear-shaped rounded teeth at its base (Fig. 1.38c). The distal extremities of elements of the leaf crowns are fringed.

Life cycle: The free-living phase is as described for the other two species. Following ingestion, the L_3 penetrate the intestinal mucosa and moult to L_4 in the submucosa of the caecum and ventral colon 7 days later. These then enter small arteries and arterioles and migrate on the endothelium to their predilection site in the cranial mesenteric artery and its main branches. After a period of development of several months the larvae moult to L_5 and return to the intestinal wall via the arterial lumina. Nodules are formed around the larvae mainly in the wall of the caecum and colon when, due to their size, they can travel no further within the arteries and subsequent rupture of these nodules releases the young adult parasites into the lumen of the intestine. The prepatent period is 6–7 months.

Fig. 1.39 Head of *Triodontophorus* spp. showing the location of teeth at the base of the buccal capsule.

Triodontophorus

Members of the genus *Triodontophorus* are non-migratory, large strongyles frequently found in large numbers in the colon of horses and donkeys. They are reddish worms 1.0–2.5 cm in length readily visible on the colonic mucosa. The buccal capsule is subglobular and thick-walled with three pairs of large oesophageal teeth, each composed of two plates, the anterior rim of which is thickened and surrounded by six plate-like structures (Fig. 1.39). The dorsal gutter is prominent. The spicules of the male terminate in small hooks.

Life cycle: Little information is available on the developmental cycle of this genus, but it is thought to be similar to that of cyathostomes.

***Triodontophorus* species**

| Species | Hosts | Site |
|------------------------------------|---------------|-----------------|
| <i>Triodontophorus brevicauda</i> | Horse, donkey | Large intestine |
| <i>Triodontophorus minor</i> | Horse, donkey | Large intestine |
| <i>Triodontophorus nipponicus</i> | Horse, donkey | Large intestine |
| <i>Triodontophorus serratus</i> | Horse, donkey | Large intestine |
| <i>Triodontophorus tenuicollis</i> | Horse, donkey | Large intestine |

Triodontophorus brevicauda

Description: The males measure around 10–15 mm and females 20–25 mm in length. The buccal plates are smooth, except for three elevations on each, and protrude into the buccal capsule. The sub-median papillae are short, broad and conical. The external leaf crown consists of numerous slender elements protruding from the buccal collar, with an equal number of inner leaf crown elements.

Triodontophorus minor

Description: The males measure around 12 mm and the females 14 mm in length. The buccal plates are strongly denticulated and protrude into the buccal capsule. The cuticle is strongly serrated in the cervical region. The external leaf crown consists of 44–50 slender elements protruding from the buccal collar, with an equal number of inner leaf crown elements.

Triodontophorus nipponicus

Description: The buccal plates have three large denticulations that protrude into the buccal capsule. The cuticle is strongly serrated in the cervical region. The external leaf crown consists of 56–69 slender elements protruding from the buccal collar, with an equal number of inner leaf crown elements.

Triodontophorus serratus

Description: This is the largest species of the genus. Males measure 18–20 mm and females 20–26 mm in length. The mouth collar appears as an inflated round tube around the mouth. The external leaf crown consists of numerous slender elements protruding from the buccal collar, with an equal number of inner leaf crown elements.

Triodontophorus tenuicollis

Description: Males are around 17 mm and females 22 mm long. The cuticle is strongly serrated in the cervical region; the dorsal lobe of the bursa is short, and teeth are finely denticulated.

Chabertia

Worms of this genus are usually found in low numbers in the majority of sheep and goats. The adults are 1.5–2.0 cm in length and are the largest nematodes found in the colon of ruminants. They are white with a markedly truncated and enlarged anterior end due to the presence of the very large buccal capsule. The anterior is curved slightly ventrally (Fig. 1.40).

Life cycle: The life cycle is direct. Eggs are passed in the faeces and hatch on the ground releasing the first-stage larva, which moults to the second stage, and then to the infective third stage. The host is infected by ingestion of the larva with the herbage. In the parasitic phase the L₃ enter the mucosa of the small intestine and occasionally that of the caecum and colon; after a week they moults, the L₄ emerge on to the mucosal surface and migrate to congregate in the caecum where development to the L₅ is completed about 25 days after infection. The young adults then travel to the colon. There is no migration stage in the body. The prepatent period is about 6–7 weeks.

Chabertia species

| Species | Hosts | Site |
|------------------------|----------------------------------|-----------------|
| <i>Chabertia ovina</i> | Sheep, goat, occasionally cattle | Large intestine |

Fig. 1.40 Head of *Chabertia ovina* illustrating the large bell-shaped buccal capsule.

Chabertia ovina

Description: Males measure 13–14 mm and females 17–20 mm in length. The huge buccal capsule, which is bell-shaped, has a double row of small papillae around the rim. There are no teeth. There is a shallow ventral cervical groove, and anterior to this is a cephalic vesicle. In the male, the bursa is well developed with a gubernaculum and the spicules are of medium size.

Oesophagostomum

Worms of this genus are stout and whitish with a narrow cylindrical buccal capsule and measure 1–2 cm in length (Fig. 1.41). The body is often slightly curved. A ventral cervical groove is located near the anterior end of the worm, and the anterior cuticle is dilated to form a cervical vesicle. Leaf crowns are present.

Life cycle: The preparasitic phase is typically strongyloid. The egg hatches on the ground releasing the first-stage larva, which moults to the second stage, and then to the infective third stage. Infection is by ingestion of L₃. There is no migration stage in the body, although there is limited evidence that skin penetration is possible. The larvae

Fig. 1.41 Adult worms of *Oesophagostomum venulosum*.

moult again and the fourth-stage larvae attach to, or enter, the wall of the intestine. These L₄ then emerge on to the mucosal surface, migrate to the colon, and develop to the adult stage. The prepatent period is 5–7 weeks. On reinfection, the larvae may remain arrested as L₄ in nodules for up to 1 year.

Oesophagostomum species

| Species | Hosts | Site |
|--|------------------------------------|-----------------|
| <i>Oesophagostomum columbianum</i> | Sheep, goat, camel, wild ruminants | Large intestine |
| <i>Oesophagostomum venulosum</i> (syn. <i>Oesophagostomum virginimembrum</i>) | Sheep, goat, deer, camel | Large intestine |
| <i>Oesophagostomum asperum</i> | Sheep, goat | Large intestine |
| <i>Oesophagostomum multifoliatum</i> | Sheep, goat | Large intestine |
| <i>Oesophagostomum radiatum</i> | Cattle, water buffalo | Large intestine |
| <i>Oesophagostomum dentatum</i> | Pig | Large intestine |
| <i>Oesophagostomum brevicaudum</i> | Pig | Large intestine |
| <i>Oesophagostomum longicaudatum</i> | Pig | Large intestine |
| <i>Oesophagostomum quadrispinulatum</i> | Pig | Large intestine |
| <i>Oesophagostomum georgianum</i> | Pig | Large intestine |
| <i>Oesophagostomum granatensis</i> | Pig | Large intestine |
| <i>Oesophagostomum apiostomum</i> | Primates | Large intestine |
| <i>Oesophagostomum bifurcum</i> | Primates | Large intestine |
| <i>Oesophagostomum aculeatum</i> | Primates | Large intestine |
| <i>Oesophagostomum stephanostomum</i> | Primates | Large intestine |

Oesophagostomum columbianum

Description: Male worms are 12–17 mm and females 15–22 mm with large cervical alae, which induce a dorsal curvature of the anterior part of the body. The cuticle forms a high mouth collar shaped like a truncate cone. This is separated from the remainder of the body by a constriction. The cephalic vesicle is anterior to a cervical groove, behind which arise the cervical alae pierced by cervical papillae. External leaf crowns consist of 20–24 elements and the internal ones have two small elements to each external element. The male bursa is well developed with two alate spicules of equal length.

Life cycle: The prepatent period is about 45 days.

Oesophagostomum venulosum

Synonym: *Oesophagostomum virginimembrum*

Description, gross: Males worms are 11–16 mm and females 13–24 mm long. Around the anterior oesophagus there is an inflated cuticular cephalic vesicle (Fig. 1.42). The head has a shallow buccal capsule with an external leaf crown of 18 elements. The external crown is compressed and so there is only a narrow opening into the buccal capsule. There are no lateral cervical alae and the worms are therefore not curved anteriorly. The cervical papillae are posterior to the oesophagus.

Life cycle: The prepatent period is about 5–7 weeks.

Oesophagostomum multifolium

Description: Males measure 12–14 mm and females 14–17 mm in length.

Fig. 1.42 Anterior of *Oesophagostomum venulosum* showing the large inflated cephalic vesicle.

Oesophagostomum radiatum

Description: Adult male worms are 12–17 mm and females 16–22 mm long. The cephalic vesicle is large and is constricted around the middle by a shallow annular groove (Fig. 1.43). The cuticle forms a rounded mouth collar. External leaf crowns are missing and the internal ring consists of 38–40 small triangular denticles. Cervical papillae are present, just posterior to the cervical groove. The male bursa is well developed.

Life cycle: The prepatent period is about 40 days.

Fig. 1.43 Anterior of *Oesophagostomum radiatum* showing the large cephalic vesicle.

Oesophagostomum dentatum

Description: Adult males are 8–10 mm and females 11–14 mm in length. The cephalic vesicle is prominent, but cervical alae are virtually absent. The nine elements of the leaf crown project forward and the internal leaf crown has 18 elements. The buccal capsule is shallow with parallel sides and the oesophagus is club-shaped with a narrow anterior end.

Oesophagostomum brevicaudum

Description: Males measure 6–7 mm and females 6.5–8.5 mm in length. There are 28–32 elements and 14–16 elements in the internal and external leaf crowns respectively. In the female the tail is bent dorsally.

Oesophagostomum quadrispinulatum

Description: This worm is similar to *O. dentatum*, although the oesophagus is slightly more slender and the tail of the female is almost twice as long.

Poteriostomum

These worms measure about 9–21 mm in length. This genus is closely related to the genus *Cylicodontophorus*. The two genera are easily separated based on characteristics of the buccal capsule, especially the point of insertion of the internal leaf crowns, and on the character of the dorsal rays. The externo-dorsal ray and the dorsal ray of the bursa in this genus arise from a common trunk and the dorsal ray gives off, almost at 90°, two lateral branches near the origin of the externo-dorsal rays and the dorsal ray is cleft only to about half its length.

Poteriostomum species

| Species | Hosts | Site |
|-------------------------------------|---------------|-----------------|
| <i>Poteriostomum imparidentatum</i> | Horse, donkey | Large intestine |
| <i>Poteriostomum ratzii</i> | Horse, donkey | Large intestine |
| <i>Poteriostomum skrjabini</i> | Horse, donkey | Large intestine |

Poteriostomum imparidentatum

Description: The six elements of the internal leaf crown are markedly longer than in the other species.

Poteriostomum ratzii

Description: All elements of the internal leaf crown are of equal lengths.

Poteriostomum skrjabini

Description: Distinguished by a poorly defined dorsal gutter.

Craterostomum

These are relatively small worms, 6–11 mm long, and in general are similar to *Triodontophorus* (apart from the lack of protruding teeth and also the female vulva is located more anteriorly). The buccal capsule is of greatest diameter in the middle, with the wall thickened behind the anterior edge. The dorsal gutter is strongly developed. There is a shallow oesophageal funnel with three small triangular teeth that do not project into the buccal cavity. Elements of the external leaf crown are large and transparent and less numerous than the short broad elements of the inner leaf crown that ring the anterior ridge of the buccal capsule. Sub-median papillae extend beyond the depressed mouth collar. In the female the tail is long and pointed and the vulva is relatively far from the anus.

Craterostomum species

| Species | Hosts | Site |
|---|----------------------|-----------------|
| <i>Craterostomum acuticaudatum</i> (syn. <i>Craterostomum mucronatum</i>) | Horse, other equines | Large intestine |
| <i>Craterostomum tenuicauda</i> | Horse, zebra | Large intestine |

Craterostomum acuticaudatum

Description: The males measure about 6–10 mm and the females 7–11 mm in length. The internal leaf crown has 22–26 short elements and the external leaf crown bears six to eight petal-shaped elements. The bottom of the buccal capsule is funnel-shaped and possesses a row of papillae which appear like a leaf crown. Teeth are absent from the buccal cavity.

Craterostomum tenuicauda

Description: The inner leaf crown has 18 elements and the external leaf crown nine elements.

Oesophagodontus

There is only one species in the genus. Male worms are 15–18 mm and females 19–24 mm in size. There is a slight constriction between the anterior region and the remainder of the body.

Oesophagodontus species

| Species | Hosts | Site |
|---------------------------------|---------------|-----------------|
| <i>Oesophagodontus robustus</i> | Horse, donkey | Large intestine |

Oesophagodontus robustus

Description: Males measure around 18 mm and females 19–22 mm long. The buccal capsule is shaped like a funnel with a thickened ring encircling its posterior margin. The oesophageal funnel has three lancet-like teeth that do not project into the buccal capsule. There are prominent sub-median papillae and the dorsal gutter is absent.

Codiostomum

Codiostomum species

| Species | Hosts | Site |
|--------------------------------|---------------|-------------------------|
| <i>Codiostomum struthionis</i> | Ostrich, rhea | Large intestine, caecum |

Codiostomum struthionis

Description: Adult worms are 13–17 mm in length. The large buccal capsule is subglobular with external and internal leaf crowns, but no teeth. The male bursa has a large projecting dorsal lobe.

Life cycle: The life cycle is unknown but is considered to be direct.

SUBFAMILY CYATHOSTOMINAE

The 'small strongyles' embraces over 50 species, popularly known as trichonemes, cyathostomes or cyathostomins. For many years there has been a great deal of confusion in the classification of this group of parasites and in a new revision it has been proposed that the genus *Trichonema* be discarded and replaced by four main genera, namely *Cyathostomum*, *Cylicocyclus*, *Cylicodontophorus* and *Cylicocostephanus*, these being collectively referred to as cyathostomes or, more recently, cyathostomins.

Small strongyles are small (5–12 mm long) bursate nematodes ranging in colour from white to dark red, the majority being visible on close inspection of the large intestinal mucosa or contents (Fig. 1.44). The well-developed short buccal capsule is cylindrical, without teeth, and species differentiation is based on characteristics of the buccal capsule, and the internal and external leaf crowns.

Life cycle: Hatching of eggs and development to L₃ is complete within 2 weeks during the summer in temperate areas, after which the larvae migrate from the faeces on to the surrounding herbage. After ingestion, the L₃ exsheath and invade the wall of the ileum and large intestine where they develop to L₄ before emerging into the gut lumen and moulting to become young adult worms. The prepatent periods of members of this genus are generally between 2 and 3 months, although this may be extended due to hypobiosis in some species.

Fig. 1.44 Small strongyles (cyathostomins) on the mucosa of the ventral colon.

Cyathostomum

Cyathostomum have a moderately high mouth collar, with cephalic papillae not very prominent. The buccal capsule is broader than deep, thin-walled, and has no dorsal gutter. Elements of the external leaf crown are larger, broader and fewer than elements of the internal leaf crown. The inner leaf crown is situated deep in the buccal capsule and has sclerotised extra-chitinous supports at or near the anterior edge of the buccal capsule (Fig. 1.45a).

The dorsal ray of the male bursa is split to the origin of the externo-dorsal rays and the spicules are filiform, equal in length with pick-shaped tips. In the female, the vulva is close to the anus. The tail may be straight or bent dorsally with a ventral bulge, anterior to the vulva.

Cyathostomum species

| Species | Hosts | Site |
|--|---------------|-----------------|
| <i>Cyathostomum alveatum</i> (syn. <i>Cylichnostomum alveatum</i> , <i>Cylicostomum alveatum</i> , <i>Trichonema alveatum</i> , <i>Cylicocercus alveatus</i>) | Horse, donkey | Large intestine |
| <i>Cyathostomum catinatum</i> (syn. <i>Cylichnostomum catinatum</i> , <i>Cylicostomum catinatum</i> , <i>Trichonema catinatum</i> , <i>Cylicocercus catinatum</i>) | Horse, donkey | Large intestine |
| <i>Cyathostomum coronatum</i> (syn. <i>Cylichnostomum coronatum</i> , <i>Cylicostomum coronatum</i> , <i>Trichonema coronatum</i> , <i>Cylicostomias coronatum</i>) | Horse, donkey | Large intestine |
| <i>Cyathostomum labiatum</i> (syn. <i>Cyathostomum labratum</i> , <i>Cylichnostomum labiatum</i> , <i>Cylicostomum labiatum</i> , <i>Trichonema labiatum</i> , <i>Cylicostomias labiatum</i>) | Horse, donkey | Large intestine |
| <i>Cyathostomum labratum</i> (syn. <i>Cylichnostomum labratum</i> , <i>Cylicostomum labratum</i> , <i>Trichonema labratum</i> , <i>Cylicostomias labratum</i>) | Horse, donkey | Large intestine |
| <i>Cyathostomum montgomeryi</i> (syn. <i>Cylicostomum montgomeryi</i> , <i>Trichonema labratum</i> , <i>Cylicotoichus montgomeryi</i>) | Horse, donkey | Large intestine |
| <i>Cyathostomum pateratum</i> (syn. <i>Cylicodontophorus pateratum</i> , <i>Cylicostomum pateratum</i> , <i>Trichonema pateratum</i> , <i>Cylicostocercus pateratum</i>) | Horse, donkey | Large intestine |
| <i>Cyathostomum saginatum</i> (syn. <i>Cylicostomum sagittatum</i> , <i>Trichonema sagittatum</i> , <i>Cylicostomias sagittatum</i> , <i>Cylicodontophorus sagittatum</i>) | Horse, donkey | Large intestine |
| <i>Cyathostomum tetracanthum</i> (syn. <i>Strongylus tetracanthus</i> , <i>Sclerostomum tetracanthum</i> , <i>Cylichnostomum tetracanthum</i> , <i>Cylicostomum tetracanthum</i> , <i>Trichonema tetracanthum</i> , <i>Trichonema arcuata</i> , <i>Trichonema aegypticum</i> , <i>Cylicostomum aegypticum</i>) | Horse, donkey | Large intestine |

Cyathostomum alveatum

Description: The walls of the buccal capsule have a uniform thickness posterior to the inner leaf crown, which is about one-third the depth of the buccal capsule.

Cyathostomum catinatum

Description: The inner leaf crown is more anterior on the lateral sides of the buccal capsule compared with the dorsal and ventral sides, but not in a sinuous line.

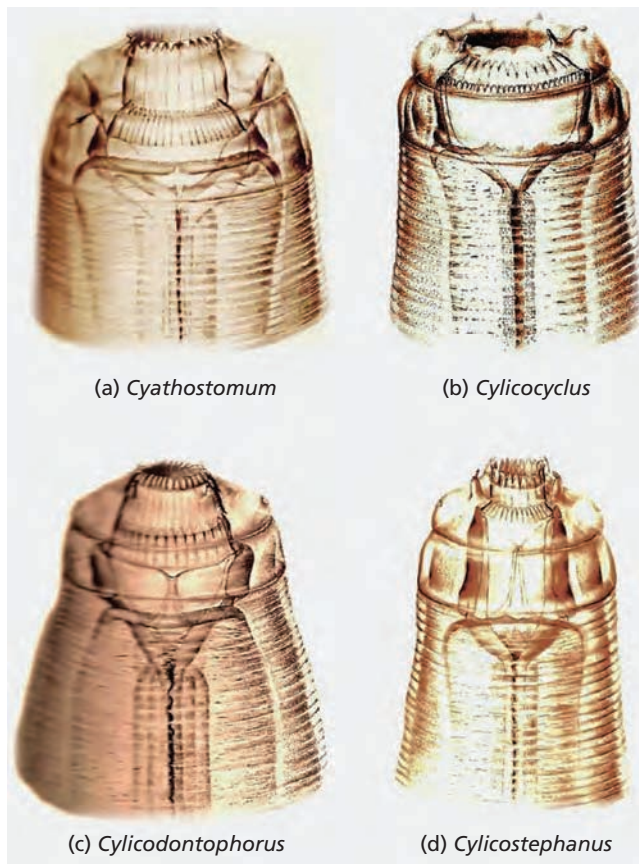

Fig. 1.45 Cystostomins showing characteristic features of the heads and buccal capsules used in generic and species identification: (a) *Cyathostomum*; (b) *Cylicocyclus*; (c) *Cylicodontophorus*; (d) *Cylicostephanus*. (Redrawn from Lichtenfels, 1975. Reproduced with permission from the Helminthological Society of Washington.)

Cyathostomum coronatum

Description: Extra-chitinous supports are prominent and the inner leaf crown forms an even line around the buccal cavity, which is as deep as it is broad and with walls that are thick and bent inwards.

Cyathostomum labiatum

Description: The mouth collar is notched and forms four distinct lips; the inner leaf crown elements are half the length of the external leaf crowns. Chitinous supports are spindle-shaped. The excretory pore is sited near the junction of the mid to posterior third of the oesophagus.

Cyathostomum labratum

Description: The mouth collar is not notched; the inner leaf crown elements are greater than half the length of the external leaf crowns. Chitinous supports are pyriform-shaped and the excretory pore is located near the middle of the oesophagus.

Cyathostomum montgomeryi

Description: Similar to *C. labiatum* but without well-defined lips. The wall of the buccal capsule is longer in dorsoventral view.

Cyathostomum pateratum

Description: The inner leaf crown is in a sinuous line deep in the buccal cavity (seen in lateral view).

Cyathostomum saginatum

Description: Similar to *C. coronatum* but the buccal capsule is shallow.

Cyathostomum tetracanthum

Description: The extra-chitinous supports are nearly as large as the wall of the buccal capsule and appear as extensions of the buccal capsule wall.

Cylicocyclus

These parasites are about 10–25 mm in length. *Cylicocyclus* have a high mouth collar with broad lateral papillae. Elements of the external leaf crown are larger, fewer and broader than the inner leaf crown, the latter being short, with thin rods at or near the anterior edge of the buccal capsule. The buccal capsule is short, broader than deep, with thin walls tapering anteriorly, with a hoop-shaped thickening around the posterior margin. A dorsal gutter is usually absent from the buccal capsule (Fig. 1.45b). In the male the dorsal ray is split to the region of origin of the externo-dorsal rays and the spicules are filiform, of equal length with pick-shaped tails. In females, the vulva is near the anus and the tail is usually straight but may be bent slightly dorsally.

Cylicocyclus species

| Species | Hosts | Site |
|---|------------------|--------------------|

| <i>Cylicocycclus radiatus</i> (syn. <i>Cyathostomum radiatum</i> , <i>Cylichnostomum radiatum</i> , <i>Trichonema radiatum</i> , <i>Cylicostomum prionodes</i>) | Horse, donkey | Large intestine |
| <i>Cylicocycclus tiramosus</i> (syn. <i>Cylicostomum tiramosum</i> , <i>Trichonema tiramosum</i>) | Horse, donkey | Large intestine |
| <i>Cylicocycclus ultrajectinus</i> (syn. <i>Cylicostomum ultrajectinum</i> , <i>Trichonema ultrajectinum</i>) | Horse, donkey | Large intestine |

Cylicocycclus adersi

Description: Buccal capsule is not shallow and the walls are of uniform thickness. The dorsal gutter is short but well developed. The inner leaf crown elements are few and wider than the external leaf crown elements and are of uniform length.

Cylicocycclus auriculatus

Description: The buccal capsule is not shallow and the dorsal gutter is absent. Lateral papillae are long ear-like or horn-like extending much higher than the mouth collar. The excretory pore and cervical papillae are located behind the oesophago-intestinal junction.

Cylicocycclus brevicapsulatus

Description: The buccal capsule is extremely shallow with delicate inconspicuous walls.

Cylicocycclus elongatus

Description: The buccal capsule is not shallow, the dorsal gutter is absent and the lateral papillae are not long. The excretory pore and cervical papillae are anterior to the oesophago-intestinal junction. The oesophageal funnel is nearly as large as the buccal capsule, and the oesophagus is greatly elongated with the posterior half enlarged and cylindrical.

Cylicocycclus insigne

Description: The buccal capsule is not shallow, the dorsal gutter is absent and the lateral papillae are not long. The excretory pore and the cervical papillae are anterior to the oesophago-intestinal junction. The external leaf crown elements are narrow; the inner leaf crown elements are much shorter than the external leaf crown elements and are of uniform length.

Cylicocycclus largocapsulatus

Description: The oesophago-intestinal valve is not elongate, the buccal capsule is large and the elements of the external leaf crown are almost about half as long as the buccal capsule is deep.

Cylicocycclus leptostomus

Description: The oesophago-intestinal valve is elongate, the buccal capsule is small and elements of the external leaf crown are almost as long as the buccal capsule is deep.

Cylicocycclus maturmurai

Description: The buccal capsule is not shallow and the walls are of uniform thickness. The inner leaf crown elements outnumber the external leaf crown elements and are of uniform length.

Cylicocycclus nassatus

Description: The buccal capsule is not shallow with both lateral papillae and external leaf crown extending beyond the mouth collar. A dorsal gutter is present extending half of the depth of the buccal capsule. Sub-median papillae are long and extend beyond the mouth collar. The external leaf crown has 20 elements. The buccal capsule has an internal shelf-like cuticular projection.

Cylicocycclus radiatus

Description: The oesophago-intestinal valve is not elongate, the buccal capsule is large and the elements of the external leaf crown are almost about one-third as long as the buccal capsule is deep.

Cylicocycclus tiramosus

Description: The buccal capsule is not shallow, with both lateral papillae and the external leaf crown extending beyond the mouth collar. The dorsal gutter is short and button-like. The sub-median papillae are short and do not extend beyond the mouth collar. The external leaf crown has 30 elements. The buccal capsule is without an internal projection.

Cylicocycclus ultrajectinus

Description: The buccal capsule is not shallow, the dorsal gutter is absent and the lateral papillae are not long. The excretory pore and the cervical papillae are located near the oesophago-intestinal junction. The external leaf crown elements are broad; the inner leaf crown elements are as long, or longer, than the external leaf crown elements.

Cylicodontophorus

These are small to medium-sized worms about 7–15 mm in length. *Cylicodontophorus* have a high mouth collar, with lateral papillae inconspicuous and sub-median papillae short and conical. The buccal capsule is short, thick-walled, of nearly uniform thickness, and broader than deep. Inner leaf crown elements are longer, broader and less numerous than the external leaf crown elements, and are inserted near the anterior edge of the buccal capsule (Fig. 1.45c).

The dorsal ray of the male bursa is split only to the proximal branch, and the spicules are filiform, equal in length with hook-shaped tips. In the female, the tail is short with a sharp tip and a prominent ventral bulge may be present anterior to the vulva.

Cylicodontophorus species

| Species | Hosts | Site |
|--|------------------|--------------------|
| <i>Cylicodontophorus bicoronatus</i> (syn. <i>Cyathostomum bicoranatum</i> , <i>Cylichnostomum bicoronatum</i> , <i>Cylicostomum bicoranatum</i> , <i>Trichonema bicoranatum</i>) | Horse, donkey | Large intestine |
| <i>Cylicodontophorus euproctus</i> (syn. <i>Cylichnostomum euproctus</i> , <i>Cylicostomum euproctus</i> , <i>Trichonema euproctus</i>) | Horse, donkey | Large intestine |
| <i>Cylicodontophorus mettami</i> (syn. <i>Cylicostoma mettami</i> , <i>Cylicostomum mettami</i> , <i>Trichonema mettami</i> , <i>Cylicocercus mettami</i> , <i>Cylicostomum ihlei</i>) | Horse, donkey | Large intestine |

Cylicodontophorus bicoronatus

Description: The dorsal gutter is well developed. The elements of the external and internal leaf crowns are nearly equal in size.

Cylicodontophorus euproctus

Description: The dorsal gutter is absent. The elements of the internal leaf crowns are twice as long as the elements of the external leaf crown. The oesophageal funnel is not well developed.

Cylicodontophorus mettami

Description: The dorsal gutter is absent. The elements of the internal leaf crowns are less than twice as long as the elements of the external leaf crown. The oesophageal funnel is well developed.

Cylicostephanus

These small worms are only about 4–10 mm in length. *Cylicostephanus* have a depressed mouth collar, with lateral papillae inconspicuous and sub-median papillae prominent. The buccal capsule is slightly narrow anteriorly, with a wall of varying thickness, and with a dorsal gutter. External leaf crown elements are longer, broader and less numerous than the internal leaf crown elements, which are short thin rods inserted near the anterior edge of the buccal capsule (Fig. 1.45d).

The dorsal ray of the male bursa is split only to the proximal branch, and the spicules are filiform, equal in length with pick-shaped tips. In the female, the vulva is near the anus, and the tail is usually straight.

Cylicostephanus species

| Species | Hosts | Site |
|--|------------------|--------------------|
| <i>Cylicostephanus asymmetricus</i> (syn. <i>Cylicostomum asymmetricum</i> , <i>Cylicotrapedon asymmetricum</i> , <i>Schulzitriconema asymmetricum</i>) | Horse, donkey | Large intestine |
| <i>Cylicostephanus bidentatus</i> (syn. <i>Cylicostomum bidentatum</i> , <i>Cylicotrapedon bidentatum</i> , <i>Trichonema bidentatum</i> , <i>Schulzitriconema bidentatum</i>) | Horse, donkey | Large intestine |

| Species | Hosts | Site |
|---|------------------|--------------------|
| <i>Cylicostephanus calicatus</i> (syn. <i>Cyathostomum calicatum</i> , <i>Cylichnostomum calicatum</i> , <i>Cylicostomum calicatum</i> , <i>Trichonema calicatum</i> , <i>Cylicostomum barbatum</i> , <i>Trichonema tsengi</i>) | Horse, donkey | Large intestine |
| <i>Cylicostephanus goldi</i> (syn. <i>Cylichnostomum goldi</i> , <i>Cylicostomum goldi</i> , <i>Trichonema goldi</i> , <i>Schulzitriconema goldi</i> , <i>Cylicostomum tridentatum</i>) | Horse, donkey | Large intestine |
| <i>Cylicostephanus hybridus</i> (syn. <i>Cylicostomum hybridus</i> , <i>Trichonema hybridum</i> , <i>Schulzitriconema hybridum</i> , <i>Trichonema parvibursatus</i>) | Horse, donkey | Large intestine |
| <i>Cylicostephanus longibursatus</i> (syn. <i>Cylicostomum longibursatum</i> , <i>Trichonema longibursatum</i> , <i>Cylicostomum nanum</i> , <i>Cylicostomum caliciforme</i>) | Horse, donkey | Large intestine |
| <i>Cylicostephanus minutus</i> (syn. <i>Cylicostomum minutum</i> , <i>Trichonema minutum</i>) | Horse, donkey | Large intestine |
| <i>Cylicostephanus ornatus</i> (syn. <i>Cylicostomum ornatum</i> , <i>Trichonema ornatum</i> , <i>Cylicostomias ornatum</i> , <i>Cyathostomum ornatum</i> , <i>Cylicodontophorus ornatum</i>) | Horse, donkey | Large intestine |
| <i>Cylicostephanus poculatus</i> (syn. <i>Cyathostomum poculatum</i> , <i>Cylichnostomum poculatum</i> , <i>Cylicostomum poculatum</i> , <i>Trichonema poculatum</i> , <i>Petrovina poculatum</i>) | Horse, donkey | Large intestine |
| <i>Cylicostephanus skrbjani</i> (syn. <i>Trichonema skrbjani</i> , <i>Petrovinema skrbjani</i>) | Horse, donkey | Large intestine |

Cylicostephanus asymmetricus

Description: The walls of the buccal capsule are markedly thicker anteriorly, the elements of the external leaf crown are as broad as long, and the dorsal gutter extends almost to the base of the inner leaf crown. The buccal capsule is asymmetrical in lateral view and the walls of the capsule are concave. The teeth in the oesophageal funnel are not prominent.

Cylicocyclus bidentatus

Description: The walls of the buccal capsule are markedly thicker anteriorly, the elements of the external leaf crown are as broad as long, and the dorsal gutter extends almost to the base of the inner leaf crown. The buccal capsule is asymmetrical in lateral view and the walls of the capsule are concave. The teeth in the oesophageal funnel are not prominent.

Cylicostephanus calicatus

Description: The buccal capsule is as broad as deep and the wall is of uniform thickness. The external leaf crowns are composed of 8–18 triangular elements and the sub-median papillae are notched near their tips.

Cylicostephanus goldi

Description: The walls of the buccal capsule are of uniform thickness, the elements of the external leaf crown are twice as numerous as the elements of the inner leaf crown, and the dorsal gutter is button-like. The walls of the buccal capsule have a slight compound curve, being slightly thicker posteriorly. The female tail is bent dorsally. There are no prominent teeth in the oesophageal funnel.

Cylicostephanus hybridus

Description: The walls of the buccal capsule are of uniform thickness, the elements of the external leaf crown are twice as long as broad, and the dorsal gutter extends halfway to the base of the inner leaf crown. The walls of the buccal capsule are straight, slightly thicker posteriorly in dorsal view.

Cylicostephanus longibursatus

Description: The walls of the buccal capsule are of uniform thickness, the elements of the external leaf crown are twice as long as broad, and the dorsal gutter is button-like. The walls of the buccal capsule have a slight compound curve and are slightly thicker posteriorly.

Cylicostephanus minutus

Description: The buccal capsule is as broad as deep and the walls are of uniform thickness. The external leaf crowns are composed of 8–18 triangular elements and the sub-median papillae are notched midway.

Cylicostephanus ornatus

Description: The walls of the buccal capsule are markedly thicker anteriorly, the elements of the external leaf crown are as broad as long, and the dorsal gutter extends almost to the base of the inner leaf crown. The buccal capsule is asymmetrical in lateral view and the walls of the capsule are concave. The teeth in the oesophageal funnel are not prominent.

Cylicostephanus poculatus

Description: The buccal capsule is deeper than broader in lateral view and the walls are much thicker posteriorly. The external leaf crown is composed of approximately 36 elements.

Cylicostephanus skrjabini

Description: The buccal capsule is deeper than broader in lateral view and the walls are much thicker posteriorly. The external leaf crown is composed of approximately 36 elements. It lacks a lateral projection on the inner wall of the buccal capsule and has a rim of dentiform processes at the bottom of the buccal capsule.

FAMILY SYNGAMIDAE

Syngamus

The large reddish female and the small whitish male are permanently *in copula* forming a 'Y' shape (Fig. 1.46). They are the only parasites found in the trachea of domestic birds. Males possess two spicules.

Life cycle: Eggs escape under the bursa of the male and are carried up the trachea in the excess mucus produced in response to infection; they are then swallowed and passed in the faeces. Unlike other strongyloids the L₃ develops within the egg. Infection may

Fig. 1.46 *Syngamus trachea* male and female worms *in copula*. (Redrawn from Neumann, trans. Fleming, 1892.)

occur by one of three ways: firstly by ingestion of the L₃ in the egg, secondly by ingestion of the hatched L₃, or thirdly by ingestion of a transport (paratenic) host containing the L₃. The most common paratenic host is the common earthworm, but a variety of other invertebrates including slugs, snails, beetles and some flies may act as transport hosts. After penetrating the intestine of the final host the L₃ travel, via the liver, to the lungs, probably in the blood since they are found in the alveoli 4–6 hours after experimental infection. The two parasitic moults take place in the lungs within 5 days, by which time the parasites are 1.0–2.0 mm long. Copulation occurs around day 7 in the trachea or bronchi after which the female grows rapidly. The prepatent period is 16–20 days. Longevity is around 9 months.

Syngamus species

| Species | Hosts | Site |
|-------------------------|---|---------|
| <i>Syngamus trachea</i> | Chicken, turkey, gamebirds (pheasants, partridges, guinea fowl), pigeons and various wild birds | Trachea |

Syngamus trachea

Synonyms: *Syngamus parvis*, *Syngamus gracilis*

Description: Female worms are reddish and 1–3 cm in size; the small whitish males measure up to 0.5 cm in length. The worms have large shallow cup-shaped buccal capsules, which have up to 10 teeth at their base. There are no leaf crowns. The bursal rays are short and thick and the spicules are long and of simple form.

Cyathostoma

The male bursa is well developed but worms in this species are not permanently *in copula*, as observed in *Syngamus*.

Life cycle: The life cycle is thought to be similar to that of *Syngamus*.

Cyathostoma species

| Species | Hosts | Site |
|--------------------------------|-------------------|------------------|
| <i>Cyathostoma bronchialis</i> | Goose, duck, swan | Trachea, bronchi |
| <i>Cyathostoma variegatum</i> | Duck, emu | Trachea, bronchi |

Cyathostoma bronchialis

Synonym: *Syngamus bronchialis*

Description: The worms are reddish in colour when fresh. Adult male worms are 4–6 mm and females much larger at 15–30 mm in length. The buccal capsule is large, deep and cup-shaped with six to seven teeth at its base. The male bursa is well developed but worms in this species are not permanently *in copula*, as seen in *Syngamus trachea*.

Cyathostoma variegatum

Description: Adult worms are 0.4–3 cm long; males are 4–6 mm and females 16–31 mm.

Mammomonogamus

These nematodes are similar to *Syngamus*. The worms are reddish in appearance and about 0.6–2 cm long. The females and males are found in permanent copulation. The large buccal capsule lacks a cuticular crown. There is a cervical papilla. Species of *Mammomonogamus* found in cats may be synonyms of the species found in ruminants.

Life cycle: The life cycle is direct but the mode of transmission is unknown.

Mammomonogamus species

| Species | Hosts | Site |
|--|--|------------------------|
| <i>Mammomonogamus nasicola</i> (syn. <i>Syngamus nasicola</i> , <i>Syngamus kingi</i>) | Sheep, goat, cattle, deer | Nasal cavities |
| <i>Mammomonogamus laryngeus</i> (syn. <i>Syngamus laryngeus</i>) | Cattle, buffalo, goat, sheep, deer, rarely human | Larynx |
| <i>Mammomonogamus auris</i> (syn. <i>Syngamus auris</i>) | Cat | Ear canals |
| <i>Mammomonogamus ierei</i> (syn. <i>Syngamus ierei</i>) | Cat | Nasal cavities |
| <i>Mammomonogamus mcgaughei</i> (syn. <i>Syngamus mcgaughei</i>) | Cat | Nasal sinuses, pharynx |

Mammomonogamus nasicola

Synonym: *Syngamus nasicola*, *Syngamus kingi*

Description: Males are 4–6 mm and females 11–23 mm long.

Mammomonogamus laryngeus

Synonym: *Syngamus laryngeus*

Description: Male worms are 3–6.3 mm and the larger females 8.7–23.5 mm long. Males possess spicules ranging from 23 to 30 µm in length and have cup-shaped buccal capsules that open at the

anterior end. Located deep in the buccal cavity are 8–10 teeth that are not thought to be used for attachment.

Mammomonogamus ierei

Synonym: *Syngamus ierei*

Description: Female worms are about 20 mm long, while male worms are 5–6.9 mm long and rather stocky in appearance. The worms are found with the bursa of the male attached at the level of the vulva of the female. There is a large buccal capsule that has eight large teeth at its base.

Stephanurus

Large worms found in the kidneys and perirenal tissues.

Life cycle: Preparasitic development from egg to L₃ is typically strongyloid, though earthworms may intervene as transport hosts. There are three modes of infection: by ingestion of the free L₃, ingestion of earthworms carrying the L₃ and percutaneously. After entering the body, there is an immediate moult and the L₄ travel to the liver in the bloodstream, either from the intestine by the portal stream or from the skin by the lungs and systemic circulation. In the liver the final moult takes place, and the young adults wander in the parenchyma for 3 months or more before piercing the capsule and migrating in the peritoneal cavity to the perirenal region. There they are enclosed in a cyst by the host reaction, and complete their development. The cyst communicates with the ureter either directly or, if it is more distant, by a fine connecting canal, allowing the worm eggs to be excreted in the urine. The prepatent period ranges from 6 to 19 months and the worms have a longevity of about 2–3 years.

Stephanurus species

| Species | Hosts | Site |
|-----------------------------|-------|--------|
| <i>Stephanurus dentatus</i> | Pig | Kidney |

Stephanurus dentatus

Description: A large stout worm up to 4.5 cm long, with a prominent buccal capsule and transparent cuticle through which the internal organs may be seen. Males are 2–3 cm and females 3–4.5 cm long. The colour is usually pinkish. The size and site are diagnostic. The buccal capsule is cup-shaped with small leaf crowns and six external cuticular thickenings (epaulettes), of which the ventral and dorsal are most prominent, and six cusped teeth at the base. The male bursa is short and the two spicules of either equal or unequal length.

FAMILY DELETROCEPHALIDAE**Deletrocephalus****Deletrocephalus species**

| Species | Hosts | Site |
|-----------------------------------|-------|-----------------|
| <i>Deletrocephalus dimidiatus</i> | Rhea | Small intestine |

Deletrocephalus dimidiatus

Description: Adult worms are stout and robust with a well-developed buccal capsule. Male worms are 9–11 mm and females 14–16 mm long. Males are bursate with long thin spicules.

Paradeletrocephalus

Paradeletrocephalus species

| Species | Hosts | Site |
|---------------------------------|-------|-----------------|
| <i>Paradelorocephalus minor</i> | Rhea | Small intestine |

Paradeletrocephalus minor

Description: Adult worms are similar in size and appearance to *Deletrocephalus* spp. The buccal capsule has vertical ridges and there are no external, or internal, coronary rings.

SUPERFAMILY ANCYLOSTOMATOIDEA

Hookworms are parasites of the small intestine and the genera of veterinary importance are *Ancylostoma*, *Uncinaria*, *Bunostomum* and, to a lesser extent, *Gaigeria*, *Globocephalus* and *Agriostomum*. In humans important hookworm genera are *Ancylostoma* and *Necator*.

FAMILY ANCYLOSTOMATIDAE

Ancylostoma

Ancylostoma are reddish-grey worms, the colour depending on whether the worm has fed, and are readily recognised on the basis of size. The anterior extremity is usually bent dorsally. The worms have a well-developed buccal capsule, which is devoid of leaf crowns, but is armed with teeth or chitinous cutting plates on its ventral edge.

Ancylostoma species

| Species | Hosts | Site |
|---|---|-----------------|
| <i>Ancylostoma braziliense</i> | Dog, fox, cat, wild canids | Small intestine |
| <i>Ancylostoma caninum</i> | Dog, fox, wild canids, occasionally human | Small intestine |
| <i>Ancylostoma ceylanicum</i> | Dog, cat, wild felids, occasionally human | Small intestine |
| <i>Ancylostoma tubaeforme</i> (syn. <i>Strongylus tubaeforme</i>) | Cat | Small intestine |
| <i>Ancylostoma duodenale</i> | Human, primates | Small intestine |

Ancylostoma caninum

Description: This is the largest species. Male worms are about 12 mm and females 15–20 mm in length. The anterior end is angled dorsal and the oral aperture is directed anterodorsally. The buccal capsule is large, with three pairs of marginal teeth and a pair of ventrolateral teeth, and possesses a dorsal gutter (Fig. 1.47). A dorsal cone is absent. The male bursa is well developed.

Fig. 1.47 Head of *Ancylostoma caninum* showing the large buccal capsule containing pairs of teeth.

Life cycle: The life cycle is direct and, given optimal conditions, the eggs may hatch and develop to L₃ in as little as 5 days. Infection is by skin penetration or by ingestion, both methods being equally successful. Paratenic hosts can also be important. In percutaneous infection, larvae migrate via the bloodstream to the lungs where they moult to L₄ in the bronchi and trachea, and are then swallowed and pass to the small intestine where the final moult occurs. If infection is by ingestion, the larvae may either penetrate the buccal mucosa and undergo the pulmonary migration or pass directly to the intestine where the adult worms burrow their buccal capsules into the mucosa. Whichever route is taken, the prepatent period is 14–21 days. The worms are prolific egg layers and an infected dog may pass millions of eggs daily for several weeks.

An important feature of *A. caninum* infection is that, in susceptible bitches, a proportion of the L₃ that reach the lungs migrate to the skeletal muscles where they remain dormant until the bitch is pregnant. They are then reactivated and, still as L₃, are passed in the milk of the bitch for a period of about 3 weeks after whelping. Transplacental transmission does not occur.

Ancylostoma braziliense

Description: In the dog, males measure around 7.5 mm and females 9–10 mm in length. The buccal capsule is deep with two pairs of large dorsal and very small ventral teeth.

Life cycle: Similar in many respects to *A. caninum*, with both oral and percutaneous routes of infection, but transmammmary transmission has not been demonstrated. Rodents can act as paratenic hosts. The prepatent period is about 2 weeks in the dog and cat.

Ancylostoma ceylanicum

Description: Almost identical to *A. braziliense*. The cuticular striations are wider than in *A. braziliense* and the inner pair of ventral teeth in the buccal capsule are larger.

Life cycle: Similar to *A. braziliense*. The prepatent period is about 2 weeks in the dog.

Ancylostoma tubaeforme

Synonym: *Strongylus tubaeforme*

Description: Almost identical to *A. caninum*, but slightly smaller, the males measuring around 10 mm and the females 12–15 mm. The buccal capsule is deep with the dorsal gutter ending in a deep notch on the dorsal margin of the buccal capsule, the ventral margin of which bears three teeth on each side. The cuticle is thicker and the deep ‘oesophageal’ teeth are slightly larger than in *A. caninum*. The male bursa is well developed and the spicules are about 50% longer than in *A. caninum*.

Life cycle: As for *A. braziliense*. The prepatent period is about 3 weeks.

Ancylostoma duodenale

Description: A small greyish-white worm ranging from around 8–13 mm in size. The buccal capsule is armed with two large teeth and a lower pair of small teeth.

Life cycle: Similar to *A. caninum*. The prepatent period is about 5 weeks in the dog.

Uncinaria

The genus consists of a single species. The worms are small, up to about 1.0 cm long; males are 5–8.5 mm and females 7–12 mm long.

Life cycle: Infection with infective L₃ by oral infection, without pulmonary migration, is the usual route. Although the infective larvae can penetrate the skin, the infection rarely matures and there is no evidence as yet of transmammary or intrauterine transmission. Carnivores may become infected via the consumption of paratenic hosts, such as infected mice. The prepatent period is about 15 days.

Uncinaria species

| Species | Hosts | Site |
|-------------------------------|---|-----------------|
| <i>Uncinaria stenocephala</i> | Dog, cat, fox, other wild canids and felids | Small intestine |

Uncinaria stenocephala

Description: The adult whitish worms have a large funnel-shaped buccal capsule, which has a pair of chitinous plates, lacks dorsal teeth but has a pair of subventral teeth at the base (Fig. 1.48). The dorsal cone does not project into the buccal capsule. The male worm has a well-developed bursa with a short dorsal lobe and two large lateral lobes, which are separate. The spicules are narrow.

Necator

Male worms are usually 7–9 mm long and females about 9–11 mm in length.

Necator species

| Species | Hosts | Site |
|---------------------------|--------------------------------|-----------------|
| <i>Necator americanum</i> | Human, primates, dog, cat, pig | Small intestine |

Fig. 1.48 Head of *Uncinaria stenocephala* showing the funnel-shaped buccal capsule and the pair of chitinous plates.

Necator americanum

Description: The buccal capsule has two dorsal and two ventral cutting plates around the anterior margin. There is also a pair of subdorsal, and a pair of subventral teeth located close to the rear of the buccal capsule.

Bunostomum

Bunostomum is one of the larger nematodes of the small intestine of ruminants, being 1.0–3.0 cm long, stout, greyish-white and characteristically hooked at the anterior end, with the buccal capsule opening anterodorsally (Fig. 1.49). In the buccal capsule area there are cuticular festoons.

Life cycle: Infection with the L₃ may be percutaneous or oral. After skin penetration, the larvae travel to the lungs and moult to fourth-stage larvae before re-entering the gastrointestinal tract after approximately 11 days. Ingested larvae usually develop without a migration. Further development continues in the gut.

Bunostomum species

| Species | Hosts | Site |
|-----------------------------------|--------------------------|-----------------|
| <i>Bunostomum phlebotomum</i> | Cattle | Small intestine |
| <i>Bunostomum trigonocephalum</i> | Sheep, goat, deer, camel | Small intestine |

Bunostomum phlebotomum

Description: Male worms are 10–18 mm and female worms 24–28 mm in length. This species is very similar to *B. trigonocephalum* in sheep, but the dorsal cone is shorter and there are two pairs of small subventral lancets at its base. In the male, the bursa is well developed and has very long and slender spicules.

Fig. 1.49 Head of *Bunostomum phlebotomum* showing the large buccal capsule and cutting plates.

Life cycle: The prepatent period is about 6 weeks after skin penetration, and 7–10 weeks after ingestion.

Bunostomum trigonocephalum

Synonym: *Monodontus trigonocephalum*

Description: Male worms are 12–17 mm and females 19–26 mm. The large buccal capsule opens anterodorsally and bears on the ventral margin a pair of chitinous cutting plates and internally a large dorsal cone. Dorsal teeth are absent from the buccal capsule but there are a pair of small subventral lancets at its base. In the male the bursa is well developed and the dorsal lobe is asymmetrical. The right externo-dorsal ray emerges higher up on the dorsal stem and is longer than the left. The left externo-dorsal ray arises near the bifurcation of the dorsal ray, which divides into two tri-digitate branches. The spicules are slender, twisted and relatively short. In the female the vulva opens a short distance in front of the middle of the body.

Life cycle: The prepatent period is 4–8 weeks.

Gaigeria

The single species of this genus is a hookworm that occurs mainly in the duodenum of small ruminants.

Life cycle: The life cycle is thought to be direct; the main route of infection is percutaneous. Infective L₃ larvae resemble those of *Bunostomum trigonocephalum* and are susceptible to desiccation.

Gaigeria species

| Species | Hosts | Site |
|-----------------------------|------------------------------|------------------------------|
| <i>Gaigeria pachyscelis</i> | Sheep, goats, wild ruminants | Duodenum and small intestine |

Gaigeria pachyscelis

Description: The worms are very similar in shape and size to *Bunostomum trigonocephalum*. Adult male worms measure up to 2 cm and females up to 3 cm long. The buccal capsule contains a large dorsal cone, and a pair of subventral lancets, which have several cusps each. There is no dorsal tooth. The male bursa has a large dorsal lobe and small lateral lobes, which are joined together ventrally. The anterolateral ray is short and rounded and is separated quite widely from the other lateral rays. The externo-dorsal rays arise from the main stem of the dorsal ray. The dorsal ray is split for about one-quarter of its length, and the two short branches terminate in three minute digitations. The spicules are short and stout and terminate with recurved unbarbed ends.

Globocephalus

Several species of this genus parasitise the small intestine of pigs. The worms are stout and whitish, and approximately 4–8 mm in length. The mouth opens subdorsally and the buccal capsule is globular in shape but with an absence of chitinous structures in the buccal capsule. There are no leaf crowns. The male bursa is well developed and possesses a gubernaculum and the spicules are slender.

Life cycle: The life cycle is direct, either by oral ingestion of L₃ larvae or by percutaneous penetration. Larval migration through the heart, lungs, trachea, oesophagus and stomach occurs.

Globocephalus species

| Species | Hosts | Site |
|---|----------------|-----------------|
| <i>Globocephalus urosubulatus</i> (syn. <i>Globocephalus longemucronatus</i> , <i>Globocephalus samoensis</i>) | Pig, wild boar | Small intestine |

Globocephalus urosubulatus

Synonym: *Globocephalus longemucronatus*, *Globocephalus samoensis*

Description: A very small, stout, whitish worm. Males measure 4–7 mm and females 6–9 mm in length. The mouth opens subdorsally and the buccal capsule is globular. There are two raised cuticular rings near the opening of the mouth. There are small triangular chitinous plates in the buccal capsule. Leaf crowns are absent. The male bursa is well developed and the spicules are slender.

Agriostomum

Worms are stout and greyish-white in colour. Males are around 9–11 mm and females 13–16 mm in length.

Agriostomum species

| Species | Hosts | Site |
|-----------------------------|---------------------------|-----------------|
| <i>Agriostomum vryburgi</i> | Cattle, buffalo, ox, zebu | Small intestine |

Agriostomum vryburgi

Description: The shallow buccal capsule opens anterodorsally and contains four pairs of large teeth on its margin and has a rudimentary

leaf crown. The large wide oesophageal opening at the base of the buccal capsule houses two small subventral lancets. The bursa is well developed and the ventral rays are close together and parallel. A gubernaculum is present and the spicules are equal in length.

SUPERFAMILY DIAPHANOCEPHALOIDEA

FAMILY DIAPHANOCEPHALIDAE

Nematodes of the genus *Kalicephalus* are hookworms of snakes. The life cycle is direct with a prepatent period of 2–4 months.

SUPERFAMILY METASTRONGYLOIDEA

Most worms in this superfamily inhabit the lungs or the blood vessels adjacent to the lungs. The typical life cycle is indirect, and the intermediate host is usually a mollusc.

They may be conveniently divided into four groups according to host: those occurring in **pigs** (*Metastrongylidae*: *Metastrongylus*); in **sheep** and **goats** (*Protostrongylidae*: *Muellerius*, *Protostrongylus*, *Cystocaulus*, *Spiculocaulus*, *Neostrongylus* and *Varestrongylus*); in **deer** (*Elaphostrongylus*, *Parelaphostrongylus*); and in the domestic and wild **carnivores** (*Filaroididae*: *Oslerus*, *Filaroides*, *Aelurostrongylus*; *Angostrongylidae*: *Angiostrongylus*; and *Crenosomidae*: *Crenosoma*).

FAMILY METASTRONGYLIDAE

Metastrongylus

Members of this genus are slender white worms, up to 6.0 cm in length, found in pigs. The site and long slender form are sufficient for generic identification. These worms have two lateral trilobed lips. Individual species are differentiated on the size and shape of the male spicules. The dorsal ray of the bursa is small. The life cycle involves an earthworm intermediate host.

Life cycle: In cold temperatures the eggs are very resistant and can survive for over a year in soil. Normally, however, they hatch almost immediately, the intermediate host ingesting the L₁. In the earthworm, development to L₃ takes about 10 days at optimal temperatures of 22–26°C. The longevity of the L₃ in the earthworm is similar to that of the intermediate host itself and may be up to 7 years. The pig is infected by ingestion of earthworms and the L₃, released by digestion, travel to the mesenteric lymph nodes and moult. The L₄ then reach the lungs by the lymphatic–vascular route, the final moult occurring after arrival in the air passages.

Metastrongylus species

| Species | Hosts | Site | Intermediate hosts |
|---|----------------|------|--|
| <i>Metastrongylus apri</i> (syn. <i>Metastrongylus elongatus</i>) | Pig, wild boar | Lung | Earthworms (<i>Lumbricus</i> , <i>Dendrobaena</i> , <i>Eisena</i> , <i>Helodrilus</i> spp.) |
| <i>Metastrongylus pudendotectus</i> (syn. <i>Metastrongylus brevivaginitus</i>) | Pig, wild boar | Lung | Earthworms (<i>Lumbricus</i> , <i>Dendrobaena</i> , <i>Eisena</i> , <i>Helodrilus</i> spp.) |
| <i>Metastrongylus salmi</i> | Pig, wild boar | Lung | Earthworms (<i>Lumbricus</i> , <i>Dendrobaena</i> , <i>Eisena</i> , <i>Helodrilus</i> spp.) |

Metastrongylus apri

Synonym: *Metastrongylus elongatus*

Description: The slender white adult male worms measure up to 25 mm and the females up to 58 mm in length. There are six small papillae located around the oral opening. The male bursa is relatively small and the dorsal rays are reduced. The spicules are filiform, around 4 mm long, and each terminates in a single hook. The vulva of the female is near the anus and both are covered in cuticular swellings.

Life cycle: The prepatent period is about 24 days.

Metastrongylus pudendotectus

Synonym: *Metastrongylus brevivaginitus*

Description: Differs from *M. apri* in having a larger bursa, and smaller spicules (<1.5 mm long) with double hooks in the male. Males are about 16–18 mm and females 20–37 mm in length. The female possesses a straight tail.

Life cycle: The prepatent period is about 4 weeks.

Metastrongylus salmi

Description: Similar to *M. pudendotectus* but with longer spicules, which are approximately 2 mm in length.

FAMILY PROTOSTRONGYLIDAE

Muellerius

These are grey-reddish, slender hair-like worms about 1.0–4.0 cm long, which, although large, are often difficult to discern with the naked eye as they are embedded in lung tissue.

Life cycle: The life cycle is indirect and involves a molluscan intermediate host. The worms are ovoviviparous, the L₁ being passed in the faeces; these penetrate the foot of the molluscan intermediate host, and develop to L₃ in a minimum period of 2–3 weeks. The sheep or goat is infected by ingesting the mollusc. The L₃, freed by digestion, travel to the lungs by the lymphatic–vascular route, the parasitic moults occurring in the mesenteric lymph nodes and lungs. The prepatent period of *Muellerius* is 6–10 weeks. The period of patency is very long, exceeding 2 years.

Muellerius species

| Species | Hosts | Site | Intermediate hosts |
|------------------------------|-----------------------------------|------|--|
| <i>Muellerius capillaris</i> | Sheep, goat, deer, wild ruminants | Lung | Slugs (<i>Limax</i> , <i>Agrolima</i> spp.) and snails (<i>Helix</i> , <i>Succinea</i> spp.) |

Muellerius capillaris

Description: Males are 12–14 mm and females 19–25 mm. The posterior end of the adult male is spirally coiled and the bursa is very small and folded inwards. The curved spicules consist of a proximal alate region and two distal serrated arms, which terminate in points. Two sclerotised rods represent the gubernaculum.

Protostrongylus

Adult worms are slender, hair-like, reddish worms found in the small bronchioles of the lung.

Life cycle: The worms are ovoviviparous, the L₁ being passed in the faeces; these penetrate the foot of the molluscan intermediate host, and develop to L₃ in a minimum period of 2–3 weeks. The final host is infected by ingesting the mollusc. The L₃, freed by digestion, travel to the lungs by the lymphatic–vascular route, the parasitic moults occurring in the mesenteric lymph nodes and lungs. The prepatent period of *Protostrongylus* is 5–6 weeks. The period of patency is very long, exceeding 2 years.

Protostrongylus species

| Species | Hosts | Site | Intermediate hosts |
|--------------------------------------|-----------------------------------|------|--|
| <i>Protostrongylus rufescens</i> | Sheep, goat, deer, wild ruminants | Lung | Snails (<i>Helicella</i> , <i>Theba</i> , <i>Abida</i> , <i>Zebrina</i> spp.) |
| <i>Protostrongylus brevispiculum</i> | Sheep | Lung | Snails |
| <i>Protostrongylus stilesi</i> | Sheep | Lung | Snails |
| <i>Protostrongylus skrjabini</i> | Sheep | Lung | Snails |
| <i>Protostrongylus rushi</i> | Sheep | Lung | Snails |
| <i>Protostrongylus davtiani</i> | Sheep | Lung | Snails |

Protostrongylus rufescens

Description: Male worms are up to 4.5 cm and females up to 6.5 cm in length. In the male, the bursa is well developed but small and reinforced by two chitinous plates. The dorsal ray is thick and globular in shape with six papillae on the ventral side. The tubular spicules are almost straight; the distal ends bear two membranous alae. The gubernaculum has two boot-shaped prolongations bearing several knobs posteriorly. A telamon is also present. In the female, the vulva is close to the conoid tail.

Protostrongylus brevispiculum

Description: The adult worms are small and hair-like. In the male, the dorsal ray is small and rounded and the externo-dorsal rays are elongate. The spicules are much shorter than in *P. rufescens* and the gubernaculum consists of two parts that are smooth and pointed and curve medially and ventrally. The telamon is well developed.

Cystocaulus

Adult worms are slender, thread-like, dark-brown worms found in the small bronchioles of the lung.

Life cycle: Similar to *Muellerius*. The prepatent period is 5–6 weeks.

Cystocaulus species

| Species | Hosts | Site | Intermediate hosts |
|-------------------------------|-----------------------------------|------|--|
| <i>Cystocaulus ocreatus</i> | Sheep, goat, deer, wild ruminants | Lung | Snails (<i>Helix</i> , <i>Helicella</i> , <i>Theba</i> , <i>Cepaea</i> , <i>Monacha</i> spp.) |
| <i>Cystocaulus nigrescens</i> | Sheep | Lung | Snails |

Cystocaulus ocreatus

Description: Male worms are up to 4–5 cm and females up to 9 cm long. In the male, the bursa is small; the spicules consist of a proximal cylindrical region joined distinctly to a distal lance-shaped region. The gubernaculum has a complex structure, with the posterior part consisting of two pointed boot-shaped structures. In the female, the vulva is protected by a bell-shaped expansion of the cuticle.

Spiculocaulus

Spiculocaulus species

| Species | Hosts | Site | Intermediate hosts |
|---------------------------------|-------------|------|--------------------|
| <i>Spiculocaulus austriacus</i> | Sheep, goat | Lung | Snails |

Neostrongylus

Small worms found in the lungs.

Life cycle: Similar to the other metastrongylid lungworms. The prepatent period in sheep is around 8–10 weeks.

Neostrongylus species

| Species | Hosts | Site | Intermediate hosts |
|-------------------------------|-------------|------|--------------------|
| <i>Neostrongylus linearis</i> | Sheep, goat | Lung | Snails |

Neostrongylus linearis

Description: Adult worms are small worms; the males are 5–8 mm and females 13–15 mm long. In the male, the spicules are unequal in size.

Varestrongylus

Thread-like worms found in the lung parenchyma and bronchioles.

Life cycle: Ingested third-stage larvae present within the intermediate host migrate through the intestinal wall to the lymph nodes, migrating via the lymph and blood to the lungs. They then form 'breeding clusters' in which they grow to sexual maturity. Female worms are ovoviviparous with first-stage larvae coughed up and swallowed. When ingested by a molluscan intermediate host the larvae develop to infective L₃ in 3–4 weeks.

Varestrongylus species

| Species | Hosts | Site | Intermediate hosts |
|--|-----------------------|------|--------------------|
| <i>Varestrongylus schulzi</i> (syn. <i>Bicaulus schulzi</i>) | Sheep, goats | Lung | Snails |
| <i>Varestrongylus sagittatus</i> | Red deer, fallow deer | Lung | Slugs and snails |
| <i>Varestrongylus capreoli</i> | Red deer, fallow deer | Lung | Snails |

Varestrongylus schulzi

Description: Adult worms are slender small worms; males are 12–15 mm and females 13–15 mm long.

Varestrongylus sagittatus

Description: Worms are slender and measure 14–34 mm in length.

Elaphostrongylus

Elaphostrongylus species

| Species | Hosts | Site | Intermediate hosts |
|--|---------------------------------|------------------------|--------------------|
| <i>Elaphostrongylus cervi</i> (syn. <i>Elaphostrongylus rangiferi</i>) | Deer (red, roe, sika, reindeer) | Connective tissue, CNS | Slugs and snails |

Elaphostrongylus cervi

Synonym: *Elaphostrongylus rangiferi*

Description: The mature reddish worms are long and slender. Males are up to 40 mm long and females up to 60 mm long.

Parelaphostrongylus

Parelaphostrongylus species

| Species | Hosts | Site | Intermediate hosts |
|---|--|-----------------------|--------------------|
| <i>Parelaphostrongylus tenuis</i> (syn. <i>Odocoileostrongylus tenuis</i> , <i>Elaphostrongylus tenuis</i>) | White-tailed deer, moose, wapiti, other deer species, llama, guanaco, alpaca | Cranial meninges, CNS | Slugs and snails |

Parelaphostrongylus tenuis

Synonyms: *Odocoileostrongylus tenuis*, *Elaphostrongylus tenuis*

Description: The mature worms are reddish in colour, long and thread-like; males are up to 40 mm long and females 90 mm.

FAMILY FILAROIDIDAE

Oslerus

This genus was part of the larger genus *Filaroides*, but has now been separated on morphological grounds from the other members. Though distinction has been made on morphology, it is also useful from the veterinary standpoint, for it separates the single harmful species, *Oslerus osleri*, living in the upper air passages, from the relatively harmless species which are retained in the genus *Filaroides*, and which live in the lung parenchyma. *Oslerus*, and its closely related genus *Filaroides*, are exceptional in the superfamily Metastrongyloidea in having direct life cycles.

Life cycle: The females are ovoviviparous, and most eggs hatch in the trachea. Many larvae are coughed up and swallowed and passed in the faeces and infection may occur by ingestion of these; more commonly, transmission occurs when an infected bitch licks the pup and transfers the newly hatched L₁, which are present in her sputum. After ingestion, the first moult occurs in the small intestine and the L₂ travel to the lungs by the lymphatic-

vascular route. Development through to L₅ takes place in the alveoli and bronchi, and the adults migrate to their predilection site, the tracheal bifurcation. The prepatent period varies from 10 to 18 weeks.

Oslerus species

| Species | Hosts | Site |
|--|------------------|------------------|
| <i>Oslerus osleri</i> (syn. <i>Filaroides osleri</i>) | Dog, wild canids | Trachea, bronchi |
| <i>Oslerus rostratus</i> (syn. <i>Anafilaroides rostratus</i> , <i>Filaroides rostratus</i>) | Wild cats, cat | Bronchi |

Oslerus osleri

Description: The worms, which are embedded in fibrous nodules in the trachea in the region of the bifurcation and in the adjacent bronchi, are small, pale and slender; males are 5 mm and females 9–15 mm long and slightly thicker. The tail of the male is rounded without obvious bursal lobes and bears a few papillae. The short spicules are slightly unequal. In the female the vulva is located close to the anus.

Oslerus rostratus

Synonym: *Anafilaroides rostratus*, *Filaroides rostratus*

Description: The adult males are about 28–37 mm long and the adult females 48–64 mm long. The vulva in the female is located just anterior to the anus.

Filaroides

The worms are very small (0.5–1.0 cm long), slender, hair-like and greyish, and are not only difficult to see with the naked eye in the lung parenchyma but are also unlikely to be recovered intact from the tissue. These lungworms have a direct life cycle.

Filaroides species

| Species | Hosts | Site |
|--|---------------------------------|------|
| <i>Filaroides hirthi</i> | Dog | Lung |
| <i>Filaroides milksi</i> (syn. <i>Andersonstrongylus milksi</i>) | Dog | Lung |
| <i>Filaroides bronchialis</i> (syn. <i>Filaroides martis</i>) | Mink, polecat, other Mustelidae | Lung |

Filaroides hirthi

Description: The worms are very small (0.5–1.0 cm long), slender, hair-like and greyish, and are not only difficult to see with the naked eye in the lung parenchyma but are unlikely to be recovered intact from the tissue.

Life cycle: The life cycle is direct. The worms are ovoviviparous and the hatched L₁ are passed in faeces or expelled in sputum. Though infection may be acquired by ingestion of faecal larvae, the important route, as in *Oslerus* infection, is thought to be by transfer of L₁

in the bitch's saliva when the pup is licked. The prepatent period of *F. hirthi* is around 5 weeks.

Filaroides milksi

Description: As for *F. hirthi*. *Filaroides milksi* is larger than *F. hirthi*.

Aelurostrongylus

The genus consists of one species, *Aelurostrongylus abstrusus*, which is common in the lungs of the domestic cat.

Life cycle: The life cycle is indirect. The worms are ovoviviparous, and the L₁ are passed in the faeces. These penetrate the foot of the molluscan intermediate host and develop to the infective L₃ and during this phase paratenic hosts, such as birds and rodents, may eat the mollusc. The cat is usually infected by ingestion of these paratenic hosts and less frequently by ingestion of the intermediate hosts. The L₃ released in the alimentary tract travel to the lungs by the lymphatics or bloodstream. After the final moult the adults are located in the alveolar ducts and the terminal bronchioles. The prepatent period is between 4 and 6 weeks, and the duration of patency is about 4 months, though some worms may survive in the lungs for several years despite the absence of larvae in the faeces.

Aelurostrongylus species

| Species | Hosts | Site | Intermediate hosts |
|-----------------------------------|-------|------|--------------------|
| <i>Aelurostrongylus abstrusus</i> | Cat | Lung | Slugs and snails |

Aelurostrongylus abstrusus

Description: Aggregations of worms, eggs and larvae are present throughout the lung tissue. The worms, about 1.0 cm long, are very slender and delicate, and are difficult to recover intact for examination; a squeeze preparation from a cut surface of the lung will show the worm material including the characteristic L₁, which bear a subterminal spine on their S-shaped tail (Fig. 1.50). The male bursa is short and the lobes are indistinct. The spicules are simple in form.

Fig. 1.50 *Aelurostrongylus abstrusus* L₁: S-shaped tail bears a subterminal spine.

FAMILY ANGIOSTRONGYLIDAE

Angiostrongylus

Angiostrongylus species

| Species | Hosts | Site | Intermediate hosts |
|--------------------------------------|------------|---|--------------------|
| <i>Angiostrongylus vasorum</i> | Dog, fox | Heart, pulmonary vessels | Slugs and snails |
| <i>Angiostrongylus cantonensis</i> | Rat, human | Pulmonary artery (rat), meninges (human) | Slugs and snails |
| <i>Angiostrongylus costaricensis</i> | Rat, human | Ileocaecal arteries (rat), intestines (human) | Slugs and snails |

Angiostrongylus vasorum

Description: These are small reddish worms. The slender male worms measure 14–18 mm and the stouter females 18–25 mm in length. Males have a small bursa and the female has a 'barber's pole' appearance with the white ovaries coiled round the red intestine, similar to that in *Haemonchus*.

Life cycle: The genus is ovoviviparous. The adult worms in the larger pulmonary vessels lay eggs, which are carried to the capillaries, where they hatch. The L₁ break into the alveoli, migrate to the trachea and thence to the alimentary tract to be passed in the faeces. Further development takes place after entry into the intermediate host, the infective third stage being reached in 17 days. After the mollusc has been ingested by the dog, the infective L₃, freed by digestion, travel to the lymph nodes adjacent to the alimentary tract, where both parasitic moults take place, and then to the vascular predilection site. L₅ have also been found in the liver. The prepatent period is around 7 weeks, and the worms can live in the dog for more than 2 years.

Angiostrongylus cantonensis

Description: The body is filariform and tapered at both ends. Males measure about 18 mm and females 23 mm in length. Fresh female worms have a 'barber's pole' appearance as the white uterine tubules spiral round the blood-filled intestine. The slender spicules are of equal length and are striated. A gubernaculum is present.

Life cycle: Infection is acquired through ingestion of a mollusc containing L₃ larvae. The larvae are released in the digestive tract and migrate via the hepatic portal system and lungs to the central nervous system where they undergo two moults. The young worms eventually migrate via the cerebral vein to the pulmonary arteries. The adult worms mate and lay eggs that pass to the capillaries; these eggs embryonate and hatch and L₁ larvae enter the alveoli and eventually are coughed up, swallowed and pass out in the faeces. These larvae are about 270–300 µm long. The L₁ are ingested by, or penetrate, the intermediate host. The prepatent period is around 6 weeks.

Angiostrongylus costaricensis

Description: The worms are tapered at both ends and are filiform in shape. Males measure about 20 mm and females 30–40 mm in length. The spicules are equal in length, slender and striated. The cephalic ends of the spicules are blunt and the caudal tips are pointed. A gubernaculum is present.

Life cycle: Larvae are shed in the faeces of the rodent and are ingested by a mollusc in which development to the L₃ stage takes place. Following ingestion of the mollusc by rats, or ingestion of vegetation that is contaminated with infective mucous trails, the L₃ migrate via the lymphatics. After two moults the worms migrate to the ileocaecal arteries where they mature, reproduce and lay eggs, which are then carried to the intestinal wall. Eggs embryonate and hatch to L₁ larvae which migrate to the lumen of the intestine and pass out in the faeces. The prepatent period is around 3–4 weeks.

FAMILY CRENOSOMATIDAE

Crenosoma

This genus contains several species that are parasitic in carnivores and insectivores.

Crenosoma species

| Species | Hosts | Site | Intermediate hosts |
|-------------------------|----------------|-------------------------------|--------------------|
| <i>Crenosoma vulpis</i> | Dog, fox, wolf | Trachea, bronchi, bronchioles | Slugs and snails |

Crenosoma vulpis

Description: These slender white worms are characterised by having a crenated cuticle that is thrown into folds (18–26 overlapping circular folds) on the anterior end, making this portion of the worm appear superficially segmented. The males are 4–8 mm long and possess a well-developed bursa and a gubernaculum. The posterior third of the spicules possess a dorsal slender spur. The females are 12–16 mm long and have the vulva located near the mid-body. *Crenosoma vulpis* is ovoviviparous.

Life cycle: Adult females deposit thin-shelled eggs containing first-stage larvae (L₁), which ascend the trachea and pass into the intestinal tract and out in the faeces. These larvae penetrate the foot of the intermediate molluscan host and are present as infective third-stage larvae (L₃) in about 3 weeks. After ingestion of the molluscan host by the final host, the L₃ are released by digestion and travel to the lungs, via the lymphatic glands and hepatic circulation, where both parasitic moults take place. The prepatent period is around 3 weeks.

SUPERFAMILY RHABDITOIDEA

This is a primitive group of nematodes which are mostly free-living, or parasitic in lower vertebrates and invertebrates. *Rhabdias* are respiratory parasites in reptiles. Although a few normally free-living genera such as *Halicephalobus* (*Micronema*) and *Rhabditis* occasionally cause problems in animals, the only important genus from the veterinary point of view is *Strongyloides*.

FAMILY STRONGYLOIDIDAE

Strongyloides

Members of this genus are common parasites of the small intestine in very young animals and although generally of little pathogenic

Fig. 1.51 *Strongyloides* spp. adult female.

significance, under certain circumstances may give rise to severe enteritis.

These are slender, hair-like, colourless worms generally less than 10 mm long and only the female worms are parasitic. The long cylindrical oesophagus (typically rhabditiform in shape) may occupy up to one-third of the body length and the filamentous uterus is intertwined with the intestine, giving the appearance of contorted twisted thread (Fig. 1.51). Unlike other intestinal parasites of similar size the tail has a blunt point. Species identification is generally based on identification of the characteristic female worms, or eggs, in the host species.

Life cycle: *Strongyloides* is unique among the nematodes of veterinary importance, being capable of both parasitic and free-living reproductive cycles. The parasitic phase is composed entirely of female worms in the small intestine and these produce larvated eggs by parthenogenesis, i.e. development from an unfertilised egg. In herbivores it is the larvated egg which is passed out in the faeces, but in other animals it is the hatched L₁. After hatching, larvae may develop through four larval stages into free-living adult male and female worms and this can be followed by a succession of free-living generations. However, under certain conditions, possibly related to temperature and moisture, the L₃ can become parasitic, infecting the host by skin penetration or ingestion and migrating via the venous system, the lungs and trachea to develop into adult female worms in the small intestine.

Young animals may acquire infection immediately after birth from the mobilisation of arrested larvae in the tissues of the ventral abdominal wall of the dam, which are subsequently excreted in the milk. In addition, prenatal infection has been demonstrated experimentally in cattle. The prepatent period in most species is 8–14 days.

Strongyloides species

| Species | Hosts | Site |
|---|---|-------------------------|
| <i>Strongyloides papillosus</i> | Sheep, cattle, goat, wild ruminants, rabbit | Small intestine |
| <i>Strongyloides westeri</i> | Horse, donkey, zebra, rarely pig | Small intestine |
| <i>Strongyloides ransomi</i> | Pig | Small intestine |
| <i>Strongyloides avium</i> | Chicken, turkey, goose, wild birds | Small intestine, caecae |
| <i>Strongyloides stercoralis</i> (syn. <i>Strongyloides canis</i> , <i>Strongyloides intestinalis</i> , <i>Anguillula stercoralis</i>) | Dog, fox, cat, human, Old World monkeys, apes | Small intestine |
| <i>Strongyloides planiceps</i> | Cat | Small intestine |
| <i>Strongyloides felis</i> (syn. <i>Strongyloides cati</i>) | Cat | Small intestine |
| <i>Strongyloides tumefaciens</i> | Cat | Large intestine |
| <i>Strongyloides ratti</i> | Rat | Small intestine |
| <i>Strongyloides cebus</i> | New World monkeys | Small intestine |
| <i>Strongyloides fulleborni</i> | Old World monkeys, apes | Small intestine |

Strongyloides papillosus

Description: Adult female worms are 3.5–6 mm long with an oesophagus 0.6–0.8 mm in length.

Strongyloides westeri

Description: Adult female worms are up to 9 mm long with an oesophagus measuring 1.2–1.5 mm in length.

Strongyloides ransomi

Description: Female worms are around 3.5–4.5 mm long.

Life cycle: The prepatent period is 6–9 days.

Strongyloides avium

Description: Adult female worms are approximately 2 mm long with an oesophagus 0.7 mm in length.

Strongyloides stercoralis

Synonym: *Strongyloides canis*, *Strongyloides intestinalis*, *Anguillula stercoralis*

Description: The parasitic female is approximately 2.2 mm long. The oesophagus is about 0.6 mm in length.

Strongyloides planiceps

Description: Parasitic females are 2.4–3.3 mm long (mean 2.8 mm). The tail of the parasitic female narrows abruptly to a blunt tip, and the worms have ovaries with a spiral appearance.

Strongyloides felis

Synonym: *Strongyloides cati*

Description: Similar to *S. planiceps*. Parasitic females of *S. felis* have a long tail narrowing slowly to the tip. Ovaries are straight.

Strongyloides tumefaciens

Description: The parasitic females are 5 mm long and found in tumours of the large intestine.

FAMILY PANAGROLAIMIDAE***Halicephalobus* (syn. *Micronema*)**

Occasional cases of infection of horses with the saprophytic free-living nematode *Halicephalobus deletrix* (syn. *Halicephalobus gingivalis*, *Micronema deletrix*) have been described from various parts of the world. In affected animals the very small worms, less than 0.5 mm in length, have been found in nasal and maxillary granulomas and in the brain and kidney.

FAMILY RHABDITIDAE***Rhabditis***

Several members of this free-living genus of nematodes may become casual parasites, the larvae invading the skin and causing an intense pruritus. The larvae do not migrate but die and so adults are not present in animals. Cases have been most frequently reported in dogs housed in kennels with damp hay or straw bedding and the lesions, usually confined to areas of the body in contact with the ground, show hair loss, erythema and pustule formation if infected with bacteria. The very small worms (1.0–2.8 mm in length) with a rhabditiform oesophagus may be recovered from skin scrapings. Treatment is symptomatic and the condition can be prevented by housing animals on clean dry bedding.

Rhabditis infection has also been associated with otitis externa in cattle in the tropics.

***Rhabditis* species**

| Species | Hosts | Site |
|--|--------------------|---------------------------|
| <i>Rhabditis strongyloides</i> (syn. <i>Pelodera strongyloides</i>) | Dog, cattle, horse | Subcutaneous tissue, skin |

FAMILY RHABDIASIDAE

Lungworms of the genus *Rhabdias* are common parasites of amphibians and reptiles, with about 60 species reported worldwide.

Life cycle: Only females are parasitic and these produce larvated, oval, thin-shelled eggs. After hatching, larvae may develop through four larval stages into free-living adult male and female worms and this can be followed by a succession of free-living generations. Infection is usually via the oral route (but percutaneous infection is also possible) and larvae penetrate the oesophageal tissue and then pass via the body cavity and primarily reside near the lower lung as

ungravid adults. These adults then penetrate the lungs and feed on blood, becoming gravid and passing embryonated eggs in the faeces. Usually no intermediate hosts are involved. However, transport hosts such as physid snails, earthworms or frogs can be involved for some *Rhabdias* species.

SUPERFAMILY ASCARIDOIDEA

The ascaridoids are among the largest nematodes and occur in most domestic animals, both larval and adult stages being of veterinary importance. While the adults in the intestine may cause unthriftiness in young animals, and occasional obstruction, an important feature of the group is the pathological consequences of the migratory behaviour of the larval stages.

With a few exceptions the genera have the following characters in common. They are large, white or cream, opaque worms that inhabit the small intestine. There is no buccal capsule, the mouth consisting simply of a small opening surrounded by three large conspicuous lips. A posterior bulb is usually absent from the oesophagus. The males possess two spicules but do not have a bursa. The common mode of infection is by ingestion of the thick-shelled egg containing the L₂. However, the cycle may involve transport and paratenic hosts.

Genera of veterinary interest include *Ascaris*, *Toxocara*, *Toxascaris*, *Parascaris*, *Ascaridia*, *Heterakis*, *Porrocaecum*, *Bayliascaris*, *Paraspidodera* and to a lesser extent the anisakids (Anisakidae: *Anisakis*, *Contracaecum*, *Hysterothylacium*, *Pseudoterranova*). Other ascaridoids occur in reptiles and include *Ophidascaris* and *Polydelphus* found in snakes and *Angusticaecum* and *Sulcascaris* found in chelonia.

FAMILY ASCARIDIDAE

Ascaris

Large, stout, white worms around 15–40 cm in length.

Ascaris species

| Species | Hosts | Site |
|-----------------------------|-----------------------|-----------------|
| <i>Ascaris suum</i> | Pig | Small intestine |
| <i>Ascaris lumbricoides</i> | Human (some primates) | Small intestine |

Ascaris suum

Description: The rigid females are up to 40.0 cm long and 5 mm in width and the males up to 25 cm in length. The dorsal lip possesses two double papillae, and each ventrolateral lip has one double papilla and a small lateral papilla. These lips have a row of very small denticles on their interior surface. The oesophagus is about 6.5 mm long and simple in shape. The male spicules are stout and the males tend to be slightly curved posteriorly.

Life cycle: The life cycle is direct. Though the preparasitic moults occur by about 3 weeks after the egg is passed, a period of maturation is necessary, and the egg is not usually infective until a minimum of 4 weeks after being passed, even in the optimal temperature range of 22–26°C. The egg is very resistant to temperature extremes, and is viable for more than 4 years. After ingestion, the larvated egg

hatches in the small intestine, the L₃ larva penetrates the intestinal mucosa and then travels to the liver. The larva then passes in the bloodstream to the lungs and thence to the small intestine via the bronchi, trachea and pharynx. In the intestine the final moult occurs and the young adult worms inhabit the lumen of the small intestine. If the eggs are ingested by an earthworm or dung beetle they will hatch, and the L₃ travel to the tissues of these paratenic hosts, where they can remain, fully infective for pigs, for a long period. The prepatent period is between 7 and 9 weeks, and each female worm is capable of producing more than 200,000 eggs per day. Longevity is around 6–9 months.

Ascaris lumbricoides

Description: Male worms are 15–31 cm long and the posterior end is curved ventrally and has a bluntly pointed tail. Female worms are 20–49 cm long with the vulva located in the anterior end, which accounts for about one-third of its body length.

Toxocara

Nematodes in this genus are large white/cream-coloured worms, with females up to 18 cm and males up to 10 cm in length. There are no interlabia or intestinal caeca.

Toxocara species

| Species | Hosts | Site |
|---|-----------------|-----------------|
| <i>Toxocara canis</i> | Dog, fox | Small intestine |
| <i>Toxocara mystax</i> (syn. <i>Toxocara cati</i>) | Cat | Small intestine |
| <i>Toxocara malayiensis</i> | Cat | Small intestine |
| <i>Toxocara vitulorum</i> (syn. <i>Neosascaris vitulorum</i>) | Buffalo, cattle | Small intestine |

Toxocara canis

Description: Adult male worms measure up to 10 cm and females 18 cm in length, although the size can vary considerably (see Fig. 12.3). The adult head is elliptical due to the presence of a pair of large lanceolate cervical alae and the anterior body is curved ventrad. The mouth is surrounded by three large lips. There is no buccal capsule and the oesophagus lacks a posterior bulb. The tail of the male has caudal alae and a narrow terminal appendage. Female genital organs extend both anteriorly and posteriorly to the vulval area.

Life cycle: This species has the most complex life cycle in the superfamily, with four possible modes of infection. The basic form is typically ascaridoid, the egg containing the L₃ being infective, at optimal temperatures, 4 weeks after being passed. After ingestion, and hatching in the small intestine, the larvae travel by the bloodstream via the liver to the lungs, where the second moult occurs. The larvae then return via the trachea to the intestine where the final two moults take place. This form of ascaridoid migration occurs regularly only in dogs of up to about 2–3 months old.

In dogs over 3 months of age, hepatic–tracheal migration occurs less frequently, and at around 4–6 months it has almost ceased and

is replaced by somatic migration, followed by hypobiosis. However, some dogs will support hepatic–tracheal migration as adults. Instead of hepatic–tracheal migration, the L₃ travel to a wide range of tissues including the liver, lungs, brain, heart and skeletal muscle, and the walls of the alimentary tract.

In the pregnant bitch, prenatal infection occurs, larvae becoming mobilised at about 3 weeks prior to parturition and migrating to the lungs of the fetus where they moult just before birth. In the newborn pup the cycle is completed when the larvae travel to the intestine via the trachea, and the final moults occur. A bitch, once infected, will usually harbour sufficient larvae to infect all her subsequent litters, even if she never again encounters the infection. A few of these mobilised larvae, instead of going to the uterus, complete the normal migration in the bitch, and the resulting adult worms produce a transient but marked increase in faecal *Toxocara* egg output in the weeks following parturition.

The suckling pup may also be infected by ingestion of L₃ in the milk during the first 3 weeks of lactation. There is no migration in the pup following infection by this route. Paratenic intermediate hosts such as rodents, sheep, pigs or birds may ingest the infective eggs and the L₃ travel to their tissues where they remain until eaten by a dog, when subsequent development is apparently confined to the gastrointestinal tract.

A final complication is recent evidence that bitches may be reinfected during late pregnancy or lactation, leading directly to transmammary infection of the suckling pups and, once patency is established in the bitch, to contamination of the environment with eggs. The bitch may be reinfected via the ingestion of larval stages from the fresh faeces of puppies through her coprophagic activities.

The known minimum prepatent periods are as follows.

- Direct infection following ingestion of eggs or larvae in a paratenic host: 4–5 weeks.
- Prenatal infection: 2–3 weeks.

Toxocara mystax

Synonym: *Toxocara cati*

Description: Males are 3–6 cm and females 4–10 cm long. The anterior end of the worm is curved ventrad. The striated cervical alae have a broad arrowhead form, with the posterior margins almost at a right angle to the body (Fig. 1.52a). The tail of the male has a terminal narrow appendage.

Life cycle: The life cycle of *T. mystax* is migratory when infection occurs by ingestion of the L₂ in the egg, and non-migratory after transmammary infection with L₃ or after ingestion of a paratenic host.

Following ingestion of eggs containing an infective second-stage larva, the larvae enter the stomach wall and then migrate via the liver, lungs and trachea back to the stomach and moult to L₃, while L₄ occur in the stomach contents, the intestinal wall and bowel contents. Rodent infections also play an important part in the life cycle. In these, larvae remain as second-stage forms but when an infected mouse is eaten by a cat the larvae, liberated by digestion, enter the stomach wall of the cat and develop to L₃. As well as mice acting as ‘intermediate hosts’, L₂ may be found in the tissues of earthworms, cockroaches, chickens, sheep and other animals fed infective eggs.

Transmammary infection is common throughout lactation, particularly in acutely infected cats, and the lactogenic route of

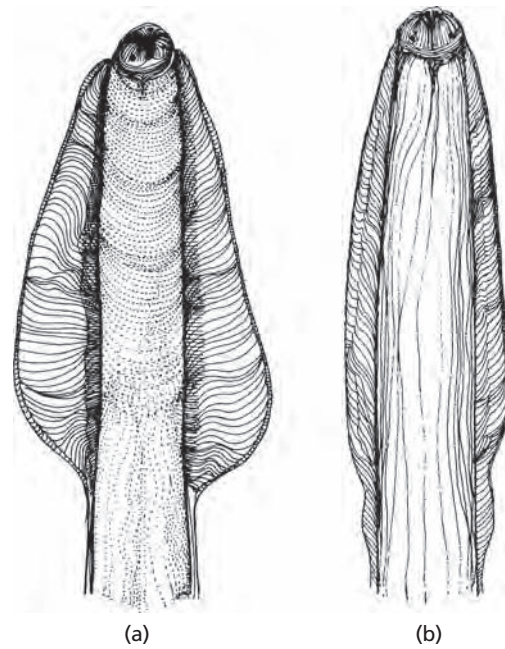

Fig. 1.52 Comparison of the anterior region of (a) *Toxocara mystax* and (b) *Toxascaris leonina*. The cervical alae of *Toxocara mystax* are arrow-shaped whereas those of *Toxascaris leonina* are more slender and less protrusive.

transmission is the most important. Prenatal infection through the placenta does not occur, which is dissimilar to *T. canis*. The prepatent period from egg infection is about 8 weeks.

Toxocara malayiensis

Description: *Toxocara malayiensis* is a large white worm; males are 5.3–8.5 cm, females 1.1–1.4 cm, morphologically similar to *T. canis* in dogs. There are three well-defined lips, each with a deep median notch lined with denticles: a dorsal lip with two large outer papillae, and two subventral lips each with one outer papilla. Cervical alae arise immediately behind the lips, gradually increasing in width to mid-length, then tapering gradually posteriorly.

Life cycle: The life cycle has not been fully described.

Toxocara vitulorum

Description: Adult male worms measure 20–25 cm and females 25–30 cm in length. There are three lips, which are broad at the base and narrow anteriorly. The tail of the male has a small spike-like appendage. There are a variable number of pre-cloacal papillae and five post-cloacal papillae, of which the anterior pair are large and double.

Life cycle: The most important source of infection is the milk of the dam, in which larvae are present for up to 3–4 weeks after parturition. There is no tissue migration in the calf following milk-borne infection and the prepatent period is 3–4 weeks. The ingestion of larvated eggs by calves over 6 months of age seldom results in patency, the larvae migrating to various tissues where they remain dormant; in female animals, resumption of development in late pregnancy allows further transmammary transmission.

Toxascaris

Large worms grossly very similar to *Toxocara canis* with cervical alae present. A posterior bulb is absent from the oesophagus. The tail of the male does not possess a narrow terminal appendage as is the case for *T. canis* and *T. mystax*.

Toxascaris species

| Species | Hosts | Site |
|--|---------------------------------------|-----------------|
| <i>Toxascaris leonina</i> (syn. <i>Toxascaris limbata</i>) | Dog, cat, fox, wild canids and felids | Small intestine |

Toxascaris leonina

Synonym: *Toxascaris limbata*

Description: Males measure up to 7 cm long and females up to 10 cm and their anterior bodies are curved dorsad. The cervical alae are slender and arrow-like, tapering posteriorly (Fig. 1.52b). The tail of the male is simple. The female genital organs are positioned behind the level of the vulva.

Life cycle: The infective stage is the egg containing a second-stage larva or the third-stage larvae present in a mouse intermediate host. The eggs develop rapidly to the infective stage (about 1 week) compared with that for *Toxocara* species (around 4 weeks). Following ingestion and hatching, larvae enter the wall of the small intestine and remain for about 2 weeks. No migration of larvae occurs, as with other ascarid species. Third-stage larvae appear after about 11 days and moult to L₄ about 3–5 weeks post infection. Adult stages appear from about 6 weeks post infection and lie in the lumen of the intestine. The prepatent period is 10–11 weeks.

Parascaris

This very large, rigid, stout, whitish nematode, up to 40 cm in length, is found in the small intestine of equids (Fig. 1.53).

Life cycle: The life cycle is direct and migratory, involving a hepatopulmonary route. Eggs produced by the adult female worms are passed in the faeces and can reach the infective stage containing the L₂ in as little as 10–14 days, although development may be delayed

Fig. 1.53 *Parascaris equorum* adult worms in the small intestine.

at low temperatures. After ingestion and hatching the larvae penetrate the intestinal wall and within 48 hours have reached the liver. By 2 weeks they have arrived in the lungs where they migrate up the bronchi and trachea, are swallowed and return to the small intestine. The site of occurrence and timing of the parasitic larval moults of *P. equorum* are not precisely known, but it would appear that the moult from L₂ to L₃ occurs between the intestinal mucosa and the liver and the two subsequent moults occur in the small intestine. The minimum prepatent period of *P. equorum* is 10 weeks; longevity is up to 2 years. There is no evidence of prenatal infection.

Parascaris species

| Species | Hosts | Site |
|--|----------------------|-----------------|
| <i>Parascaris equorum</i> (syn. <i>Ascaris equorum</i> , <i>Ascaris megacephala</i>) | Horse, donkey, zebra | Small intestine |

Parascaris equorum

Description: Males measure 15–28 cm and females up to 40–50 cm long with a stout head. In heavy infections the worms can be smaller. The three main lips are separated by three smaller intermediate lips (interlabia) and are divided into anterior and posterior sections by horizontal grooves. Small lateral alae are present on the tail of the male. There are three single pairs and two double pairs of post-cloacal papillae. A large number of pre-cloacal papillae are present, with a single median papilla on the anterior border of the cloaca.

Ascaridia

These large worms are stout and densely white, the females measuring up to 12.0 cm in length (Fig. 1.54). The narrow lateral alae are often not apparent grossly.

Life cycle: The egg becomes infective at optimal temperatures in a minimum of 3 weeks and the parasitic phase is non-migratory, consisting of a transient histotrophic phase in the intestinal mucosa after which the adult parasites inhabit the lumen of the intestine. The egg is sometimes ingested by earthworms, which may act as transport hosts. Eggs can remain viable for several months under moist cool conditions but are killed by a dry hot environment. The

Fig. 1.54 *Ascaridia galli* adult worms in the small intestine.

prepatent period ranges from 4 to 6 weeks in chicks to 8 weeks or more in adult birds. The worms live for about 1 year.

Ascaridia species

| Species | Hosts | Site |
|--|--|-----------------|
| <i>Ascaridia galli</i> (syn. <i>Ascaridia lineata</i> , <i>Ascaridia perspicillum</i>) | Chicken, turkey, goose, duck, guinea fowl and a number of wild galliform birds | Small intestine |
| <i>Ascaridia dissimilis</i> | Turkey | Small intestine |
| <i>Ascaridia columbae</i> (syn. <i>Ascaridia maculosa</i>) | Pigeon | Small intestine |

Ascaridia galli

Synonyms: *Ascardia lineata*, *Ascaridia perspicillum*

Description: Male worms are 50–75 mm and female worms 70–120 mm long. The anterior end is characterised by a prominent mouth, which is surrounded by three large trilobed lips. The edges of the lips bear teeth-like denticles. A posterior bulb is absent from the oesophagus. The tail of the male possesses small alae and also bears 10 pairs of papillae. Spicules are almost equal in length. In the male there is a circular pre-cloacal sucker, which has a thick cuticular rim.

Ascaridia dissimilis

Description: The worms are stout and densely white. Males measure 35–50 mm and females 50–75 mm in length. The males of this species and those of *A. galli* are separated by differences in the position of the first and fourth pairs of ventral caudal papillae, and by the form of the spicules.

Ascaridia columbae

Synonym: *Ascardia maculosa*

Description: The worms are stout and densely white; males are 16–70 mm and females 20–95 mm in length.

Heterakis

These are small to medium whitish worms up to 1.5 cm long, with elongated pointed tails. Gross examination readily indicates the genus, but for specific identification microscopic examination is necessary to determine the shape of the oesophagus (in *Heterakis* the oesophagus has a large posterior bulb) and the size and shape of spicules. A buccal capsule is absent. Generic identity may be confirmed by the presence of a large, chitinous, circular pre-cloacal sucker in the male and prominent caudal alae supported by 12 pairs of caudal papillae (Fig. 1.55). The pre-cloacal sucker is much less prominent in *Ascaridia*.

Life cycle: The direct life cycle is similar to that of *Ascaridia* spp. The egg is infective on the ground in about 2 weeks at optimal temperatures. Eggs may remain viable in the soil for several months. Earthworms may be transport hosts, the eggs simply passing through the gut, or paratenic hosts in which the egg

Fig. 1.55 Tail of male *Heterakis gallinarum* showing prominent caudal alae supported by 12 pairs of caudal papillae.

hatches and the L₃ travel to the tissues to await ingestion by the fowl. The prepatent period of the genus is about 4 weeks. Longevity is about 12 months.

Heterakis species

| Species | Hosts | Site |
|--|--|-------|
| <i>Heterakis gallinarum</i> (syn. <i>Heterakis papillosa</i> , <i>Heterakis gallinae</i> , <i>Heterakis vesicularis</i>) | Chicken, turkey, pigeon, pheasant, partridge, grouse, quail, guinea fowl, duck, goose and a number of wild galliform birds | Caeca |
| <i>Heterakis isolonche</i> | Pheasant, grouse, quail, duck, chicken | Caeca |
| <i>Heterakis dispar</i> | Duck, goose, chicken | Caeca |
| <i>Heterakis brevispeculum</i> | Duck, goose, guinea fowl, chicken | Caeca |

Heterakis gallinarum

Description: The male is 7–13 mm and the female 10–15 mm long. The body possesses large lateral alae. The spicules are unequal in length, the left (about 0.7 mm long) has broad alae and the right is slender and longer (about 2 mm).

Heterakis isolonche

Description: Male worms measure about 7–13 mm and females 10–15 mm in length. The spicules are long and of equal length.

Heterakis dispar

Description: Worms are larger than the other species, with males measuring 11–18 mm and females 16–23 mm in length. The spicules are short and equal in length (40–50 μm).

Heterakis brevispeculum

Description: The spicules are of equal length (about 0.5 mm) and possess a barb near the tip.

Porrocaecum

Species of this genus are parasites of a range of birds and various fish-eating mammals.

Life cycle: Similar to other ascarid species.

Porrocaecum species

| Species | Host | Intermediate host | Site |
|----------------------------|------|-------------------|-----------------|
| <i>Porrocaecum crassum</i> | Duck | Earthworms | Small intestine |

Porrocaecum crassum

Description: The worms are reddish-white in colour, males measuring 12–30 mm and females 40–55 mm in length. Caudal alae are absent. The tail of the male is conical.

Bayliascaris

Species of the genus *Bayliascaris* are found in a wide range of mammal hosts. *Bayliascaris procyonis*, whose definitive host is the raccoon, is of veterinary importance because it has the ability to infect a wide range of wild and domestic animals and occasionally humans, causing visceral larva migrans.

Life cycle: The definitive hosts for this parasite are mammals such as skunks and raccoons, which when infected pass eggs out in their faeces. These eggs can remain viable in the environment for several years. When ingested by a ratite paratenic host the larvae develop and penetrate into the circulation and eventually enter the brain and spinal cord.

Bayliascaris species

| Species | Hosts | Site |
|-------------------------------|---|--|
| <i>Bayliascaris procyonis</i> | Raccoon, skunk Dog, cat, rodents, lagomorphs, gallinaceous birds, ostrich, occasionally humans | Small intestine Other organs (e.g. brain) |

Bayliascaris procyonis

Description: Adult worms are whitish in colour, and measure 15–20 cm in length and 1 cm in width.

Other ascarids found in reptiles are briefly mentioned and covered in Chapter 16. Members of the genera *Ophidascaris* and *Polydelphus* are mainly parasites of snakes and lizards, occasionally of amphibians. *Angusticaecum* spp. are ascarids of tortoises.

Reptilian ascarid species

| Species | Hosts | Site |
|----------------------------------|-----------------------|-----------|
| <i>Ophidascaris</i> spp. | Snakes, lizards | Intestine |
| <i>Polydelphus</i> spp. | Snakes | Intestine |
| <i>Angusticaecum holopteryum</i> | Reptiles (chelonians) | Intestine |

FAMILY ANISAKIDAE

Members of the Anisakidae have life cycles involving marine mammals and fish and are of importance mainly in human medicine as some species can cause disease through the ingestion of raw or uncooked fish. Detailed descriptions are not within the scope of this book.

Anisakidae species

| Species | Final hosts | Site | Intermediate hosts |
|---|------------------------------|-----------------------|---|
| <i>Anisakis simplex</i> | Whales, dolphins, seals | Stomach and intestine | Crustaceans, fish |
| <i>Contracaecum spiculigerum</i> | Duck, goose, swan, waterfowl | Small intestine | Invertebrates (copepods, crustacea, insects, etc.) Damselflies, fish, tadpoles |
| <i>Contracaecum</i> spp. | Whales, dolphins, seals | Stomach and intestine | Copepods, fish |
| <i>Hysterothylacium aduncum</i> | Fish | Intestine | Crustaceans |
| <i>Pseudoterranova decipiens</i> (syn. <i>Phocanema decipiens</i>) | Seals | Stomach | Crustaceans, fish |
| <i>Sulcascaris</i> spp. | Reptiles (turtles) | Intestine | Molluscs |

SUPERFAMILY DIOCTOPHYMATOIDEA

This group contains three genera: *Dioctophyma*, found in the kidney of carnivores, and *Hystrichis* and *Eustrongyloides*, which occur in aquatic fowl. The alimentary canal is attached to the abdominal wall by four longitudinal muscles and the tail of the male has a terminal cup-shaped bursa which lacks bursal rays. A single spicule is present.

FAMILY DIOCTOPHYMATIDAE

Dioctophyma

Dioctophyma renale ('kidney worm') is the largest parasitic nematode known in domestic animals and is found in the kidneys of carnivores.

Dioctophyma species

| Species | Hosts | Site | Intermediate hosts |
|---|--|--------------------------|---------------------------------|
| <i>Dioctophyma renale</i> (syn. <i>Dioctophyme renale</i> , <i>Eustrongylus gigas</i>) | Dog, fox, mink, ferret, otter, pine marten, polecat, mink; seal, occasionally in cat, pig, horse, cattle and human | Kidney, abdominal cavity | Aquatic oligochaetes (annelids) |

Dioctophyma renale

Synonym: *Dictophyme renale*, *Eustrongylus gigas*

Description: Female worms usually measure more than 60 cm in length, with a diameter of around 1.0 cm but can occasionally be as long as 100 cm. The male is about 35–40 cm long with a bell-shaped bursa which is lined with papillae and a supporting ray is absent

Fig. 1.56 Male and female worms of the kidney worm *Dioctophyma renale*.

(Fig. 1.56). A single brown spicule is present. The worms are deep red–purple in colour. Their size and predilection site are sufficient for identification.

Life cycle: The worms are oviparous. The eggs, in the single-cell stage, are passed in the urine in clumps or chains and are ingested by the annelid intermediate host, in which the two preparasitic moults occur. The development phase in the annelid is about 2–4 months. The final host is infected by swallowing the annelid with the drinking water, or by the ingestion of a paratenic host, such as a frog or fish, which has itself eaten the infected annelid. In the final host, the infective larvae penetrate the intestinal wall, enter the peritoneal cavity and eventually penetrate the kidney. The prepatent period is about 6 months but has been observed to be as long as 2 years.

Hystrichis

Hystrichis species

| Species | Hosts | Site | Intermediate hosts |
|----------------------------|--|----------------------------|---------------------------------|
| <i>Hystrichis tricolor</i> | Domestic and wild ducks and anatic birds | Proventriculus, oesophagus | Aquatic oligochaetes (annelids) |

Hystrichis tricolor

Description: Adult female worms are up to about 4 cm and males 2.5 cm in length. The cephalic area is expanded, and possesses many regularly positioned spines.

Life cycle: This is indirect. Fowl and other birds become parasitised through ingestion of infected oligochaetes. The adult worms are deeply embedded in the mucosa, with their caudal and cephalic regions lying within the lumen of the tract. The prepatent period is around 2 weeks.

Eustrongyloides

Parasites of waterfowl found in the oesophagus and proventriculus.

Life cycle: The life cycles of *Eustrongyloides* species are not fully known but oligochaetes are likely to be involved as intermediate hosts and various fish as paratenic hosts.

Eustrongyloides species

| Species | Hosts | Site | Intermediate hosts |
|--|-------------|----------------------------|------------------------------|
| <i>Eustrongyloides papillosus</i> | Duck, goose | Proventriculus, oesophagus | Aquatic oligochaetes Fish |
| <i>Eustrongyloides tubifex</i> (syn. <i>Strongylus tubifex</i> , <i>Eustrongylus tubifex</i> , <i>Hystrichis tubifex</i>) | Waterfowl | Proventriculus, oesophagus | Aquatic oligochaetes Fish |

Eustrongyloides papillosus

Description: Females measure about 3 cm in length. The male has a bursal cup with a fringed margin.

Eustrongyloides tubifex

Description: Males measure around 3.0–3.5 cm and females 3.5–4.5 cm in length. This worm has a small mouth and the head lacks spines. The cuticle is annulated. The male bursal cup is shaped like a trumpet and the spicule is slender and long.

SUPERFAMILY OXYUROIDEA

Adult oxyuroids of animals inhabit the large intestine and are commonly called ‘pinworms’ because of the long pointed tail of the female parasite. The ventrolateral papillae are often absent and where present are very much reduced. The number of spicules can vary in the males from zero, one or two depending on the species. They have a double bulb oesophagus, the posterior bulb being well developed. The life cycle is direct. The genera of veterinary interest are *Oxyuris* and *Probstmayria*, both parasitic in the horse; *Skrjabinema*, which are parasites of ruminants; *Syphacia* and *Aspicularis* found in rodents; *Paraspidodera* found in guinea pigs; *Passalurus* and *Dermatoxys* found in rabbits and hares; and *Tachygonetria* found in reptiles. Oxyurids also include the common human pinworm, *Enterobius*.

FAMILY OXYURIDAE

Oxyuris

The adult female worms, which may reach 10–15 cm in length, are found in the lumen of the caecum and large colon of equids. The much smaller males are difficult to observe in digesta.

Life cycle: The life cycle is direct. The adult worms are found in the lumen of the caecum and the small and large colon. After fertilisation the gravid female migrates to the anus, extrudes her anterior end and lays her eggs in clumps (up to 50,000 eggs per female), seen grossly as yellowish-white gelatinous streaks on the perineal skin or perianal region. Development is rapid, and within 4–5 days the egg contains the infective L₃. Eggs are rubbed off and contaminate the environment. Infection is by ingestion of embryonated eggs on fodder, grass, bedding, etc. The larvae are released in the small intestine, move into the large intestine and migrate into the mucosal crypts of the caecum and colon where development to L₄ takes place within 10 days. The L₄ then emerge and feed on the mucosa before maturing to adult stages that inhabit the lumen and feed

on intestinal contents. The prepatent period of *O. equi* is about 5 months. Longevity of female worms is around 6 months.

Oxyuris species

| Species | Hosts | Site |
|---------------------|---------------|-----------------------|
| <i>Oxyuris equi</i> | Horse, donkey | Caecum, colon, rectum |

Oxyuris equi

Description: The mature females are large greyish-white opaque worms with very long narrow tapering tails (the tail can account for about three times the length of the rest of the body). Mature males are generally less than 12 mm long. There is a double oesophageal bulb in both sexes (see Fig. 1.3 and Fig. 1.57) and the tiny males have a pair of expanded caudal alae, a blunt tail and a single pin-shaped spicule. In the female the vulva is situated anteriorly.

Skrjabinema

Skrjabinema are small non-pathogenic pinworms in the caecum of domestic and wild ruminants.

Life cycle: The life cycle is direct. Embryonated eggs are deposited on the perineal skin by the adult female worms. Infection is by ingestion of the embryonated egg.

Skrjabinema species

| Species | Hosts | Site |
|--|---------------------|---------------|
| <i>Skrjabinema ovis</i> (syn. <i>Oxyuris ovis</i>) | Goat, sheep | Caecum, colon |
| <i>Skrjabinema alata</i> | Sheep | Caecum, colon |
| <i>Skrjabinema caprae</i> | Goat | Caecum, colon |
| <i>Skrjabinema parva</i> | Deer (white-tailed) | Caecum, colon |

Fig. 1.57 Head of *Oxyuris equi* with double oesophageal bulb.

Skrjabinema ovis

Description: Small worms, up to 7 mm in size; male are around 3 mm and females 6–7 mm in length. There are three large intricate lips and three small intermediate lips. The oesophagus is cylindrical in cross-section and ends in a large spherical bulb. The male worm has a single spicule and the tail is rounded with a cuticular expansion supported by two pairs of processes.

Life cycle: The prepatent period for this species is about 25 days.

Aspicularis

These are small pinworms of rodents. Males are 2–4 mm and females 3–4 mm long.

Life cycle: The life cycle is direct. Females deposit embryonated eggs on the perineal skin. Infection occurs in three ways:

- 1 directly by ingestion of embryonated eggs from the perineum;
- 2 indirectly with food;
- 3 by retro-infection when eggs hatch in the perineal region and migrate back via the anus.

Aspicularis species

| Species | Hosts | Site |
|-------------------------------|------------|---------------|
| <i>Aspicularis tetraptera</i> | Mouse, rat | Caecum, colon |

Aspicularis tetraptera

Description: The oesophageal bulb is oval, the oesophagus is club-shaped and the mouth has three lips. The cervical alae are broad and their posterior margin ends abruptly. There is no spicule or gubernaculum in the male.

Syphacia

These are small whitish worms, up to 6 mm in size. Males measure 1.0–1.5 mm and females 3.4–6 mm. The mouth has three distinct lips without a buccal capsule. The oesophagus has a pre-bulbular swelling and a posterior globular bulb. Small cervical alae, with rounded posterior margins, are present. The males have a single long slender spicule.

Syphacia species

| Species | Hosts | Site |
|--------------------------|------------|---------------|
| <i>Syphacia obvelata</i> | Mouse, rat | Caecum, colon |
| <i>Syphacia muris</i> | Mouse, rat | Caecum, colon |

Syphacia obvelata

Description: The adult male is 1.1–1.6 mm long and 125 µm wide with the tail length about equal to its body width. Female worms measure 3.4–5.0 mm in length.

Syphacia muris

Description: The adult male is 1.2–1.3 mm long and 100 µm wide and the tail length is about twice its body width. The females

measure 2.8–3.4 mm in length. The vulva of *S. muris* is further posterior, in relation to the esophageal bulb, than that of *S. obvelata*.

Passalurus

Species of *Passalurus* are common pinworms of rabbits and hares.

Life cycle: Development is direct and infection occurs through the ingestion of infective eggs. Immature stages are found in the mucosa of the small intestine and caecum.

Passalurus species

| Species | Hosts | Site |
|--------------------------------|--------------|---------------|
| <i>Passalurus ambiguus</i> | Rabbit, hare | Caecum, colon |
| <i>Passalurus nonannulatus</i> | Rabbit, hare | Caecum, colon |

Passalurus ambiguus

Description: Adult worms are 4–11 mm in size and semi-transparent; males are 4–5 mm and females 9–11 mm. The oesophagus has the typical oxyurid oesophageal bulb. The distal extremity of the female tail possesses around 40 circular striations. The male spicule is simple in appearance and the tail has an appendix shaped like a whip.

Dermatoxys

Species of *Dermatoxys* are common pinworms of rabbits and hares.

Life cycle: Details of the life cycle are not known. It is probably direct and similar to other pinworms.

Dermatoxys species

| Species | Hosts | Site |
|----------------------------|--------------|---------------|
| <i>Dermatoxys veligera</i> | Rabbit, hare | Caecum, colon |

Dermatoxys veligera

Description: Female worms are 16–17 mm and males 8–11 mm long. Males have small spicules. Females have a vulva located in the cranial half of their body.

Enterobius

This genus includes the human pinworm, *Enterobius vermicularis*, which is also found in apes.

Life cycle: Gravid female worms in the caecum and colon migrate to the rectum and deposit eggs on the perineum. Eggs become infective within a few days and infection is via the embryonated egg. The prepatent period is about 8 weeks.

Enterobius species

| Species | Hosts | Site |
|------------------------------------|-------------------|---------------|
| <i>Enterobius vermicularis</i> | Human, chimpanzee | Caecum, colon |
| <i>Enterobius anthropopithecii</i> | Chimpanzee | Caecum, colon |

Enterobius vermicularis

Description: Adults are slender cream-coloured worms with long tails. Males measure 2–5 mm and females 8–13 mm in length.

FAMILY COSMOCERCIDAE

Probstmayria

Small, slender, viviparous nematodes that are perpetual parasites, living from generation to generation in the equine large intestine.

Probstmayria species

| Species | Hosts | Site |
|------------------------------|-------|-------|
| <i>Probstmayria vivipara</i> | Horse | Colon |

Probstmayria vivipara

Description: Adult worms are 2–3 mm long with long filamentous tails. The mouth has six small lips and the buccal capsule is cylindrical and long. The oesophagus has an expanded posterior bulb. A large sucker-like excretory pore is present. The tail of the male is curved into a hook shape.

Life cycle: *Probstmayria vivipara* is unusual in that it is a perpetual parasite and lives from generation to generation in the equine caecum and colon. The females are viviparous and give birth to larvae almost as large as the adults. Both adults and larvae may be passed in the faeces.

FAMILY ASPIDODERIDAE

Paraspidodera

Paraspidodera species

| Species | Hosts | Site |
|-------------------------------|------------|-----------------|
| <i>Paraspidodera uncinata</i> | Guinea pig | Large intestine |

Paraspidodera uncinata

Description: Male worms are 16–17 mm and females 18–21 mm in length. Both sexes have a large bulb-shaped oesophagus. Caudal alae are absent. The male spicules are of equal length. The male has a pre-cloacal sucker.

FAMILY PHARYNGODONIDAE

The Pharyngodonidae includes a number of genera that are pinworms of reptiles. The genus *Tachygonetria* is commonly found in Mediterranean tortoises (*Testudo* spp.).

SUPERFAMILY SPIRUROIDEA

The precise classification of a number of genera currently assigned to this superfamily is controversial, but there are some of significance in veterinary medicine: *Spirocerca*, *Habronema*,

Draschia, *Parabronema*, *Thelazia*, *Gnathostoma*, *Gongylonema* and to a lesser extent *Ascarops*, *Physocephalus*, *Simondsia*, *Physaloptera*, *Spirura*, *Odontospirura*, *Tetrameres*, *Histiocephalus*, *Hartertia*, *Oxyspirura*, *Metathalazia* and *Vogeloides*. A major characteristic of this group is the tight spirally-coiled tail of the male. The life cycles are indirect involving arthropod intermediate hosts.

Members of the genus *Thelazia* are principally found in or around the eyes of animals and can be responsible for keratitis. Unlike most spiruroids, the L₁ stage is not ingested from the faeces but by flies feeding on ocular secretions.

The genus *Gongylonema* is unusual among the spiruroids in having a very wide final host range, which includes all the domesticated animals, though it is most prevalent in ruminants. Like most spiruroids the favoured location of the adults is in the upper alimentary tract, in the oesophagus, and in the forestomachs and stomach of mammals and the crop of birds.

Species belonging to the genera *Cheilospirura*, *Echinuria*, *Dispharynx* and *Streptocara* are now considered to be members of the superfamily Acuarioidea.

FAMILY SPIROCERCIDAE

Spirocerca

These are stout, reddish, spirally-coiled worms, 3–8 cm long and are found in tumour-like granulomas in the wall of the oesophagus and stomach.

Life cycle: The thick-shelled elongate egg containing a larva is passed in the faeces or vomit, and does not hatch until ingested by a dung beetle. In this, the intermediate host, the larva develops to the L₃ and encysts. Paratenic hosts may also be involved if the dung beetle, in turn, is ingested by any of a variety of other animals including the domestic chicken, wild birds and lizards. In these the L₃ becomes encysted in the viscera. On ingestion of the intermediate or paratenic host by the final host the L₃ are liberated, penetrate the stomach wall and migrate via the coeliac artery to the thoracic aorta. About 3 months later the majority of larvae cross to the adjacent oesophagus where they provoke the development of granulomas as they develop to the adult stage in a further 3 months. Adults are usually located in cystic nodules which communicate with the lumen of the stomach or oesophagus through fistulae. The prepatent period is therefore about 5–6 months. Eggs, however, may not be found in the faeces of a proportion of animals with adult infections where the granulomas have no openings into the oesophageal lumen.

Spirocerca species

| Species | Hosts | Site | Intermediate hosts |
|-----------------------|---|----------------------------|----------------------|
| <i>Spirocera lupi</i> | Dog, fox, wild canids; occasionally cat and wild felids | Oesophagus, stomach, aorta | Coprophagous beetles |

Spirocera lupi

Description: Adult male worms are around 30–55 mm and females 55–80 mm long. The mouth aperture is hexagonal in shape and the pharynx is short and the lips are trilobed. The male tail possesses caudal alae (four pairs and one unpaired), median pre-cloacal papillae and post-cloacal papillae (two pairs). There is a group of minute papillae near the tail tip. The right spicule is only about one-quarter the length of the left spicule. The tail of the female is blunt.

Ascarops

Worms of this genus, and of the genera *Physocephalus* and *Simondsia*, live on the stomach wall of pigs under a layer of mucus.

Life cycle: The life cycle is typically spiruroid. Eggs passed in the faeces of the infected host develop into infective larvae, if ingested by coprophagous beetles. The life cycle is completed when pigs ingest the beetles. The prepatent period is about 4 weeks.

Ascarops species

| Species | Hosts | Site | Intermediate hosts |
|---|----------------|---------------------------------------|----------------------|
| <i>Ascarops strongylina</i> (syn. <i>Arduenna strongylina</i>) | Pig, wild boar | Stomach, occasionally small intestine | Coprophagous beetles |
| <i>Ascarops dentata</i> (syn. <i>Arduenna dentata</i>) | Pig | Stomach, occasionally small intestine | Coprophagous beetles |

Ascarops strongylina

Synonym: *Arduenna strongylina*

Description: Small slender filiform worms, the males measuring up to 15 mm and the reddish females about 22 mm long. A cervical alae is located only on the left side of the body. The wall of the pharynx contains several spiral supports and a small tooth is present on each of the two lips. The right caudal alae in the male are much larger than the left and there are four pairs of asymmetrical pre-cloacal papillae and one pair of caudal papillae. The left spicule is about four to five times longer than the right spicule.

Ascarops dentata

Synonym: *Arduenna dentata*

Description: Similar to *A. strongylina* but much bigger; male worms are 35 mm and female worms are 55 mm long. The buccal capsule has two teeth anteriorly.

Physocephalus

Small slender worms found on the surface of the stomach wall.

Life cycle: The life cycle is typically spiruroid. Eggs passed in the faeces of the infected host develop into infective larvae, if ingested by coprophagous beetles. The prepatent period is about 6 weeks.

Physocephalus species

| Species | Hosts | Site | Intermediate hosts |
|--------------------------------|---------------------------------|---------|----------------------|
| <i>Physocephalus sexalatus</i> | Pig, camel, rarely rabbit, hare | Stomach | Coprophagous beetles |

Physocephalus sexalatus

Description: Small slender filiform worms which are reddish when fresh, the males measuring about 10–12 mm and the females up to 22 mm long. The anterior of the body is thinner than the posterior region and just posterior to the vestibule is a cuticular swelling. There are three cervical alae on either side and the cervical papillae

are asymmetrically located. The wall of the pharynx contains a single spiral support. In the male worm the caudal alae are narrow and symmetrical and there are four pairs of pre-cloacal papillae. The left spicule is about six to seven times longer than the right spicule.

Simondsia

Male worms live on the surface of the gastric mucosa, but the females are found in small cysts in the mucosal crypts with their anterior ends protruding.

Life cycle: The life cycle is indirect. Eggs are passed in the faeces and ingested by beetles in which they hatch and develop to infective larvae. The parasites continue development when the intermediate host is ingested by a pig.

Simondsia species

| Species | Hosts | Site | Intermediate hosts |
|--|--------------------------|---------|----------------------|
| <i>Simondsia paradoxa</i> (syn. <i>Spiroptera cesticillus</i>) | Pig, rarely rabbit, hare | Stomach | Coprophagous beetles |

Simondsia paradoxa

Synonym: *Spiroptera cesticillus*

Description: The males are small slender worms measuring about 12–15 mm in length and possess a spirally-coiled tail. Female worms measure up to about 15–20 mm in length. They have large lateral alae and a large ventral and dorsal tooth. The gravid female has a characteristic form, the posterior end of the body being a rounded sac filled with eggs and the anterior end is slender.

Streptopharagus

Worms of this genus are found in the stomachs of Old World monkeys and apes.

Streptopharagus species

| Species | Hosts | Site | Intermediate hosts |
|-----------------------------------|--|---------|----------------------|
| <i>Streptopharagus armatus</i> | Rhesus, cynomolgus monkeys, Japanese macaque, guenon, baboon, gibbon | Stomach | Coprophagous beetles |
| <i>Streptopharagus pigmenatus</i> | Rhesus, cynomolgus monkeys, Japanese macaque, guenon, baboon, gibbon | Stomach | Coprophagous beetles |

FAMILY HABRONEMATIDAE

Habronema

Members of the genus *Habronema* are small, slender, white translucent worms 1.5–2.5 cm long (Fig. 1.58). The male has wide caudal alae and the tail has a spiral twist. Together with the closely related genus *Draschia*, they are parasitic in the stomach of the horse. *Habronema* inhabits the mucus layer of the gastric mucosa and may cause a catarrhal gastritis, but is not considered an important pathogen. The chief importance of these parasites is as a cause of cutaneous habronematidosis or 'summer sores' in warm countries.

Fig. 1.58 Adult *Habronema* worms alongside a bot larva (*Gastrophilus*).

Life cycle: The life cycle is similar for all species. Eggs or L₁ are passed in the faeces and the L₁ are ingested by the larval stages of various muscid flies that are often present in faeces. Development to L₃ occurs synchronously with the development to maturity of the fly intermediate host. When the fly feeds around the mouth, lips, ocular conjunctiva, and nostrils of the horse, the larvae pass from its mouthparts on to the skin and are swallowed. Alternatively, infected flies may be swallowed whole in feed and drinking water. Development to adult takes place in the stomach where the larvae burrow into the glandular area of the mucosa and induce the formation of nodules. The worms develop to mature adults within the nodules in about 8 weeks. When the larvae are deposited on a skin wound or around the eyes they can invade the tissues; they do not complete their development but may cause granulomatous skin lesions.

Habronema species

| Species | Hosts | Site | Intermediate hosts |
|---|-------|---------|---|
| <i>Habronema microstoma</i> (syn. <i>Habronema majus</i>) | Horse | Stomach | Dipteran flies, <i>Musca</i> , <i>Stomoxys</i> , <i>Haematobia</i> (<i>Lyperosia</i>) |
| <i>Habronema muscae</i> | Horse | Stomach | Dipteran flies, <i>Musca</i> , <i>Stomoxys</i> , <i>Haematobia</i> (<i>Lyperosia</i>) |

Habronema microstoma

Synonym: *Habronema majus*

Description: Adult males are 16–22 mm and females 15–25 mm long. The anterior region of the cylindrical pharynx contains a small dorsal and ventral tooth in its anterior region. Four pairs of pre-cloacal papillae are present in the male worm. Spicules are uneven in length, with the left spicule (0.8 mm) being about twice as long as the right (0.4 mm).

Habronema muscae

Description: Adult males are 8–14 mm and females 13–22 mm in length. There are two lateral trilobed lips; the pharynx is cylindrical in cross-section and has a thick cuticular lining. The male possesses wide caudal alae. There are four pairs of pre-cloacal papillae and one or two papillae behind the cloaca. Small cuticular ridges cover the cloacal region. Spicules are uneven in length, with the left

spicule being long and slender (2.5 mm long) and the right spicule much shorter (0.5 mm) and stouter. The vulva is situated near the middle of the body and opens dorsolaterally.

Draschia

These worms are very similar to *Habronema* but smaller with a distinct collar in the anterior region. *Draschia* parasitises the fundic region of the stomach wall and provokes the formation of large fibrous nodules that are occasionally significant. The female worms are ovoviviparous.

Draschia species

| Species | Hosts | Site | Intermediate hosts |
|---|---------------------|---------|---|
| <i>Draschia megastoma</i> (syn. <i>Habronema megastoma</i>) | Horse, other equids | Stomach | Dipteran flies, <i>Musca</i> , <i>Stomoxys</i> , <i>Haematobia</i> (<i>Lyperosia</i>) |

Draschia megastoma

Description: Slender white translucent worms 7–13 mm long; adult males are 7–10 mm and females 10–13 mm. The worms are recognised by their heads, which are slightly constricted from the main body by a deep groove which circles the body just posteriorly to the oral region (Fig. 1.59). The pharynx is funnel-shaped. Male worms have four pairs of pre-cloacal papillae. The spicules are short and uneven in length with the left (0.5 mm) longer than the right (0.25 mm).

Parabronema

Parabronema are found in the abomasum of ruminants. The genus is readily distinguished from the other abomasal worms by the presence of large cuticular shields and cordons in the cephalic region.

Fig. 1.59 Head of *Draschia megastoma*.

Life cycle: Eggs or L₁ are passed in the faeces and the L₁ are ingested by the larval stages of various muscid flies that are often present in faeces. Development to L₃ occurs synchronously with the development to maturity of the fly intermediate host. When the fly feeds around the mouth, lips and nostrils of the host the larvae pass from its mouthparts on to the skin and are swallowed. Alternatively, infected flies may be swallowed whole in feed and drinking water. Development to adult takes place in the glandular area of the abomasum.

Parabronema species

| Species | Hosts | Site | Intermediate hosts |
|------------------------------|----------------------------|----------|---|
| <i>Parabronema skrjabini</i> | Sheep, goat, cattle, camel | Abomasum | Muscid flies of the genera <i>Stomoxys</i> , <i>Lyperosia</i> , <i>Haematobia</i> |

Parabronema skrjabini

Description: The white slender adult worms are up to 3.6 cm long. Males are 15–18 mm with a spiral tail, four pairs of pre-anal papillae and with one spicule.

Histiocephalus

Histiocephalus species

| Species | Hosts | Site | Intermediate hosts |
|------------------------------------|---------------|---------|--------------------|
| <i>Histiocephalus latacaudatus</i> | Chicken, duck | Gizzard | Unknown |

Histiocephalus latacaudatus

Description: Males measure around 7–7.5 mm and females 13–16 mm in length. The mouth is surrounded by four lips and the pseudolips are indented forming 10 finger-like expansions, each with two or three points. Adult worms have ornate leaf-like structures and the presence of a cervical collar. The buccal cavity is cylindrical. Males have two large alae and four pairs of pre-cloacal papillae and two pairs of post-cloacal papillae. Spicules are long and of equal length. A gubernaculum is absent. The vulva in the female is situated anteriorly.

Life cycle: Little is known of the life cycle.

FAMILY THELAZIDAE

Thelazia

Members of this genus are parasites of the conjunctival sac and lacrimal duct and because of their location are also known as 'eye-worms'. Worms have a large vestibule and lips are absent in this genus. Prominent striations are present on the anterior cuticle. Caudal alae are absent in the male worms.

Life cycle: The worms are viviparous. The L₁ passed by the female worm into the lacrimal secretion is ingested by the fly intermediate host as it feeds. Development from L₁ to L₃ occurs in the ovarian follicles of the fly in 15–30 days during the summer months. L₃ migrate to the mouthparts of the fly and are transferred to the final host when the fly feeds. Development in the eye takes place without further migration.

***Thelazia* species**

| Species | Hosts | Site | Intermediate hosts |
|--|--|--------------------------------------|---|
| <i>Thelazia rhodesi</i> | Cattle, buffalo, occasionally sheep, goat, camel | Eye, conjunctival sac, lacrimal duct | Muscid flies, particularly <i>Fannia</i> spp. |
| <i>Thelazia gulosa</i> (syn. <i>Thelazia alfortensis</i>) | Cattle, sheep, wild ruminants | Eye, conjunctival sac, lacrimal duct | Muscid flies (<i>Musca</i> spp.) |
| <i>Thelazia skrjabini</i> | Cattle, sheep, wild ruminants | Eye, conjunctival sac, lacrimal duct | Muscid flies (<i>Musca</i> spp.) |
| <i>Thelazia callipaeda</i> | Dog, cat, human, primates, rabbit | Eye, conjunctival sac, lacrimal duct | Muscid flies, fruit flies |
| <i>Thelazia californiensis</i> | Dog, cat, sheep, deer, human | Eye, conjunctival sac, lacrimal duct | Muscid flies |
| <i>Thelazia lacrymalis</i> | Horse, cattle | Eye, conjunctival sac, lacrimal duct | Face flies (<i>Musca</i> spp.) |
| <i>Thelazia leesi</i> | Camel | Conjunctival sac | Muscid flies |

Thelazia rhodesi

Description: Small, thin, yellowish-white worms 1.0–2.0 cm long. Males are 8–12 mm and females are 12–20 mm in length. The cuticle has prominent striations at the anterior end. The male worms have about 14 pairs of pre-cloacal and three pairs of post-cloacal papillae.

Life cycle: The prepatent period is 20–25 days.

Thelazia gulosa

Synonym: *Thelazia alfortensis*

Description: *Thelazia gulosa* are milky-white worms, with thin transverse cuticular striations (less evident in rear part of the body), and a large deep cup-shaped buccal cavity. Males are 4.8–10.9 mm long and have a variable number of pre-cloacal papillae (from 8 to 33 pairs) and three pairs of post-cloacal papillae. There are two asymmetric spicules. The females are 4.8–18.8 mm long with a tapered caudal extremity.

Thelazia skrjabini

Description: Adult worms are whitish in colour, with transverse fine cuticular striations. The buccal cavity is small and shallow. Males are 5–11.5 mm long and curved posteriorly, with 16–32 pairs of pre-cloacal and three pairs of post-cloacal papillae. The spicules are unequal in length. The females are 7.5–21 mm long with a truncated caudal extremity.

Thelazia callipaeda

Description: Small thin white worms 1.0–1.7 cm long; males are 7–11.5 mm and females 7–17 mm in length. The cuticle bears fine transverse striations. The male has one single and five pairs of pre-cloacal papillae and two pairs of post-cloacal papillae. The left

spicule is much longer (about 10 times) than the right. In the female the vulva is in the oesophageal region.

Thelazia californiensis

Description: Small thin white worms 1.0–1.5 cm long. A mouth capsule is present and the cuticle has prominent striations at the anterior end. The male has 10 pairs of caudal papillae. The left spicule is long and slender and the right spicule short and stout.

Thelazia lacrymalis

Description: Small thin yellowish-white worms 1.0–2.0 cm long. Males are 8–12 mm and females 14–18 mm. A mouth capsule is present and the cuticle has prominent striations at the anterior end. In the male, the tail is blunt and recurved with caudal alae.

Life cycle: The prepatent period is about 3–6 weeks.

Oxyspirura

Eyeworms of birds found on the conjunctiva, under the nictitating membrane, or in the nasal–lacrimal ducts.

Life cycle: The life cycle is indirect. Eggs pass through the lacrimal duct, are swallowed and shed in the faeces. These are ingested by an intermediate host and development to the infective stage occurs. Following consumption of the intermediate host by the definitive host the larvae migrate from the oesophagus and pharynx to the eye via the lacrimal duct.

***Oxyspirura* species**

| Species | Hosts | Site | Intermediate hosts |
|---|---------------------------------------|----------------------------------|-------------------------------------|
| <i>Oxyspirura mansonii</i> (syn. <i>Oxyspirura parvorum</i>) | Chicken, turkey, guinea fowl, peafowl | Eye, conjunctiva, lacrimal ducts | Cockroaches, mayfly (Ephemeroptera) |

Oxyspirura mansonii

Synonym: *Oxyspirura parvorum*

Description: These are slender worms with a smooth cuticle and a globular-shaped pharynx; in the female, the vulva is near the tail. The males measure around 10–15 mm and the females 14–20 mm. The tail is finely pointed in both sexes. The tail of the male is curved ventrally and alae are absent. Spicules are uneven, the right being short and stubby, the left long (about 15 times that of the right spicule) and slender.

FAMILY GNATHOSTOMATIDAE***Gnathostoma***

These are parasites of the stomach of carnivores. The presence of the worms in gastric nodules is sufficient for generic diagnosis.

Gnathostoma species

| Species | Hosts | Site | Intermediate hosts |
|-------------------------------|--|---------|---|
| <i>Gnathostoma spinigerum</i> | Cat, dog, human, mink, polecat and several wild carnivores | Stomach | Freshwater crustaceans, copepods |
| <i>Gnathostoma hispidum</i> | Pig, rarely human | Stomach | Freshwater crustaceans, <i>Cyclops</i> spp. |
| <i>Gnathostoma doloresi</i> | Pig, wild boar | Stomach | Freshwater crustaceans |

Gnathostoma spinigerum

Description: Thick-bodied short worms, reddish at the front, and greyish posteriorly. The males are 1–2.5 cm and the females up to 3–4 cm long. The head is swollen and is covered with transverse rows of 6–11 small hooks, and contains four sub-medial cavities that each communicate with a cervical sac. The anterior section of the body is covered with flat cuticular spines and the ventral caudal region of the male has small spines, and four pairs of large pedunculate papillae. Several smaller sessile papillae are also present. The left spicule is about three times longer than the right spicule.

Life cycle: The adult worms live in tunnels in the gastric nodules, and the eggs pass from there into the lumen and are dropped into the water in the faeces where they hatch after several days. The crustaceans (first intermediate hosts) ingest L₁ and development to L₂ takes place. The crustaceans are themselves ingested by vertebrates (second intermediate hosts), such as fish, frogs and reptiles, and development to L₃ occurs and the larvae become encysted. The L₃ can also encyst in many mammals such as mice, rats and dogs. The final host is infected by ingestion of the vertebrate vector and further development occurs in the stomach wall, where the worms provoke the growth of fibrous lesions.

Gnathostoma hispidum

Description: Thick-bodied worms; the males are 1.5–2.5 cm and the females 2–4.5 cm long. Spiny scales cover the whole body of the worm. The left spicule is about three times longer than the right spicule.

Life cycle: The young worms migrate in the abdominal organs of the host, particularly the liver. Adult worms live in tunnels in the gastric nodules, and the eggs pass from there into the lumen and are dropped into the water in the faeces where they develop to L₂ before hatching after several days. Crustaceans ingest L₂ and development to L₃ takes place within about 10 days. The final host is infected by ingestion of the crustacean intermediate host and further development occurs in the stomach wall, where the deeply embedded worms provoke the growth of fibrous lesions. A second intermediate host is not required with *G. hispidum*.

Gnathostoma doloresi

Description: Adult male worms are 2.6–2.8 cm long and female worms 3–4 cm long. The entire body surface has numerous transverse rows of backwardly directed cuticular spines. Anteriorly the

spines are broad and short, with several unequal teeth, becoming gradually smaller, with single-pointed spines posteriorly. The spicules are unequal, stout, curved, tapering evenly from root to tip.

Life cycle: As for *G. hispidum*.

FAMILY GONGYLONEMATIDAE***Gongylonema***

Thread-like parasitic worms of mammals and birds often referred to as 'gullet worms', with over 30 species described. Both sexes have cervical alae and the males possess caudal alae which are often asymmetrical.

Life cycle: The life cycle is typically spiruroid. Eggs are passed in faeces and when eaten by an intermediate host they hatch and develop to the infective stage within about 4 weeks. Infection of the definitive host is through the ingestion of infected coprophagous beetles or cockroaches. The adult worms live spirally (in a zipper fashion) embedded in the mucosa or submucosa with their anterior and/or posterior ends protruding into the lumen. The prepatent period is about 8 weeks.

***Gongylonema* species**

| Species | Hosts | Site | Intermediate hosts |
|---|--|-----------------------------------|-----------------------------------|
| <i>Gongylonema ingluvicola</i> | Chicken, turkey, partridge, pheasant, quail | Crop, oesophagus | Coprophagous beetles, cockroaches |
| <i>Gongylonema monnigi</i> | Sheep, goat | Rumen | Coprophagous beetles, cockroaches |
| <i>Gongylonema pulchrum</i> (syn. <i>Gongylonema scutatatum</i>) | Sheep, goat, cattle, pig, zebu, buffalo, horse, donkey, deer, camel, human, primates | Oesophagus, rumen | Coprophagous beetles, cockroaches |
| <i>Gongylonema verrucosum</i> | Cattle, sheep, goat, deer, zebu | Rumen, reticulum, omasum | Coprophagous beetles, cockroaches |
| <i>Gongylonema macrogubernaculum</i> | Old and New World Monkeys | Oesophagus, tongue, buccal cavity | Coprophagous beetles, cockroaches |

Gongylonema ingluvicola

Description: These are long slender worms. The female worm is about 32–55 mm and the males around 18 mm long. The anterior end of the body has a number of longitudinal rows of round or oval, wart-like cuticular plaques.

Gongylonema monnigi

Description: A long, slender, whitish worm, the males being about 4 cm and the females up to about 11 cm in length. Similar to *G. verrucosum* except the cervical ala is not festooned and the shape of the gubernaculum differs.

Gongylonema pulchrum

Synonym: *Gongylonema scutatium*

Description: A long, slender, whitish worm, the males being about 5.0 cm and the females up to about 14.0 cm in length. Asymmetrical cervical alae are prominent and the anterior end has longitudinal rows of cuticular plaques. The tail of the male has asymmetrical alae with 10 pairs of papillae. The left spicule is long and slender whereas the right spicule is short and stout. The male has a gubernaculum.

Gongylonema verrucosum

Description: Long slender worms, reddish when fresh. The males are about 3.5 cm and the females 7.0–9.5 cm in length. The adult worms have a festooned cervical ala and cuticular bosses only on the left side of the body. The males' spicules are unequal in length with the left spicule considerably longer than the right.

Gongylonema macrogubernaculum

Description: These are long thin whitish worms, the males measuring about 5 cm and the females around 14 cm in length. The anterior of the worm possesses longitudinal rows of cuticular bosses.

FAMILY PHYSALOPTERIDAE

Physaloptera

The genus *Physaloptera* includes a number of species that are parasites of the stomach of mammals and other vertebrates.

Life cycle: The life cycle is typically spiruroid. Eggs passed in the faeces of the infected host develop into infective larvae if ingested by coprophagous beetles, crickets and other insects. The life cycle is completed when cats ingest the intermediate hosts. Various cold-blooded transport hosts may also be involved in transmission of infection. The prepatent period is around 8–10 weeks.

Physaloptera species

| Species | Hosts | Site | Intermediate hosts |
|----------------------------------|---------------------------------|---------|--------------------------------|
| <i>Physaloptera praeputialis</i> | Cat and wild felids; rarely dog | Stomach | Beetles, cockroaches, crickets |
| <i>Physaloptera rara</i> | Cat, dog | Stomach | Beetles, cockroaches, crickets |

Physaloptera praeputialis

Description: Adult worms are larger than most spiruroids, being stout and resembling ascarids. Males measure 1.0–4.5 cm and females 2–6 cm in length. The cuticle in both sexes extends posteriorly as a sheath beyond the end of the body. The mouth is surrounded by a cuticular collar and possesses pseudolabia. The lips are simple and triangular in shape and bear a set of three small flattened internal teeth and a single conical external tooth. The posterior of the male bears asymmetrical lateral alae, joined anteriorly across the

ventral surface. The spicules are slightly unequal in length. In the female the vulva is slightly anterior to the mid-body.

Physaloptera rara

Description: Adult male worms are 2.5–3 cm and females 3–6 cm long. This species differs from *P. praeputialis* in that there is no sheath over the posterior portion of the body in both sexes. The female vulva is anterior to the middle of the body.

FAMILY SPIRURIDAE

Nematodes of the family Spiruridae are found in the upper digestive tract of mammals and birds.

Spirura/Odontospirura

Life cycle: The life cycle is typically spiruroid. Eggs develop into infective larvae within an intermediate host. Larvae may be ingested by paratenic hosts, such as rodents and lizards, in which they become encapsulated. The final host becomes infected by ingesting the insects or their transport hosts.

Spirura species

| Species | Hosts | Site | Intermediate hosts |
|--|----------------------|-------------------------|----------------------|
| <i>Spirura ritypleurites</i> | Cat; rarely dog, fox | Stomach | Beetles, cockroaches |
| <i>Spirura uncinipenis</i> (syn. <i>Sicarius uncinipenis</i>) | Rhea | Proventriculus | Beetles, cockroaches |
| <i>Spirura zschokkei</i> (syn. <i>Vaznema zschokkei</i>) | Rhea | Proventriculus | Beetles, cockroaches |
| <i>Odontospirura cetiopenis</i> | Rhea | Proventriculus, gizzard | Beetles, cockroaches |

Spirura ritypleurites

Description: Thick, short, white worms with the posterior region thicker than the anterior of the worm and twisted in a spiral. Male worms measure up to 26 mm and females can be 30 mm in length. The anterior area of the cuticle is inflated on the underside and the transverse striations are prominent.

Spirura uncinipenis

Synonym: *Sicarius uncinipenis*

Description: Males measure 15–20 mm and females 16–26 mm. The spicules are short and unequal in length.

Spirura zschokkei

Synonym: *Vaznema zschokkei*

Description: Males measure 16–17 mm and female worms 17–25 mm in length. The spicules are long and filiform.

Odontospirura cetiopenis

Description: The body is spirally-coiled, with males measuring 15–17 mm and female worms 20–23 mm. Four pairs of cephalic papillae are present at the base of the lips. Males have caudal alae and long spicules of equal length.

FAMILY TETRAMERIDAE

Tetrameres

Parasites of this genus show sexual dimorphism. The male worms are pale white, small, and slender and lie in the lumen of the proventriculus of birds. The females are bright red and almost spherical, and lie embedded in the proventricular glands. Cordons are absent.

Life cycle: Eggs are shed with the faeces and hatch when eaten by an intermediate host. The final host becomes infected following ingestion of the intermediate host and the males and females locate in the glands of the proventriculus. Males inhabit the mucosal surface and upper regions of the glands but after mating the males leave the glands and die. The females are embedded deep in the mucosal glands.

Tetrameres species

| Species | Hosts | Site | Intermediate hosts |
|---|---|----------------|--|
| <i>Tetrameres americana</i> (syn. <i>Tropisurus americana</i>) | Chicken, turkey, duck, goose, grouse, quail, pigeon | Proventriculus | Cockroaches, grasshoppers, beetles |
| <i>Tetrameres fissispina</i> (syn. <i>Tropisurus fissispina</i>) | Duck, goose, chicken, turkey, pigeon and wild aquatic birds | Proventriculus | Crustaceans (<i>Daphnia</i> and <i>Gammarus</i>), grasshoppers, earthworms |
| <i>Tetrameres crami</i> | Domestic and wild ducks | Proventriculus | Crustaceans (<i>Gammarus</i> and <i>Hyalella</i>) |
| <i>Tetrameres confusa</i> | Chicken | Proventriculus | ? |
| <i>Tetrameres mohtedai</i> | Chicken | Proventriculus | ? |
| <i>Tetrameres pattersoni</i> | Quail | Proventriculus | ? |

Tetrameres americana

Synonym: *Tropisurus americana*

Description: Males are 5–6 mm long and females are subspherical, measuring 3.5–5.0 mm long by 3 mm wide (see Fig. 13.1). Males have spiny cuticles and no cordons; females have four longitudinal deep furrows on the surface.

Tetrameres fissispina

Synonym: *Tropisurus fissispina*

Description: Males are 5–6 mm long and females 2.5–6.0 mm long by 1–3.5 mm in width.

Tetrameres crami

Description: Males are white, slender and about 4 mm long. The red ovoid/spherical females measure around 2 mm by 1.5 mm.

FAMILY HARTERTIIDAE

Hartertia

Hartertia species

| Species | Hosts | Site | Intermediate hosts |
|-----------------------------|-------------------|-----------------|--------------------|
| <i>Hartertia gallinarum</i> | Chicken, bustards | Small intestine | Termites |

Hartertia gallinarum

Description: Slender worms and exceptionally long for a spiruroid. The males measure up to around 40 mm and the females up to 110 mm in length. The gross appearance of the worms closely resembles that of *Ascaridia galli* and they have two lateral lips, each divided medially into three lobes. The posterior of the male has lateral alae, ventral cuticular bosses, and four pairs of pre-cloacal and two pairs of post-cloacal papillae. The left spicule has a barbed expansion at its tip and is about four times larger than the blunt-ended right spicule.

Life cycle: Eggs are passed in faeces and, when ingested by a termite, develop to the infective stage in the body cavity. Following ingestion of an infected intermediate host the larvae develop to maturity in the final host in about 3 weeks.

FAMILY PNEUMOSPIRIDAE

Members of this family are lungworms of wild felids and include species within the genera *Metathelazia* and *Vogeloides*.

SUPERFAMILY SUBULUROIDEA

Members of this superfamily are parasites mainly of rodents and are characterised by weakly developed lips with sensilla and a thick-walled stoma that is armed with three teeth. The only genus of veterinary importance is *Subulura*, species of which are parasites of poultry.

FAMILY SUBULIRIDAE

Subulura

Species of this genus, found in birds, are small worms located in the caecae. They are similar to *Heterakis*, although the tail is not as pointed. The males measure around 8–10 mm and the females up to 14–18 mm in length.

Life cycle: Eggs passed in faeces are ingested by the intermediate host where they develop to the infective L₃ stage after about 2 weeks. Following ingestion by the final host the larvae migrate to the lumen of the caeca. The prepatent period is 6–8 weeks.

Subulura species

| Species | Hosts | Site | Intermediate hosts |
|---|---|-------|----------------------|
| <i>Subulura suctorica</i> (syn. <i>Subulura brumpti</i> , <i>Subulura differens</i> , <i>Allodapa suctorica</i>) | Chicken, turkey, guinea fowl, quail, grouse, pheasant, duck | Caeca | Beetles, cockroaches |

Subulura suctoria

Synonyms: *Subulura brumpti*, *Subulura differens*, *Allodapa suctoria*

Description: The buccal capsule is small and possesses three teeth at its base. The oesophagus is dilated posteriorly, followed by a bulb. The tail of the male has large lateral alae and is curved ventrad. Two long thin curved spicules are present. A slit-like pre-cloacal sucker is present, surrounded by radiating muscle fibres. In the female, the vulva is situated just anterior to the middle of the body.

SUPERFAMILY DRACUNCULOIDEA

Members of this superfamily are parasites of the subcutaneous tissues. The two genera of veterinary significance are *Dracunculus* and *Avioserpens*. The life cycle involves development in a species of *Cyclops* before becoming infective to the final host.

FAMILY DRACUNULIDAE

Dracunculus

This genus includes the 'guinea worm', an important parasite affecting humans, and the North American guinea worm found in carnivores. The male worms are very much smaller than the females and the latter are one of the longest of the common nematodes in human and animals.

Life cycle: This is indirect. Adult worms mature in deep connective tissue and then migrate to peripheral subcutaneous tissue about 9 months after initial infection. A cutaneous blister develops around the head end of the worm, and when this makes contact with water the uterus of the worm ruptures and liberates large numbers of L₁ larvae. Release of larvae can continue over several weeks if the lesion is repeatedly immersed in water. These larvae develop to the infective stage in a species of *Cyclops*. Infection of the final host is through ingestion of infected copepods with drinking water or within paratenic hosts.

Dracunculus species

| Species | Hosts | Site | Intermediate HOSTS |
|-------------------------------|---|--------------------------------|---|
| <i>Dracunculus medinensis</i> | Human; occasionally cattle, horse, dog, cat and other mammals | Subcutaneous connective tissue | Copepod crustaceans (<i>Cyclops</i> spp.) |
| <i>Dracunculus insignis</i> | Mink, raccoon, otter, wild carnivores; occasionally dog and cat | Subcutaneous connective tissue | Copepod crustaceans (<i>Cyclops</i> spp.) Frogs |

Dracunculus medinensis

Description: Males measure about 2–3 cm; females are much larger, being around 100 cm long and 1.5–2.0 mm in width, but they can reach up to 300 cm in length. The anterior of the worms possess a 'helmet'. Females have no vulva.

Life cycle: Infection is caused by drinking water containing copepods, which are infected with larvae of *D. medinensis*. Following ingestion, the copepods die and release the larvae, which penetrate the host stomach and intestinal wall and enter the abdominal cavity. After maturation into adults and copulation, the male worms die and the females migrate in the subcutaneous tissues near the skin surface, where the female worm induces a blister on the skin that ruptures. When this

lesion comes into contact with water, the female worm emerges and releases larvae, which if ingested by a copepod develop into infective larvae after about 2 weeks. The prepatent period is around 12 months.

Dracunculus insignis

Description: Adults are white cylindrical worms 17.6–23.0 cm in length and 3–4 mm at maximum width. The females are much larger than the males and are filled with first-stage larvae. This species can be differentiated from *D. medinensis* by the number of pre-anal papillae and also the length of the gubernaculum.

Life cycle: Similar to *D. medinensis*. Development in the copepod is around 3 weeks. Frogs can also act as paratenic intermediate hosts.

Avioserpens

Avioserpens are parasites of ducks and are found in subcutaneous swellings.

Life cycle: Larvae are released into water and infective stages have been shown to occur in *Cyclops*. Infection of the final host occurs through ingestion of the intermediate host.

Avioserpens species

| Species | Hosts | Site | Intermediate hosts |
|------------------------------|-------|---------------------|-----------------------------|
| <i>Avioserpens taiwana</i> | Duck | Subcutaneous tissue | Copepods (<i>Cyclops</i>) |
| <i>Avioserpens mosgovoyi</i> | Duck | Subcutaneous tissue | Copepods (<i>Cyclops</i>) |

Avioserpens taiwana

Synonyms: *Filaria taiwana*, *Oshimaia taiwana*, *Avioserpens denticulophasma*, *Petroviprocta vigissi*

Description: The female measures up to about 25 cm in length by 0.8 mm in width. The anterior end is blunt and a chitinous rim, carrying two prominent lateral papillae, surrounds the mouth. Four smaller papillae are found further back on the head. The large uterus contains larvae. The anus, vagina and vulva are atrophied. A conical papilla is sited at the termination of the tail. The male worm is unknown.

SUPERFAMILY ACUARIOIDEA

Members of the Acuarioidea (formerly Spiruroidea) are small to medium-sized nematodes inhabiting the upper alimentary tract of birds. The species are characterised by the presence of peculiar cuticular cephalic structures (cordons) extending posteriorly, and sometimes recur forwards.

FAMILY ACURIDAE

Echinuria

Echinuria species

| Species | Hosts | Site | Intermediate hosts |
|---|---|-------------------------------------|------------------------------------|
| <i>Echinuria uncinata</i> (syn. <i>Acuaria uncinata</i>) | Duck, goose, swan and various aquatic birds | Oesophagus, proventriculus, gizzard | <i>Daphnia</i> and <i>Gammarus</i> |

Echinuria uncinata

Synonym: *Acuaria uncinata*

Description: These are small whitish worms with a slender body. Males measure 8–10 mm and females 12–18.5 mm long. The cuticle is ornamented with four wavy cordons that are non-recurrent and they anastomose in pairs and do not extend beyond the oesophagus section. Four rows of longitudinal spines are present on the cuticle. In the male, there are four pairs of pre-cloacal papillae in two groups of two either side, and four pairs of post-cloacal papillae. The left spicule is about three to four times longer than the right spicule.

Life cycle: Eggs are passed in the faeces and ingested by water fleas in which they hatch and develop to infective larvae. The parasites continue development when the intermediate host is ingested by an aquatic bird.

Dispharynx

Dispharynx species

| Species | Hosts | Site | Intermediate hosts |
|---|--|----------------------------|---|
| <i>Dispharynx nasuta</i> (syn. <i>Dispharynx spiralis</i> , <i>Acuaria spiralis</i> , <i>Acuaria nasuta</i>) | Chicken, turkey, pigeon, guinea fowl, grouse, pheasant and other birds | Oesophagus, proventriculus | Isopods: sowbugs (<i>Porcellio</i>) and pillbugs (<i>Armadillidium</i>) |

Dispharynx nasuta

Synonym: *Dispharynx spiralis*, *Acuaria spiralis*, *Acuaria nasuta*

Description: The body is slender and coiled, particularly the posterior of the male. Males measure up to around 8 mm and the females 10–12 mm long. The cuticle is ornamented with four wavy cordons that recurve anteriorly and do not fuse. The male has four pairs of pre-cloacal and five pairs of post-cloacal papillae. The left spicule is slender and the right spicule shorter and oval-shaped.

Life cycle: The intermediate host ingests embryonated eggs and development to the L₃ takes place in the body cavity. When the isopod is consumed by the final host, the worms develop to the final stage in the proventriculus or oesophagus.

Cheilospirura

Cheilospirura species

| Species | Hosts | Site | Intermediate hosts |
|---|-----------------|---------|---|
| <i>Cheilospirura hamulosa</i> (syn. <i>Acuaria hamulosa</i>) | Chicken, turkey | Gizzard | Grasshoppers (<i>Melanoplus</i>), weevils and beetles |

Cheilospirura hamulosa

Synonym: *Acuaria hamulosa*

Description: The worms have four, double-wavy, irregular, cuticular ridged cordons that extend to more than half the length of the body. These cordons do not anastomose or recur anteriorly. Male worms measure up to 15 mm and females 30 mm. The males have four pairs of pre-cloacal and six pairs of post-cloacal papillae, a short flattened spicule on the right and a longer slender spicule on the left side.

Life cycle: Eggs shed in the faeces are ingested by the intermediate host where they develop to the infective stage in about 3 weeks. The final host becomes infected after consuming this intermediate host and the prepatent period is about 3 weeks.

Streptocara

These worms are of minor importance in domestic livestock.

Streptocara species

| Species | Hosts | Site | Intermediate hosts |
|--------------------------------|---------------|---------|-------------------------------|
| <i>Streptocara crassicauda</i> | Duck, chicken | Gizzard | Crustacea (<i>Gammarus</i>) |

Streptocara crassicauda

Description: Males are about 5 mm and females up to 10 mm in length. The cervical alae are well developed and possess small teeth on the posterior margin.

Life cycle: Little is known of the life cycle.

SUPERFAMILY FILARIOIDEA

This superfamily is closely related to the Spiruroidea and, as in the latter, all its genera have indirect life cycles. None of them inhabits the alimentary tract, and they depend on insect vectors for transmission.

Within the superfamily, differences in biological behaviour are seen, the more primitive forms laying eggs, which are available to the vectors in dermal exudates, and the more highly evolved forms laying larvae, termed microfilariae. The latter, which may be enclosed in a flexible sheath-like 'eggshell', are taken up by parasitic insects feeding on blood and tissue fluids. In some species, the microfilariae only appear in the peripheral blood and tissues at regular intervals, some appearing in the daytime and others at night; this behaviour is termed diurnal or nocturnal periodicity.

Genera of interest in veterinary medicine include the Filariidae: *Parafilaria*, *Stephanofilaria*, *Suifilaria*; and the Onchocercidae: *Onchocerca*, *Dirofilaria*, *Acanthocheilonema*, *Pelecitus*, *Chandlerella*, *Setaria*, *Elaeophora*, *Splendidofilaria* and *Paronchocerca*.

FAMILY FILARIIDAE

Parafilaria

Adults of this genus of primitive filarioids live under the skin where they produce inflammatory lesions or nodules.

Parafilaria species

| Species | Hosts | Site | Intermediate hosts |
|--|-----------------------------|--|---|
| <i>Parafilaria bovicola</i> | Cattle, buffalo | Subcutaneous and intermuscular connective tissue | Muscid flies; <i>Musca autumnalis</i> in Europe |
| <i>Parafilaria multipapillosa</i> (syn. <i>Filaria haemorrhagica</i>) | Horse, donkey, other equids | Subcutaneous and intermuscular connective tissue | Horn flies; <i>Haematobia</i> spp. in Europe |

Parafilaria bovicola

Description: Small slender white worms about 3.0–6.0 cm in length. Males are 2–3 cm and females 4–6 cm long. Anteriorly, there

are numerous papillae and circular ridges in the cuticle. The rest of the cuticle is striated transversely. In the female the vulva is situated anteriorly near the simple mouth opening and the tail is blunt with no papillae. The tail of the male is blunt and short. The caudal alae are supported by pre-cloacal and post-cloacal papillae.

Life cycle: Eggs or free L₁ present in exudates from bleeding points in the skin surface are ingested by muscid flies (e.g. *Musca autumnalis* in Europe, *M. lusoria* and *M. xanthomelas* in Africa) in which they develop to L₃ within several weeks to months, depending on air temperature. Transmission occurs when infected flies feed on lacrimal secretions or skin wounds in other cattle and the L₃ deposited then migrate in the subcutaneous tissue and develop to the adult stage under the skin in 5–7 months. Bleeding points develop 7–9 months after infection, which is about the same duration as patency.

Parafilaria multipapillosa

Synonym: *Filaria haemorrhagica*

Description: Slender white worms 3.0–7.0 cm in length. Adult males are 28 mm and females 40–70 mm in length. The anterior end of the worm bears a large number of papilliform thickenings.

Life cycle: Eggs or free L₁ larvae present in exudates from bleeding points in the skin surface are ingested by horn flies (*Haematobia*), in which they develop to L₃ within several weeks to months, depending on air temperature. Transmission occurs when infected flies feed on lacrimal secretions or skin wounds in other horses and the L₃ deposited then migrate in the subcutaneous tissue and develop to the adult stage under the skin in 9–12 months.

Stephanofilaria

Worms of this genus inhabit the dermis and cause chronic dermatitis in cattle, buffalo, rhinoceros and elephants in the tropics and subtropics. The genus is readily recognised because the worms are small, and the oral opening is surrounded by numerous spines.

Life cycle: The fly vectors are attracted to the open lesions in the skin caused by the adult parasites, and ingest the microfilariae in the exudate. Development to L₃ takes about 3 weeks, and the final host is infected when the flies deposit larvae on normal skin.

Stephanofilaria species

| Species | Hosts | Site | Intermediate hosts |
|-------------------------------------|-----------------------|-------------------------|--------------------------------------|
| <i>Stephanofilaria assamensis</i> | Cattle, goat, buffalo | Skin, back | Muscid flies |
| <i>Stephanofilaria kaeli</i> | Cattle | Skin, head, legs, teats | Muscid flies |
| <i>Stephanofilaria dedoesi</i> | Cattle | Skin, head, legs, teats | Muscid flies |
| <i>Stephanofilaria okinawaensis</i> | Cattle | Skin, face and teats | Muscid flies |
| <i>Stephanofilaria stilesi</i> | Cattle | Skin lower abdomen | Horn flies (<i>Haematobia</i> spp.) |
| <i>Stephanofilaria zaheeri</i> | Buffalo, cattle | Skin, ears, legs, teats | Muscid flies |

Stephanofilaria dedoesi

Description: Small nematodes; males are 2.3–3.2 mm and females 6.1–8.5 mm in length. A protruding cuticular rim, with a

denticulate edge, surrounds the oral aperture. The anterior of the worms has a circular thickening, which possesses a number of small cuticular spines. An anus is absent in female worms. The male spicules are of unequal length.

Stephanofilaria stilesi

Description: Small nematodes; males are 2.6–3.7 mm and females 3.7–6.9 mm in length. There are four to five cephalic spines and 18–19 peribuccal spines. The male spicules are unequal and the female worms have no anus.

Stephanofilaria okinawaensis

Description: The parasites are small, rounded, whitish and slender bodied. Females are 7.0–8.5 mm and males 2.7–3.5 mm in length.

Suifilaria

These worms can be associated with dermal abscesses but are generally of little veterinary significance.

Life cycle: Not known. The females appear to lay their eggs in the skin of the pig.

Suifilaria species

| Species | Hosts | Site | Intermediate hosts |
|------------------------|-------|--------------------------------|--------------------|
| <i>Suifilaria suis</i> | Pig | Subcutaneous connective tissue | Not known |

Suifilaria suis

Description: These are slender worms. Male are 17–25 mm and females 34–40 mm in length. The posterior of the male is coiled in a spiral and the spicules are uneven, the left being about six to eight times as long as the right spicule. The male only has one caudal ala and this is on the left. The female tail bears a number of small tubercles.

FAMILY ONCHOCERCIDAE

Dirofilaria

Of the two species occurring in domestic carnivores, *Dirofilaria immitis* is by far the more important. The adults, found in the right side of the heart and adjacent blood vessels of dogs, are responsible for canine heartworm disease.

Dirofilaria species

| Species | Hosts | Site | Intermediate hosts |
|--|--|--|---|
| <i>Dirofilaria immitis</i> (syn. <i>Nochtiella immitis</i>) | Dog, fox, wild canids; occasionally cat and rarely human, primates | Cardiovascular system: right ventricle, right atrium, pulmonary artery and posterior vena cava | Mosquitoes of the genera <i>Aedes</i> , <i>Anopheles</i> and <i>Culex</i> |
| <i>Dirofilaria repens</i> (syn. <i>Nochtiella repens</i>) | Dog, cat, fox, bear, occasionally human, primates | Subcutaneous, intermuscular tissues | Mosquitoes of the genera <i>Aedes</i> , <i>Anopheles</i> and <i>Culex</i> |

Dirofilaria immitis

Synonym: *Nochtiella immitis*

Description: Long slender white/grey worms measuring 15–30 cm in length with a tough cuticle. Adult females measure 25–30 cm, with the males about half as long. Many worms are usually found together in a tangled mass (Fig. 1.60). The size and site are diagnostic for *D. immitis*. The male tail has the typical loose spiral, and the tail bears small lateral alae. There are four to six pairs of ovoid papillae. The left spicule is long and pointed; the right spicule is smaller (about half as long) and ends bluntly. In the female the vulva is situated just to the rear of the end of the oesophagus.

Life cycle: The adults live in the heart and adjacent blood vessels and the females release microfilariae directly into the bloodstream. These microfilariae can live for several months in the visceral blood vessels. Microfilariae are ingested by female mosquitoes during feeding. Development to infective L₃ in the malpighian tubules of the mosquito takes about 2 weeks. The infective L₃ then migrate to the mouthparts and the final host is infected when the mosquito takes a further blood meal. In the dog the L₃ migrate to the subcutaneous or subserosal tissues in the thorax or abdomen and undergo two moults over the next few months; only after the final moult do the young *D. immitis* pass to the heart via the venous circulation. The minimum prepatent period is about 6 months. The adult worms survive for several years and patency has been recorded for over 5 years.

Dirofilaria repens

Synonym: *Nochtiella repens*

Description: The adults are long slender worms measuring from around 5 cm up to 17 cm in length. Males are 5–7 cm and females 13–17 cm.

Life cycle: The adults live in subcutaneous nodules and the females release microfilariae, which migrate to the blood and are ingested by female mosquitoes during feeding. Development to L₃ takes place in the mosquito and the final host is infected when the mosquito

Fig. 1.60 Adult *Dirofilaria immitis* heartworms.

takes a further blood meal. In the dog the L₃ migrate to the subcutaneous or subserosal tissues and undergo two moults over the next few months. The prepatent period is 27–34 weeks.

Acanthocheilonema

Several species of *Acanthocheilonema* (formerly *Dipetalonema*), transmitted mainly by ticks and fleas, occur in the subcutis of dogs in tropical and subtropical zones.

Acanthocheilonema species

| Species | Hosts | Site | Intermediate hosts |
|---|------------------------|--|--------------------------------|
| <i>Acanthocheilonema reconditum</i> (syn. <i>Dipetalonema reconditum</i>) | Dog and various canids | Subcutaneous tissues, kidney and body cavity | Fleas, ticks, lice, mosquitoes |
| <i>Acanthocheilonema dracunculoides</i> (syn. <i>Dipetalonema dracunculoides</i>) | Dog, hyena | Peritoneum | Ticks, louse fly and fleas |
| <i>Acanthocheilonema grassi</i> (syn. <i>Dipetalonema grassi</i> , <i>Cercopithifilaria grassi</i>) | Dog | Subcutaneous and intramuscular tissue | Ticks and fleas |

Acanthocheilonema reconditum

Synonym: *Dipetalonema reconditum*

Description: The slender male worms measure on average 1.5 cm and females about 2.5 cm. The male spicules are unequal.

Life cycle: Following ingestion of a blood meal the microfilariae develop to the infective third stage in about 7–14 days and then migrate to the head. Larvae pass to the host when the intermediate host next feeds. The prepatent period in the dog is 8–10 weeks. *Acanthocheilonema reconditum* shows a diurnal periodicity.

Acanthocheilonema dracunculoides

Synonym: *Dipetalonema dracunculoides*

Description: The adult worms are small; male worms are 2.4–3 cm, females 3.2–6 cm in length. Males have broad unequal spicules.

Acanthocheilonema grassi

Synonym: *Dipetalonema grassi*, *Cercopithifilaria grassi*

Description: The adult worms are small, the females measuring about 2.5 cm in length.

Life cycle: The life cycle has not been described in detail. Following ingestion of a blood meal, the microfilariae develop to infective larvae in the intermediate hosts, which are ticks and fleas. Larvae pass to the host when the intermediate host next feeds.

Dipetalonema

Several species of *Dipetalonema*, transmitted mainly by mosquitoes, occur in the subcutis, peritoneum, pleura or blood vessels of mammals in tropical and subtropical zones.

Dipetalonema species

| Species | Hosts | Site | Intermediate hosts |
|--|-------|--|--------------------------------------|
| <i>Dipetalonema evansi</i> (syn. <i>Deraiphoronema evansi</i>) | Camel | Heart, arteries and veins, pulmonary arteries, spermatic arteries, lymph nodes | Mosquitoes of the genus <i>Aedes</i> |

Dipetalonema evansi

Synonym: *Deraiphoronema evansi*

Description: These are fairly large filarial worms; adult male worms are 8–11 cm, adult females 14.5–18.5 cm.

Onchocerca

Though onchocercosis is an important filarial infection in human medicine (*Onchocerca volvulus* causing river blindness), most species in domestic animals are relatively harmless.

Life cycle: The life cycle of *Onchocerca* is typically filarioid, with the exception that the microfilariae occur in the tissue spaces of the skin rather than in the peripheral bloodstream. Microfilariae migrate in subdermal connective tissue in the skin of the back, sometimes ears and neck, where biting flies, feeding in this area, ingest microfilariae, which then develop to the infective stage in around 3 weeks. When these infected insects feed on another animal, host transmission of L₃ occurs.

***Onchocerca* species**

| Species | Hosts | Site | Intermediate hosts |
|---|--|--|--|
| <i>Onchocerca gutturosa</i> (syn. <i>Onchocerca lienalis</i>) | Cattle, camel | Connective tissue, ligamentum nuchae, gastrosplenic ligament | Blackflies (<i>Simulium</i>) |
| <i>Onchocerca gibsoni</i> | Cattle | Connective tissue | Midges (<i>Culicoides</i>) |
| <i>Onchocerca ochengi</i> (syn. <i>Onchocerca dermati</i>) | Cattle | Connective tissue, scrotum and udder | Unknown |
| <i>Onchocerca armillata</i> | Cattle, buffalo, sheep, goat, occasionally camel | Thoracic aorta | Midges (<i>Culicoides</i>), blackflies (<i>Simulium</i>) |
| <i>Onchocerca dukei</i> | Cattle | Abdomen, thorax, thighs | Unknown but probably blackflies |
| <i>Onchocerca cebei</i> (syn. <i>Onchocerca sweetae</i>) | Buffalo | Abdomen, thorax, thighs | Midges (<i>Culicoides</i>) |
| <i>Onchocerca cervicalis</i> | Horse | Cervical ligament | Midges (<i>Culicoides</i>) |
| <i>Onchocerca fasciata</i> | Camel | Connective tissue, ligamentum nuchae | Unknown |
| <i>Onchocerca tarsicola</i> | Deer | Legs | Blackflies (<i>Simulium</i>) |
| <i>Onchocerca reticulata</i> | Horse, donkey | Connective tissue, flexor tendons | Midges (<i>Culicoides</i>) |
| <i>Onchocerca volvulus</i> | Human | Dermis, eye | Blackflies (<i>Simulium</i>) |

Onchocerca gutturosa

Synonym: *Onchocerca lienalis*

Description: Slender whitish worms; males range from 2 to 6 cm, while females are up to 60 cm in length or longer and are coiled in fibrous tissues. The cuticle possesses spiral thickenings to aid attachment.

Onchocerca gibsoni

Description: The slender worms range from 2 cm to over 20 cm in length and lie tightly coiled in tissue nodules. Males are 3–5 cm and females 14–20 cm although there have been reports of worms up to 50 cm in length. The tail of the male is ventrally curved and bears lateral alae and six to nine papillae at either side. The spicules are unequal in size.

Onchocerca armillata

Description: Slender whitish worms. Male worms are about 7 cm and female worms up to 70 cm long.

Onchocerca cervicalis

Description: The male is 6–7 cm in length and the female up to 30 cm long.

Onchocerca reticulata

Description: Slender whitish worms; males are 15–20 cm and females over 50 cm long.

Life cycle: The prepatent period is around 12–16 months.

Pelecitus

The members of this genus are filarioid worms of birds and mammals.

***Pelecitus* species**

| Species | Hosts | Site | Intermediate hosts |
|--|--------------------|---------------------------------|-----------------------|
| <i>Pelecitus clavus</i> (syn. <i>Eulimdana clava</i>) | Pigeon, wild birds | Subcutaneous, connective tissue | Unknown |
| <i>Pelecitus mazzanti</i> | Pigeon | Subcutaneous, connective tissue | Unknown |
| <i>Pelecitus scapiceps</i> (syn. <i>Dirofilaria scapiceps</i> , <i>Loaina scapiceps</i>) | Rabbit, hare | Synovial sheaths of the feet | Species of mosquitoes |

Pelecitus clavus

Synonym: *Eulimdana clava*

Description: Small to medium-sized worms which have helical turns. Male worms are 6–7 mm and female worms 17–20 mm long. The male spicules are unequal in length, the left being larger than the right.

Life cycle: Microfilariae are present in the blood or subcutaneous space of infected birds and are ingested by biting ectoparasite vectors when they feed.

Pelecitus scapiceps

Synonyms: *Dirofilaria scapiceps*, *Loaina scapiceps*

Description: Male worms are 11–16 mm in length with spicules of unequal length. Female worms are 25–30 mm long.

Life cycle: Microfilariae circulate in the blood of infected lagomorph hosts (there is no circadian periodicity). Microfilariae ingested by a mosquito develop into infective third-stage larvae and these are then injected into the definitive host during feeding. These larvae migrate in the subcutaneous tissue to a maturation site, such as the main body, and develop to the early fifth stage before migrating to the hocks where they develop into mature adult worms. The prepatent period can vary around 130–220 days.

Chandlerella

Members of this genus are filarioid worms of birds.

Chandlerella species

| Species | Hosts | Site | Intermediate hosts |
|-------------------------------|------------------|-------|----------------------------------|
| <i>Chandlerella quisquali</i> | Emus, wild birds | Brain | Midges (<i>Culicoides</i> spp.) |

Chandlerella quisquali

Description: Slender worms, with males 8–15 mm and female worms 17–24 mm in length. In the male, the spicules are thick and equal in length and there are three to four pairs of post-anal papillae.

Setaria

The members of this genus are usually harmless inhabitants of the peritoneal and pleural cavities. The worms are slender whitish worms, up to 12 cm long, and the posterior end is spirally coiled. The mouth is surrounded by a cuticular ring with dorsal, ventral and frequently lateral prominences, which give the worms a characteristic appearance. The tail of the male has four pairs of pre-cloacal and usually four pairs of post-cloacal papillae. The spicules are dissimilar and unequal in length. The tail of female worms usually has spines of several large conical projections. The site and gross appearance are sufficient for generic identification (Fig. 1.61).

Setaria species

| Species | Hosts | Site | Intermediate hosts |
|---|---|----------------------------|--------------------|
| <i>Setaria congolensis</i> (syn. <i>Setaria bernardi</i>) | Pig | Peritoneum, pleural cavity | Mosquitoes |
| <i>Setaria equina</i> | Horse, donkey, other equids | Peritoneum, pleural cavity | Mosquitoes |
| <i>Setaria labiato-papillosa</i> (syn. <i>Setaria digitata</i> , <i>Setaria altaica</i> , <i>Setaria cervi</i>) | Cattle, buffalo, bison, yak, deer, antelope, rarely sheep | Peritoneum, pleural cavity | Mosquitoes |
| <i>Setaria digitatus</i> | Cattle, buffalo | Peritoneum, pleural cavity | Mosquitoes |

Fig. 1.61 *Setaria labiato-papillosa* in bovine mesentery.

Setaria congolensis

Synonym: *Setaria bernardi*

Description: Male worms are 8 cm and female worms 11–14 cm in length. The male worm has three pairs of small pre-cloacal papillae and four pairs of large post-cloacal papillae. The right spicule is spiny, and the left spicule is comparatively long with a flagellated end.

Setaria equina

Description: The adults are long and slender with cephalic papillae. Males measure 8–10 cm and females 13–15 cm in length. Worms have an elevated chitinous peribuccal ring. The spiral tail of the female terminates in a point. Male spicules are unequal, the left being about three times longer than the right.

Life cycle: Larvae produced by adult worms in the body cavity circulate in the blood and are taken up by culicine mosquitoes, including *Aedes* and *Culex* species. Infective larvae develop in the mosquito muscles in 2 weeks, and are reinjected into horses when the mosquitoes feed. The prepatent period is 8–10 months.

Setaria labiato-papillosa

Synonyms: *Setaria digitata*, *Setaria altaica*, *Setaria cervi*

Description: Males are 40–60 mm and females 60–120 mm in length. The dorsal and ventral prominences and the peribuccal ring are clearly perceptible. The tail of the female ends in a marked button, which is divided into a number of papillae. The male spicules are of unequal length, the left being around 2.5 times longer than the right.

Life cycle: Larvae produced by adult worms in the body cavity circulate in the blood and are taken up by culicine mosquitoes, including *Aedes* and *Culex* species. Infective larvae develop in the mosquito muscles in 12–16 days, and are reinjected into the final host when the mosquitoes feed. The prepatent period is 8–10 months.

Elaeophora

These long slender worms inhabit large blood vessels, but are generally of local importance causing filarial dermatosis caused by circulating microfilariae.

Elaeophora species

| Species | Hosts | Site | Intermediate hosts |
|------------------------------|-----------------------|---------------|--------------------|
| <i>Elaeophora poeli</i> | Cattle, buffalo, zebu | Aorta | Unknown |
| <i>Elaeophora schneideri</i> | Deer, sheep, goat | Blood vessels | Tabanid flies |
| <i>Elaeophora bohmi</i> | Horse | Blood vessels | Unknown |

Elaeophora poeli

Description: Slender worms, males measuring around 4–7 cm and females up to 30 cm in length. The oesophagus is very long and lips are absent. The tail of the male possesses five to seven pairs of papillae, of which two pairs are pre-cloacal. Spicules are short and robust.

Life cycle: The life cycle is indirect. The microfilariae are ingested by the intermediate host and the L₃, when developed, are released into the wound made when the insect next feeds. The male occurs in nodules in the wall of the aorta, while the female is fixed in nodules by its anterior extremity with the rest of the body free in the lumen of the aorta. Microfilariae occur in the blood and in subcutaneous connective tissue.

Elaeophora schneideri

Description: Slender worms; males are around 5–8 cm and females up to 12 cm long with a very long oesophagus. The tail of the male is coiled and the spicules are long, slender and unequal.

Life cycle: Similar to *E. poeli*. Early development in the host appears to be in the meningeal arteries, then the worms migrate to the carotid arteries and are mature and producing microfilariae about 4.5 months after infection. The adult worms are embedded in the arterial intima of the carotid, mesenteric and iliac arteries; occasionally they are found in the digital and tibial arteries with only the anterior part of the female free in the lumen. The prepatent period is around 4–5 months.

Elaeophora bohmi

Description: These are slender worms, the males measuring 4.5–6 cm and females 4–20 cm in length.

Life cycle: The microfilariae are ingested by the intermediate host (tabanid flies) when blood feeding and the L₃, when developed, are released into the wound made when the insect next feeds. Microfilariae occur in the blood and in subcutaneous connective tissue.

Splendidofilaria

Parasites of birds, characterised by a relatively long tail and sub-equal spicules.

Splendidofilaria species

| Species | Hosts | Site | Intermediate hosts |
|--|-------|---------------------|--------------------------------|
| <i>Splendidofilaria fallisensis</i> (syn. <i>Ornithofilaria fallisensis</i>) | Duck | Subcutaneous tissue | Blackflies (<i>Simulium</i>) |

Splendidofilaria fallisensis

Synonym: *Ornithofilaria fallisensis*

Description: These are delicate transparent nematodes, with male worms measuring 9–15 mm and female worms 24–40 mm in length.

Paronchocerca

This genus of filarial heartworms is of little veterinary importance. *Paronchocerca struthionis* has been reported in ostriches; *Paronchocerca ciconarum* has been reported to cause myocardial degeneration in storks.

Paronchocerca species

| Species | Hosts | Site | Intermediate hosts |
|----------------------------------|---------------|---------------------------|--------------------|
| <i>Paronchocerca struthionis</i> | Ostrich, rhea | Pulmonary arteries, lungs | Unknown |
| <i>Paronchocerca ciconarum</i> | Stork | Heart, pulmonary vessels | Unknown |

Paronchocerca struthionis

Description: Long abursate nematodes, 3–5 cm in length with bluntly rounded extremities. Male spicules are dissimilar in length; a gubernaculum is absent.

Filariosis in humans

Filarioid worms are probably the most important group of helminth infections in humans, but are of only marginal concern to the veterinarian, since domestic animals are of little significance in their epidemiology. Of greatest importance in human medicine are the genera *Onchocerca*, *Brugia*, *Loa*, *Wuchereria* and *Mansonella*.

1 *Onchocerca volvulus*. Human onchocercosis, due to *O. volvulus*, occurs around the world in the equatorial zone, and is transmitted by *Simulium* spp. (blackflies). The adult worms live in subcutaneous nodules, and almost the entire pathogenic effect is caused by the microfilariae; dermatitis and elephantiasis are common, but the most important effect is ocular onchocercosis ('river blindness'), so-called because of its distribution along the habitats of *Simulium* spp. Dying microfilariae cause a sclerosing keratitis in the cornea that leads to corneal opacification and retinochoroiditis. It has been estimated that in Africa there are about 20 million people affected by onchocercosis. The only other animals to which it is transmissible are the higher primates, chimpanzee and gorilla. Ivermectin is effective in reducing skin microfilarial counts in *O. volvulus* infection and repeated treatment should help reduce transmission. The onchocercosis-associated pathology in the eye and skin has also been shown to be reduced with ivermectin treatment.

- 2 *Brugia* spp. are carried by many species of mosquito and occur in Southeast Asia, notably in Malaysia, causing elephantiasis. The most important species, *B. malayi*, is also infective for monkeys and domestic and wild carnivores, and has been transmitted experimentally to the cat and dog. The lesser species occurring in human, *B. pahangi*, has a reservoir in many species of domestic and wild animals, including the dog and cat. Adult parasites inhabit lymph nodes and afferent lymphatic vessels.
- 3 *Wuchereria bancrofti* is also mosquito-borne and affects the lymphatic system, causing elephantiasis in Africa, Asia and South America. It is exclusive to humans. As with *Brugia* spp., the main pathogenic effects are associated with adult worms rather than with microfilariae.
- 4 *Loa loa* is transmitted by *Chrysops* spp. (tabanid flies), and occurs in West, Central and East Africa, where it causes the transient subcutaneous enlargements known as 'Calabar swellings'. It is confined to human, apes and monkeys. Longevity can be up to 20 years.
- 5 *Mansonella ozzardi*, carried by *Culicoides* spp. and *Simulium* spp., occurs in the Caribbean and in Central and South America. It lives in the fat and on the mesentery or pleural cavity, and is usually considered to be non-pathogenic, though recently it has been associated with allergic signs. The prevalence is extremely high in endemic areas, where parasites closely resembling *M. ozzardi* are commonly found in monkeys and in horses and cattle. However, there is reluctance to presume that these animals may be reservoir hosts until positive identification is made.

SUPERFAMILY TRICHUROIDEA

The members of this superfamily are found in a wide variety of domestic animals. A common morphological feature is the 'stichosome' oesophagus that is composed of a capillary-like tube surrounded by a single column of cells. The male has only one spicule within a sheath, or it may be completely absent (e.g. *Trichinella*).

There are several genera of veterinary interest in the family Trichuridae. The Trichuridae includes species of *Trichuris*, which are found in the caecum and colon of mammals; *Capillaria* (*Eucoleus*) species are most commonly present in the alimentary or respiratory tract of mammals or birds. Both lay eggs with plugs at both poles. *Trichosomoides* species are of minor interest, and are bladder worms found in rodents. *Anatrichosoma* are parasites of primates, and occasionally reported in humans, and are found in the skin and nasal passages.

FAMILY TRICHURIDAE

Trichuris

Worms belonging to this genus are commonly known as 'whipworms' because the thick broad posterior end tapers rapidly to a long filamentous anterior end (about twice as long as the posterior region) that is characteristically embedded in the mucosa (Fig. 1.62). The anterior of the worm bears a small point. The male tail is tightly coiled and possesses a single spicule in a protrusible sheath.

Fig. 1.62 *Trichuris suis* adult worms.

Trichuris trichiura, the whipworm of human and simian primates, is morphologically indistinguishable from *T. suis*. However, it is generally considered that these two parasites are strictly host-specific. Worldwide the number of cases in humans is several hundred million, with around 10,000 deaths per year attributed to trichuriasis. It is more common in children.

The taxonomic status of *Trichuris* species is very confused because many described species may be synonymous, reflecting the fact that an accepted species has been found in a different host and determined as a new species.

Life cycle: The infective stage is the L₁ within the egg, which develops within 1 or 2 months of being passed in the faeces depending on the temperature. Under optimal conditions, these larvated eggs may subsequently survive and remain viable for several years. After ingestion, the plugs are digested and the released L₁ penetrate the mucosal glands of the distal ileum, caecum and colon. Subsequently, all four moults occur within these glands, the adults emerging to lie on the mucosal surface with their anterior ends embedded in the mucosa. The prepatent period is about 7–10 weeks.

Trichuris species

| Species | Hosts | Site |
|----------------------------|--|-----------------|
| <i>Trichuris campanula</i> | Cat | Large intestine |
| <i>Trichuris capreoli</i> | Deer | Large intestine |
| <i>Trichuris discolor</i> | Cattle, buffalo, occasionally sheep, goat | Large intestine |
| <i>Trichuris globulosa</i> | Cattle, occasionally sheep, goat, camel, other ruminants | Large intestine |
| <i>Trichuris leporis</i> | Rabbit, hare, coypu | Large intestine |
| <i>Trichuris muris</i> | Rat, mouse | Large intestine |
| <i>Trichuris ovis</i> | Sheep, goat, occasionally cattle and other ruminants | Large intestine |
| <i>Trichuris serrata</i> | Cat | Large intestine |
| <i>Trichuris skrjabini</i> | Sheep, goat, camel | Large intestine |
| <i>Trichuris suis</i> | Pig, wild boar | Large intestine |
| <i>Trichuris trichiura</i> | Human, primates | Large intestine |
| <i>Trichuris vulpis</i> | Dog, fox, cat | Large intestine |
| <i>Trichuris cameli</i> | Camel | Large intestine |
| <i>Trichuris tenuis</i> | Llama, alpaca | Large intestine |

Trichuris discolor

Description: Worms are similar to *T. globulosa* but the females are yellow-orange in colour.

Trichuris globulosa

Description: The adults are long white worms, with males measuring 4–7 cm and females 4–6 cm in length. The single spicule sheath bears a terminal spherical expansion, on which are spines larger than on the rest of the sheath.

Trichuris leporis

Description: Adult males measure 1.9–2.1 cm and adult females 1.7–2.1 cm in length.

Trichuris ovis

Description: The adults are long white worms about 4–8 cm in length (males 5–8 cm, females 3.5–7 cm). Only one spicule is present in the male. The spicule sheath is equipped with an oblong swelling near its distal extremity and is covered with very small spines, the size of which decrease towards the distal end.

Trichuris skrjabini

Description: Males of *T. skrjabini* have one short spicule (0.82 mm) with a rounded tip that is always fully covered by the spicule sheath and large conical caudal papillae.

Trichuris suis

Description: The adults are whitish and about 3–5 cm long. The spicule has a blunt tip and the sheath is variable in shape and in the number of spines on its surface.

Trichuris trichiura

Description: Females are slightly larger than male worms (approximately 3.5–5.0 cm compared to 3.0–4.5 cm). The females have a bluntly round posterior compared to their male counterparts with a coiled posterior end.

Trichuris vulpis

Description: The adults are whitish and about 4.5–7.5 cm long. Only one spicule is present and the sheath bears small spines only on its anterior portion.

Trichosomoides

These are permanent hyperparasites that inhabit the urinary bladder of rats.

Life cycle: Infection is by ingestion of embryonated eggs voided in the urine. Eggs hatch in the stomach, penetrate the stomach wall and are carried in the blood to the lungs and other parts of the body. Only those larvae that reach the kidneys or urinary bladder survive. The life cycle takes 8–9 weeks and the prepatent period is 8–12 weeks.

***Trichosomoides* species**

| Species | Hosts | Site |
|-----------------------------------|-------|---------|
| <i>Trichosomoides crassicauda</i> | Rat | Bladder |

Trichosomoides crassicauda

Description: Males measure 1.5–3.5 mm and females 10–19 mm in length. The small male lives within the uterus of the female worm.

Anatrichosoma

Members of this genus have been reported from the skin and nasal mucosa of primates and the skin and mucosa of wild rodents and marsupials. There have been some reports of infections with species of these parasites in dogs, cats and humans.

Capillaria

Worms belonging to this genus, commonly known as ‘hair-worms’ or ‘threadworms’, are very fine whitish filamentous worms, the narrow stichosome oesophagus occupying about one-third to half the body length. There is a simple mouth and a buccal capsule is absent. The males have a long thin colourless single spicule and often possess a primitive bursa-like structure. The females contain eggs that resemble those of *Trichuris* in possessing bipolar plugs.

Life cycle: The life cycles are generally direct but some species found in birds have indirect life cycles, with earthworms acting as intermediate hosts. The infective L₁ develops within the egg in about 3–4 weeks. Infection of the final host is through ingestion of this embryonated infective stage and development to adult worms occurs usually without a migration phase.

The taxonomy and systematics of these parasites have been changed many times because of a difficulty in designation of particular species’ features and there are many synonyms in this group. Some species of *Capillaria* are now listed under the generic name *Eucoleus*, although they may universally still be referred to as *Capillaria*.

***Capillaria/Eucoleus* species**

| Species | Hosts | Site |
|---|--|-----------------|
| <i>Capillaria anatis</i> (syn. <i>Capillaria brevicollis</i> , <i>Capillaria collaris</i> , <i>Capillaria mergi</i> , <i>Thormix anatis</i>) | Chicken, turkey, gallinaceous birds (pheasant, partridge), pigeon, duck, goose | Caeca |
| <i>Capillaria anseris</i> (syn. <i>Baruscapillaria anseris</i>) | Goose, duck | Small intestine |
| <i>Capillaria bovis</i> (syn. <i>Capillaria brevipes</i>) | Cattle | Small intestine |

| Species | Hosts | Site |
|---|---|--------------------------------------|
| <i>Capillaria bilobata</i> | Zebu | Abomasum |
| <i>Capillaria bursata</i> | Chicken, turkey, pheasant, duck and wild birds Intermediate hosts: earthworms | Small intestine |
| <i>Capillaria caudinflata</i> (syn. <i>Aonchotheca caudinflata</i>) | Chicken, turkey, goose, pigeon and wild birds Intermediate hosts: earthworms | Small intestine |
| <i>Capillaria feliscati</i> (syn. <i>Pearsonema feliscati</i>) | Cat | Bladder |
| <i>Capillaria hepatica</i> (syn. <i>Callodium hepatica</i> , <i>Hepaticola hepatica</i>) | Rat, mouse, squirrel, rabbit and farmed mustelids; occasionally dog, cat, human, primates | Liver |
| <i>Capillaria longipes</i> | Sheep, goat, cattle | Small intestine |
| <i>Capillaria obsignata</i> (syn. <i>Baruscapillaria obsignata</i> , <i>Capillaria columbae</i>) | Pigeon, chicken, turkey, pheasant and wild birds | Small intestine |
| <i>Capillaria phasianina</i> (syn. <i>Thornix phasianina</i>) | Pheasant, grey partridge | Small intestine, caecae |
| <i>Capillaria philippinensis</i> | Human | Small intestine |
| <i>Capillaria plica</i> (syn. <i>Pearsonema plica</i>) | Dog, cat, fox, wolf | Bladder |
| <i>Capillaria putorii</i> (syn. <i>Aonchotheca putorii</i>) | Cat, dog, mustelids, hedgehog, bear, raccoon | Stomach, small intestine |
| <i>Capillaria uropapillata</i> | Pheasant | Oesophagus, crop |
| <i>Eucoleus aerophila</i> (syn. <i>Capillaria aerophila</i>) | Fox, mustelids, occasionally dog, coyote, cat and human | Trachea, bronchi |
| <i>Eucoleus boehmi</i> (syn. <i>Capillaria boehmi</i>) | Fox, dog | Nasal, frontal and maxillary sinuses |
| <i>Eucoleus annulata</i> (syn. <i>Capillaria annulata</i>) | Chicken, turkey, duck and wild birds Intermediate hosts: earthworms | Oesophagus, crop |
| <i>Eucoleus contorta</i> (syn. <i>Capillaria contorta</i>) | Chicken, turkey, pheasant, duck and wild birds Intermediate hosts: earthworms | Oesophagus, crop |
| <i>Eucoleus perforans</i> (syn. <i>Capillaria perforans</i>) | Pheasant, guinea fowl | Oesophagus, crop |

Capillaria anatis

Synonyms: *Capillaria brevicollis*, *Capillaria collaris*, *Capillaria mergi*, *Thornix anatis*

Description: Males measure around 16–24 mm and females 28–38 mm in length.

Life cycle: The life cycle is direct. The infective L₁ develops within the egg in about 3–4 weeks. Infection of the final host is through ingestion of this embryonated infective stage, and development to adult worms occurs without a migration phase. The prepatent period is 3–4 weeks.

Capillaria bursata

Description: Males measure around 6–12 mm and females up to 25 mm.

Life cycle: The life cycle of this species is indirect.

Capillaria bovis

Synonym: *Capillaria brevipes*

Description: Males measure around 8–9 mm and females up to 12 mm.

Capillaria caudinflata

Synonym: *Aonchotheca caudinflata*

Description: Males measure around 6–12 mm and females up to 25 mm in length. Females have a characteristic projecting vulval appendage and a cylindrical tail that does not taper significantly.

Life cycle: The life cycle of this species is indirect.

Capillaria hepatica

Synonyms: *Callodium hepatica*, *Hepaticola hepatica*

Description: These are very fine filamentous worms generally measuring 10–50 mm in length.

Life cycle: The life cycle is direct and differs from that of other *Capillaria* species. Adult *C. hepatica* worms reproduce in the liver and females lay groups of eggs in the parenchyma where they become encapsulated by the host's reaction. These eggs are therefore not released directly from the host. Infection is acquired by ingestion of either the liver, following predation, cannibalism or carrion feeding, or eggs on the ground, which have been freed by decomposition of the host. Eggs in the soil will embryonate and be infective in about 4 weeks. When infective eggs are ingested by the host, they hatch in the intestine and the larvae penetrate the intestinal wall and are carried to the liver via the lymphatics and the bloodstream.

Capillaria longipes

Description: Males measure around 10–13 mm and females up to 20 mm.

Life cycle: The prepatent period is 3–4 weeks.

Capillaria obsignata

Synonyms: *Baruscapillaria obsignata*, *Capillaria columbae*

Description: Males measure around 10–12 mm and females are up to 15 mm in length. The tail of the female worm tapers posteriorly.

Life cycle: This species has a direct life cycle. The infective L₁ develops within the egg in about 7–10 days. Infection of the final host is through ingestion of this embryonated infective stage, and development to adult worms occurs without a migration phase. The prepatent period is around 3 weeks.

Capillaria plica

Synonym: *Pearsonema plica*

Description: Adult males are 13–30 mm and females are 30–60 mm long.

Life cycle: This parasite requires an earthworm intermediate host, ingested eggs developing to the infective L₃ within 30 days. The prepatent period is around 8 weeks.

Capillaria feliscati

Synonym: *Pearsonema feliscati*

Description: Adult males are 13–30 mm and females 30–60 mm long.

Capillaria putorii

Synonym: *Aonchotheca putorii*

Description: Thin filamentous worms, about 10 mm long; males are 5–8 mm and females 9–15 mm.

Eucoleus aerophila

Synonym: *Capillaria aerophila*

Description: Males measure around 24 mm and females 32 mm in length. The male possesses only one spicule and the spicule sheath is covered with spines.

Eucoleus boehmi

Synonym: *Capillaria boehmi*

Description: These are fine whitish filamentous worms, with adults 15–40 mm long. The male has a long thin single spicule.

Eucoleus annulata

Synonym: *Capillaria annulata*

Description: Males measure around 15–25 mm and females 37–80 mm. This species has a cuticular swelling at the back of the head.

Life cycle: The life cycle is indirect. Eggs passed in faeces are ingested by earthworms and develop to the infective stage in 2–3 weeks. The prepatent period is about 3–4 weeks in the final host.

Eucoleus contorta

Synonym: *Capillaria contorta*

Description: Males measure around 12–17 mm and females 27–38 mm.

Life cycle: *Eucoleus contorta* appears to be able to develop both directly and indirectly. In the direct life cycle, the infective L₁ develops within the egg in about 3–4 weeks. Infection of the final host is through ingestion of this embryonated infective stage, and development to adult worms occurs without a migration phase. In the

indirect life cycle, the egg needs to be ingested by an earthworm in which it hatches, the final host being infected by ingestion of the earthworm. The prepatent period is about 3–4 weeks in the final host.

Capillariosis in humans

Three species of *Capillaria*, *C. philippinensis*, *C. hepatica* and *Eucoleus (Capillaria) aerophila*, can infect humans. Humans acquire *C. hepatica* infection through ingestion of soil containing embryonated eggs or by consuming contaminated food or water. Heavy infections in human induce similar hepatic lesions to those seen in other mammalian hosts and hepatic capillariosis is usually fatal.

Capillaria philippinensis infects the small intestine and causes a severe enteropathy that can be fatal. It occurs mainly in the Philippines and Thailand, with sporadic outbreaks in other parts of Southeast Asia, India, the Middle East and southern Europe. Eggs shed into water embryonate and are ingested by freshwater or brackish-water fish and develop to the infective stage in the intestinal mucosa. Infection is acquired through the consumption of raw or undercooked fish. Large infections can accumulate through autoinfection. Fish-eating birds are thought to be the reservoir host. Clinical signs include intermittent diarrhoea, followed by anorexia, abdominal distension and weight loss. There is a protein-losing enteropathy. Human capillariosis resulting from *E. aerophila* is very rare.

SUPERFAMILY TRICHINELLOIDEA

FAMILY TRICHINELLIDAE

Trichinella are found in the small intestine of mammals and produce larvae that immediately invade the tissues of the same host.

Trichinella

The taxonomy of the genus has been controversial until very recently. It is composed of several sibling species that cannot be differentiated morphologically but molecular typing, and other criteria, have now identified eight species of *Trichinella* (Table 1.7).

In the very small adult worms (males 1.4–1.6 mm, females 3–4 mm in length) the oesophagus is at least one-third of the total body length, and the tail in the male has two small knob-shaped conical cloacal flaps, but no copulatory spicule nor a spicule sheath. In the female, the uterus contains developing larvae. The vulva is sited in the mid-oesophageal region of the worm. *Trichinella* infection is most easily identified by the presence of coiled larvae in striated muscle (Fig. 1.63) and adult worms are unlikely to be encountered during gross examination of intestinal digesta.

Life cycle: The life cycle is indirect. The adult parasites and infective larvae (muscle trichinae) are unusual in being present within a single host (i.e. development from larva to adult to larva in a single host). *Trichinella* does not have a free-living stage. The very small developing adults lie between the villi of the small intestine. After fertilisation, the males die while the females burrow deeper into the intestinal mucosa. About a week later, they produce L₁ which enter the lymphatic vessels and travel via the bloodstream to the skeletal

Table 1.7 *Trichinella* species.

| Species | Distribution | Principal hosts | Resistance to freezing |
|----------------------------|--|---|------------------------|
| Capsule forming | | | |
| <i>T. spiralis</i> | Cosmopolitan | Pig, rat, horse, wide range of mammals, human | No |
| <i>T. nativa</i> | Arctic and subarctic zones: North America, Finland, Sweden | Wild carnivores, seal, polar bear, walrus | High |
| <i>T. nelsoni</i> | Tropical Africa | Wild carnivores and omnivores | No |
| <i>T. britovi</i> | Temperate zone of Palaearctic region | Wild carnivores, fox, wild boar, horse, human | Low |
| <i>T. murrelli</i> | North America | Wildlife, horse, human | No |
| Non-capsule forming | | | |
| <i>T. pseudospiralis</i> | Cosmopolitan | Mammals, birds | No |
| <i>T. papuae</i> | Papua New Guinea | Wild pig, human | No |
| <i>T. zimbabwensis</i> | Zimbabwe | Crocodiles | No |

Fig. 1.63 Coiled infective larvae of *Trichinella spiralis* in striated muscle.

muscles. There, still as L₁, they penetrate striated muscle cells where they are encapsulated by the host, grow and assume a characteristic coiled position; the parasitised muscle cell is transformed by microvascularisation into a ‘nurse cell’. This process is complete within about 3–4 weeks, by which time the larvae are infective and may remain so for many years. Development is resumed when muscle, containing the encysted trichinae, is ingested by another host, usually as a result of predation or carrion feeding. The L₁ is liberated in the stomach and in the intestine undergoes four moults to become sexually mature within about a week. Patent infections persist for only a few weeks at the most.

PHYLUM ACANTHOCEPHALA

This is a separate phylum, closely related to the Nematoda, that contains a few genera of veterinary importance. They are generally referred to as ‘thorny-headed worms’ due to the presence of a hook-covered proboscis anteriorly (Fig. 1.64), and most are parasites of the alimentary tract of vertebrates. The body is usually cylindrical, although some are flattened. The hollow proboscis armed with recurved hooks, which aid in attachment, is retractable and lies in a sac. There is no alimentary canal, with absorption taking place through the thick cuticle, which is often folded and invaginated to

Fig. 1.64 Head of *Macracanthorhynchus hirudinaceus* showing the retractable proboscis.

increase the absorptive surface. The sexes are separate, males being much smaller than females. Posteriorly, the male has a muscular bursa and penis. After copulation, eggs, discharged by ovaries into the body cavity of the female, are fertilised and taken up by a complex structure called the uterine bell, which only allows mature eggs to pass out. These are spindle-shaped, thick-shelled and contain a larva which has an anterior circlet of hooks and spines on its surface and is called an **acanthor**.

Life cycle: The life cycle is indirect, involving either an aquatic or terrestrial arthropod intermediate host. On ingestion by the intermediate host, the egg hatches and the acanthor migrates to the haemocoel of the arthropod where it develops to become a **cystacanth** after 1–3 months. The definitive host is infected by ingestion of the arthropod intermediate host, and the cystacanth, which is really a young adult, attaches and grows to maturity in the alimentary canal. The prepatent period varies from 5 to 12 weeks.

FAMILY OLIGACANTHORHYNCHIDAE

The major genera of veterinary significance are *Macracanthorhynchus*, which is found in pigs, *Oncicola* found in dogs and other canids, and *Prosthenorchis* (*Oncicola*) which is found in primates.

Macracanthorhynchus

Macracanthorhynchus species

| Species | Hosts | Site | Intermediate hosts |
|---|----------------|-----------------|--|
| <i>Macracanthorhynchus hirudinaceus</i> | Pig, wild boar | Small intestine | Various dung beetles and water beetles |

Macracanthorhynchus hirudinaceus

Description: Male worms are up to 10 cm long and the females around 40–60 cm in length and are slightly curved and white/pinkish in colour when fresh. The worms are thick (5–10 mm in width) and flattened and the cuticle is transversely wrinkled. This

pseudo-segmentation can sometimes cause misidentification as a tapeworm. There is no alimentary canal. The anterior of the worm possesses a small retractable proboscis, which is covered with about six transverse rows of recurved hooks. The size of the hooks decreases posteriorly.

Life cycle: The prepatent period is 2–3 months and longevity can be around 1 year.

Oncicola

Oncicola species

| Species | Hosts | Site | Intermediate hosts |
|-----------------------|-------------------------------|-----------------|--------------------|
| <i>Oncicola canis</i> | Dog, coyote, occasionally cat | Small intestine | Beetles |

Oncicola canis

Description: These are thick worms (around 2–4 mm in width). Males are 6–13 mm and females 7–14 mm in length. The body is conical tapering backwards and is dark grey in colour. The proboscis bears six transverse rows, each with six hooks. The shapes of the hooks are taenioid in the anterior region and more like a rose thorn in the posterior section.

FAMILY POLYMORPHIDAE

A few genera are parasites of rodents (*Moniliformis*), aquatic birds (*Polymorphus*, *Filicollis*) and fishes (*Echinorhynchus*, *Acanthocephalus*). These are frequently small worms with a cylindrical body, although *Moniliformis* species can be very large, up to 30 cm in length.

Life cycle: The definitive host is infected following ingestion of an intermediate host that contains an infective cystacanth. The adult worm establishes in the posterior small intestine. The prepatent period is 3–4 weeks.

Polymorphus

Polymorphus species

| Species | Hosts | Site | Intermediate hosts |
|---|---|-----------------|---|
| <i>Polymorphus boschadis</i> (syn. <i>Polymorphus minutus</i> , <i>Echinorhynchus polymorphus</i>) | Duck, goose, chicken, swan and various wild aquatic birds | Small intestine | Crustaceans: <i>Gammarus pulex</i> , freshwater shrimp and sometimes the crayfish <i>Potamobius astacus</i> |

Polymorphus boschadis

Synonyms: *Polymorphus minutus*, *Echinorhynchus polymorphus*

Description: Males measure around 3 mm and females up to 10 mm in length and are orange-coloured when fresh. The anterior region possesses small spines and the cylindrical body has a constriction along its length, about one-third from the head. The proboscis has 16 rows of small hooks, their size increasing anteriorly.

Filicollis

Filicollis species

| Species | Hosts | Site | Intermediate hosts |
|--------------------------|--|-----------------|---|
| <i>Filicollis anatis</i> | Duck, goose, swan and wild aquatic birds | Small intestine | Crustaceans, isopods such as <i>Asellus aquaticus</i> |

Filicollis anatis

Description: The whitish male is about 7 mm in length and the anterior region possesses many small spines. The ovoid proboscis is armed with 18 longitudinal rows of small hooks. The neck of the female worm is elongate, slender and bears a globular-shaped proboscis, the crown of which is armed with 18 rows of minute hooks in a star-shaped pattern.

PHYLUM PLATYHELMINTHES

This phylum contains the two classes of parasitic flatworms, the **Trematoda** and the **Cestoda**. A third class, the **Turbellaria** (planarians), which are mainly free-living carnivorous flatworms, are of no veterinary significance.

CLASS TREMATODA

The class Trematoda falls into two main subclasses, the **Monogenea**, which have a direct life cycle, and the **Digenea**, which require an intermediate host. The Digenea are found exclusively in vertebrates and are of considerable veterinary importance. The adult digenetic trematodes (commonly called ‘flukes’) occur primarily in the bile ducts, alimentary tract and vascular system. Most flukes are flattened dorsoventrally, have a blind alimentary tract, suckers for attachment and are hermaphrodite (except Schistosomatidae where the sexes are separate). Depending on the predilection site, the eggs pass out of the final host, usually in faeces or urine, and the larval stages develop in a molluscan intermediate host. For a few species, a second intermediate host is involved, but the mollusc is essential for all members of the group.

The subclass Monogenea will not be considered further in this book as they are primarily external parasites of fish and other amphibious animals. There are many families in the subclass Digenea, and those which contain parasites of major veterinary importance include the Fasciolidae, Dicrocoeliidae, Paramphistomatidae and Schistosomatidae. Of lesser importance are the Echinostomidae, Gastrodiscidae, Cyclocoelidae, Opisthorchiidae, Brachylaemidae, Heterophyidae, Diplostomatidae, Strigeidae and Lecithodendriidae. The most important family by far is the Fasciolidae and our discussion of structure, function and life cycle is largely oriented towards this group (Table 1.8).

SUBCLASS DIGENEA

STRUCTURE AND FUNCTION OF DIGENETIC TREMATODES

The adult is usually flat and leaf-like and possesses two muscular suckers for attachment. The oral sucker at the anterior end surrounds

Table 1.8 Classification of trematodes of veterinary importance.

| Kingdom | Phylum | Class Subclass | Order | Family | Genus | |
|----------|-----------------|----------------------|-------------------|--------------------|--|--|

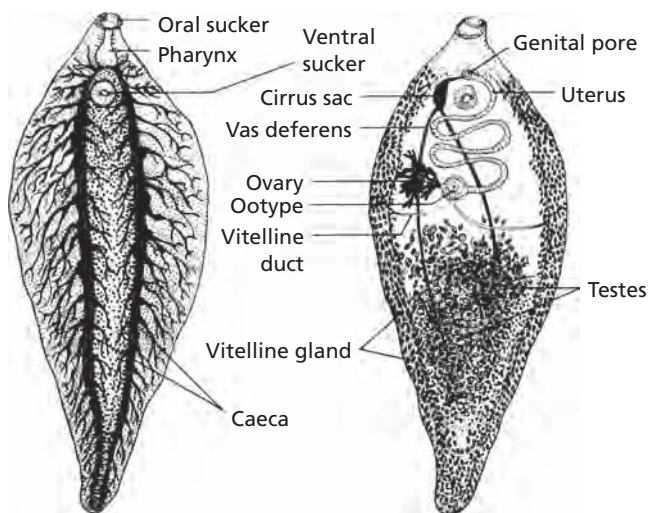

Fig. 1.65 Internal structure of a generalised digenetic trematode.

the mouth, and the ventral sucker (called the acetabulum), as the name indicates, is on that surface. The body surface is a tegument, which is absorptive and is often covered with spines or scales. The muscles lie immediately below the tegument. There is no body cavity and the organs are packed in a parenchyma (Fig. 1.65).

The digestive system is simple, the oral opening leading into a pharynx, oesophagus and a pair of branched intestinal caeca, which end blindly. Undigested material is presumably regurgitated as flukes lack an anus. The excretory system consists of a large number of ciliated flame cells, which impel waste metabolic products along a system of tubules that ultimately join and open to the exterior, or to an excretory bladder. The nervous system is simple, consisting of a pair of longitudinal trunks connecting anteriorly with two ganglia.

The trematodes are usually hermaphrodite and both cross- and self-fertilisation may occur. The male reproductive system consists of a pair of testes, simple or branched, each leading into a vas deferens; these join to enter the cirrus sac containing a seminal vesicle and the cirrus, a primitive penis which terminates at the common genital opening (Fig. 1.65). In some flukes there is a cirrus sac surrounding these terminal organs. The female system has a single ovary leading into an oviduct (where eggs are fertilised), which is expanded distally to form the ootype. There the ovum acquires a yolk from the secretion of the vitelline glands and ultimately a shell. As the egg passes along the uterus, the shell becomes hardened and toughened and is finally extruded through the genital opening adjacent to the ventral sucker. The mature egg is usually yellow because of the tanned protein shell and most species have an operculum. The eggs of many species of fluke develop in the uterus and are therefore able to hatch once they are expelled.

Food, generally blood or tissue debris, is ingested and passed into the caeca where it is digested and absorbed. Metabolism appears to be primarily anaerobic.

LIFE CYCLE OF DIGENETIC TREMATODES

There is wide variation on the complex digenetic life cycle. In general, the life cycle may have two or more obligate hosts, sometimes with transport or paratenic hosts. In most species, the first intermediate host is a mollusc in which further development of hatched larvae takes place (Fig. 1.66). The essential point of the life cycle is that whereas one nematode egg can develop into only one adult, one trematode egg may eventually develop into hundreds of adults. This is due to the phenomenon of asexual multiplication, **parthenogony**, in the molluscan intermediate host, i.e. the production of new individuals by single larval forms.

The adult flukes are always oviparous and lay eggs with an operculum or lid at one pole. In the egg the embryo develops into a

Fig. 1.66 Digenetic trematode life cycle stages (*Fasciola hepatica*).

Fig. 1.67 Miracidium of *Fasciola hepatica*.

pyriform (pear-shaped) ciliated larva called a **miracidium** (Fig. 1.67). The eggs of some digenean flukes may be passively eaten by snails, in which they hatch. In many species of digenean flukes (e.g. *Fasciola hepatica*) the egg hatches in water, and under the stimulus of light and temperature the miracidium releases an enzyme that attacks the proteinaceous cement holding the operculum in place. The latter springs open like a hinged lid and the miracidium emerges within a few minutes.

The miracidium, propelled through the water by its cilia, does not feed and must, for its further development, find a suitable snail within a few hours before it exhausts its energy reserves. It is believed to use chemotactic responses to 'home in' on the snail and, on contact, it adheres by suction to the snail and penetrates its soft tissues using its conical papilla and aided by a cytolytic enzyme. The entire process of penetration takes about 30 minutes, after which the cilia are lost and the miracidium develops into an elongated sac, the **sporocyst**, containing a number of undifferentiated germinal cells. These cells develop into **rediae**, which migrate to the hepato-pancreas of the snail; rediae are also larval forms possessing an oral sucker, some flame cells and a simple gut. From the germinal cells of the rediae arise the final stages, the **cercariae** (Fig. 1.68), although if environmental conditions for the snail are unsuitable, a second or daughter generation of rediae is often produced instead. The

Fig. 1.68 Cercaria of *Fasciola hepatica*.

Fig. 1.69 Metacercariae of *Fasciola hepatica*.

cercariae, in essence young flukes with long tails, emerge actively from the snail, usually in considerable numbers. The actual stimulus for emergence depends on the species, but is most commonly a change in temperature or light intensity. Once a snail is infected, cercariae continue to be produced indefinitely, although the majority of infected snails die prematurely from gross destruction of the hepato-pancreas.

Typically the cercariae swim for some time, utilising a film of water, and within an hour or so attach themselves to vegetation, shed their tails and encyst. This stage is called a **metacercaria** (Fig. 1.69), which is the infective stage for grazing animals.

Encysted metacercariae have great potential for survival extending to months. Once ingested, the outer cyst wall is removed mechanically during mastication. Rupture of the inner cyst occurs in the intestine and depends on a hatching mechanism, enzymatic in origin, triggered by a suitable oxidation-reduction potential and a carbon dioxide system provided by the intestinal environment. The emergent juvenile fluke, often called a **marita**, then penetrates the intestine and migrates to the predilection site where it becomes adult after several weeks and commences to lay eggs thus completing the cycle.

The location of the metacercariae varies between different flukes but in general they have a pattern. Those from fasciolids and paramphistomatids encyst on herbage. The metacercariae from troglotrematids, opisthorchiids and heterophyids encyst in fish, crab or crayfish intermediate hosts, whereas those from diplostomatids prefer amphibian or other vertebrate paratenic hosts. Schistosomatids do not have a metacercarial stage; the cercariae are able to penetrate the definitive host percutaneously.

ORDER ECHINOSTOMATIDA

FAMILY FASCIOLIDAE

These are large flat leaf-shaped flukes. The anterior end is usually elongated into the shape of a cone and the anterior sucker is located at the end of the cone. The ventral sucker is placed at the level of the 'shoulders' of the fluke. The internal organs are branched while the cuticle is covered in spines. There are three important genera: *Fasciola*, *Fascioloides* and *Fasciolopsis*.

Fasciola

The members of this genus are commonly known as liver flukes. They are responsible for widespread morbidity and mortality in sheep and cattle. The two most important species are *F. hepatica* found in temperate areas and in cooler areas of high altitude in the tropics and subtropics, and *F. gigantica* which predominates in tropical areas.

Fasciola species

| Species | Hosts | Site | Intermediate hosts |
|---------------------------|---|-------|--|
| <i>Fasciola hepatica</i> | Sheep, cattle, goat, horse, deer, rabbit, human and other mammals | Liver | Lymnaeid snails (<i>Galba</i> , <i>Lymnaea</i> , <i>Radix</i> , <i>Stagnicola</i>) |
| <i>Fasciola gigantica</i> | Cattle, buffalo, sheep, goat, pig, camel, deer, human | Liver | Lymnaeid snails (<i>Lymnaea</i> , <i>Radix</i> , <i>Austropelea</i>) |

Fasciola hepatica

Description: Adult flukes are leaf-shaped (being broader anteriorly than posteriorly), grey-brown in colour and are around 2.5–3.5 cm in length and 1.0 cm in width (Fig. 1.70a). The anterior end is conical and marked off by distinct shoulders from the body. The tegument is covered with backwardly projecting spines. An oral and ventral sucker, situated at the level of the shoulders, may be readily seen. The intestinal caeca have many branches and extend a considerable distance posteriorly. The testes and ovary are multi-branched. The uterus is positioned anterior to the testes. The cirrus is well developed. Immature flukes at the time of entry into the liver are 1.0–2.0 mm in length and lancet-like.

Life cycle: Adult flukes in the bile ducts shed eggs into the bile and these enter the intestine. Eggs passed in the faeces of the mammalian

host develop and hatch, releasing motile ciliated miracidia. This takes 9–10 days at optimal temperatures of 22–26°C and little development occurs below 10°C. The liberated miracidium has a short lifespan and must locate a suitable snail within about 3 hours if successful penetration of the latter is to occur. In infected snails, development proceeds through the sporocyst and redial stages to the final stage in the intermediate host, the cercaria; these are shed from the snail as motile forms, which attach themselves to firm surfaces, such as grass blades, and encyst there to form the infective metacercariae. It takes a minimum of 6–7 weeks for completion of development from miracidium to metacercaria, although under unfavourable circumstances a period of several months is required. Infection of a snail with one miracidium can produce over 600 metacercariae. Metacercariae ingested by the final host excyst in the small intestine, migrate through the gut wall, cross the peritoneum and penetrate the liver capsule. The young flukes tunnel through the liver parenchyma for 6–8 weeks and then enter the small bile ducts where they migrate to the larger ducts and occasionally the gallbladder and reach sexual maturity. The prepatent period is 10–12 weeks. The minimal period for completion of one entire life cycle of *F. hepatica* is therefore 17–18 weeks (Fig. 1.71). The longevity of *F. hepatica* in untreated sheep may be years; in cattle it is usually less than 1 year.

Fasciola gigantica

Description: The adult fluke is larger than *F. hepatica*, reaching 7.5 cm in length and 1.5 cm in breadth, and the body is more transparent. The shape is more leaf-like, the conical anterior end is very short and the shoulders, characteristic of *F. hepatica*, are barely perceptible (Fig. 1.70b). The gut caeca are more highly branched than in *F. hepatica*.

Life cycle: This is similar to *F. hepatica*, the main differences being in the time scale of the cycle. The immature stages migrate through the liver parenchyma, the adults reaching the bile ducts about 12 weeks after infection. Most parasitic phases are longer and the prepatent period is 13–16 weeks.

Fascioloides

The genus comprises a single species, *Fascioloides magna*, also known as the giant liver fluke, large American liver fluke or deer fluke. It is one of the largest of the trematodes and is easily identified.

Life cycle: The life cycle is similar to that of *F. hepatica*. The eggs hatch to miracidia after 4 weeks or longer. Development in the snail takes 7–8 weeks. The prepatent period in deer is around 30 weeks.

Fascioloides species

| Species | Hosts | Site | Intermediate hosts |
|---------------------------|--|-------------------------------|--|
| <i>Fascioloides magna</i> | Deer, cattle, sheep, goat, pig, horse, llama | Liver, occasionally bile duct | Lymnaeid snails (<i>Fossaria</i> spp., <i>Lymnaea</i> spp., <i>Stagnicola</i> spp.) |

Fascioloides magna

Description: Flukes are large and thick and measure up to 10 cm long by 2.5 cm broad and around 3–4 mm in depth. The flukes are oval, with a rounded posterior end. They possess no anterior cone projection and when fresh are flesh-coloured (Fig. 1.72).

Fig. 1.70 Outline of (a) *Fasciola hepatica* and (b) *F. gigantica*. The former has broader shoulders and is shorter in length.

Fig. 1.71 Life cycle of the liver fluke *Fasciola hepatica*.

Fasciolopsis

The single species of this genus is primarily a parasite of humans in India, Pakistan, Southeast Asia and China, but can occur in the pig which may act as a reservoir host.

Fig. 1.72 *Fascioloides magna*.

Life cycle: The life cycle is similar to that of *F. hepatica*. The final host is infected through ingestion of metacercariae that encyst on aquatic plants. The prepatent period is 9–13 weeks.

Fasciolopsis species

| Species | Hosts | Site | Intermediate hosts |
|---------------------------|-------------------------------|-----------------|---|
| <i>Fasciolopsis buski</i> | Humans, pig, occasionally dog | Small intestine | Freshwater snails (<i>Planorbis</i> , <i>Segmentina</i> , <i>Hippeutis</i>) |

Fasciolopsis buski

Description: Large, thick, elongate-oval, fleshy pink flukes without shoulders, broader posteriorly, and variable in size but usually measuring 30–75 mm long by 8–20 mm wide. The ventral sucker is located near the anterior extremity and is much larger than the oral sucker. The cuticle is covered in spines that are frequently lost as adults. The intestinal caeca are unbranched and extend to near the posterior of the fluke. The testes are branched and tandem; the ovary is also branched.

FAMILY PARAMPHISTOMATIDAE

Adult paramphistomes (amphistomes) are mainly parasitic in the forestomachs of ruminants, although *Gigantocotyle* is found in the liver and duodenum. Their shape is not typical of the trematodes, being conical and thick and fleshy rather than flat. All require a

water snail as an intermediate host. There are several genera: *Paramphistomum*, *Cotylophoron*, *Bothriophoron*, *Orthocoelium* and *Gigantocotyle*, of which *Paramphistomum* is the most common and widespread in ruminants. The taxonomy of the paramphistomes is complex and unresolved and many of the species described may be synonymous, being differentiated mainly on size and shape of the suckers.

Paramphistomum

Members of this genus (rumen fluke) are found in the rumen and reticulum of ruminants. The adults are small, conical (pear-shaped), maggot-like flukes about 1.0 cm long and 3–5 mm wide and light red in colour when fresh. Unlike other flukes, the large ventral sucker is located at the posterior extremity of the body and is well developed.

Life cycle: Eggs shed in the faeces are undeveloped. In an aquatic environment miracidia develop and hatch to penetrate water snails in which they develop to cercaria, following sporocyst and redial stages. The cercariae encyst (metacercariae) on vegetation in, or bordering, watercourses and ponds. Development in the snail intermediate host is similar to that of *Fasciola* and under favourable conditions (26–30°C) can be completed in 4 weeks. Following ingestion by a definitive host the metacercariae excyst in the duodenum, where the young flukes attach and feed for about 6 weeks, before migrating forward to the forestomachs where they mature. The prepatent period is between 7 and 10 weeks.

Paramphistomum (*Calicophoron*, *Cotylophoron*, *Bothriophoron*) species

| Species | Hosts | Site | Intermediate hosts |
|--|--|------------------|--|
| <i>Paramphistomum cervi</i> (syn. <i>Paramphistomum explanatum</i>) | Cattle, sheep, goat, deer, buffalo, antelope | Rumen | Freshwater snails (<i>Bulinus</i> spp., <i>Planorbis</i> spp.) |
| <i>Calicophoron daubneyi</i> (syn. <i>Paramphistomum daubnei</i> , <i>Paramphistomum daubneyi</i>) | Cattle, goat | Rumen | Freshwater snails (<i>Omphiscola</i> spp.) |
| <i>Paramphistomum microbothrium</i> | Cattle, sheep, goat, deer, buffalo, antelope | Rumen | Freshwater snails (<i>Fossaria</i> spp., <i>Bulinus</i> spp.) |
| <i>Paramphistomum ichikawa</i> | Sheep, cattle | Rumen | Planorbid snails (<i>Gyraulus</i> , <i>Helicorbis</i> , <i>Segnetilia</i>) |
| <i>Cotylophoron cotylophorum</i> (syn. <i>Paramphistomum cotylophorum</i>) | Sheep, goat, cattle and wild ruminants | Rumen, reticulum | Freshwater snails (<i>Bulinus</i> spp.) |
| <i>Paramphistomum bothriophoron</i> (syn. <i>Bothriophoron bothriophoron</i>) | Zebu | Rumen | Freshwater snails (<i>Bulinus</i> spp., <i>Planorbis</i> spp.) |
| <i>Paramphistomum streptocoelium</i> (syn. <i>Ceylonocotyle streptocoelium</i> , <i>Orthocoelium streptocoelium</i>) | Cattle, sheep, goat and wild ruminants | Rumen | Freshwater snails (<i>Glyptanisis</i> spp.) |
| <i>Calicophoron calicophorum</i> (syn. <i>Paramphistomum calicophorum</i>) | Cattle, sheep, other ruminants | Rumen, reticulum | Water snails |

Paramphistomum cervi

Synonym: *Paramphistomum explanatum*

Description: Adult flukes measure about 6–13 mm by 3–5 mm. One sucker is visible at the tip of the cone and the other at the base. The tegument has no spines. The testes are located anteriorly to the ovary and are lightly lobed. The larval stages are less than 5.0 mm, fresh specimens having a pink colour.

Cotylophoron cotylophorum

Synonym: *Paramphistomum cotylophoron*

Description: Resembles *P. cervi*, but there is a genital sucker surrounding the genital pore.

Gigantocotyle

Gigantocotyle is found in the liver and duodenum of cattle and other ruminants. The life cycle is similar to that of *F. hepatica* and requires species of snails of the genus *Galba* as intermediate hosts.

Gigantocotyle species

| Species | Hosts | Site | Intermediate hosts |
|--|----------------------------------|--|--------------------|
| <i>Gigantocotyle explanatum</i> (syn. <i>Explanatum explanatum</i> , <i>Paramphistomum explanatum</i>) | Cattle, buffalo, other ruminants | Liver, bile ducts, gallbladder, duodenum | Freshwater snails |

Gigantocotyle explanatum

Synonyms: *Paramphistomum explanatum*, *Paramphistomum fraturum*, *Explanatum explanatum*

Description: Adult fluke are 8–10 mm long and 4.7–5.7 mm wide. The body tapers anteriorly and is curved ventrally with no tegumental papillae.

Pseudodiscus

Adult flukes have a conical anterior end widening gradually to an oval leaf-like shape.

Pseudodiscus species

| Species | Hosts | Site | Intermediate hosts |
|------------------------------|-------|---------------|--|
| <i>Pseudodiscus collinsi</i> | Horse | Caecum, colon | Freshwater snails (<i>Indoplanorbis</i> spp.) |

Pseudodiscus collinsi

Description: Adult flukes are 6–12 mm by 3–7 mm in size. The conical body has conspicuous serrations along the anterior lateral margins. There is a ventral sucker and the oral sucker has paired pouch-like diverticula.

FAMILY GASTRODISCIDAE

Gastrodiscus spp. are found in the large intestines of horses and pigs. *Homalogaster* is found in the large intestine of cattle and buffalo.

Gastrodiscus

Intestinal flukes with a short conical anterior end, and a large posterior discoid body covered ventrally with large papillae.

Life cycle: The life cycle of the different species is generally similar. Eggs are passed in the faeces and, following development, release miracidia into water where they enter a species of water snail. Development in the snail proceeds through sporocyst and redial stages leading to the release of cercariae, which encyst to form metacercariae. Infection of the final host is by ingestion of metacercariae with herbage. Excystation occurs in the intestine where the immature paramphistomes develop to reach maturity.

Gastrodiscus species

| Species | Hosts | Site | Intermediate hosts |
|--|-----------------------------|---------------------------|---|
| <i>Gastrodiscus aegyptiacus</i> | Horse, donkey, pig, warthog | Large and small intestine | Freshwater snails (<i>Bulinus</i> spp., <i>Cleopatra</i> spp.) |
| <i>Gastrodiscus hominis</i> (syn. <i>Gastrodiscoides hominis</i>) | Pig, human | Caecum, colon | Planorbid snails (<i>Helicorbis</i> spp.) |
| <i>Gastrodiscus secundus</i> | Horse, elephant | Large intestine | Freshwater snails (<i>Bulinus</i> spp.) |

Gastrodiscus aegyptiacus

Description: Adult flukes are reddy-pink in colour when fresh and measure 9–17 mm by 8–11 mm. The anterior region measures up to 4 mm by 2.5 mm and is cylindrical, while the remainder of the body is saucer-shaped, with the margins curved inwards (Fig. 1.73).

Fig. 1.73 *Gastrodiscus aegyptiacus*. (Redrawn from Mönning, 1934.)

A large number of regularly arranged papillae cover the ventral surface. The oral sucker has two posterolateral pouches; the posterior sucker is small and subterminal.

Gastrodiscus hominis

Synonym: *Gastrodiscoides hominis*

Description: Adult flukes are pink in colour when fresh and measure 8–14 mm by 5–8 mm, with a conical anterior body and a large discoidal posterior body lacking tegumental papillae.

Gastrodiscus secundus

Description: Identical to *G. aegyptiacus* but the genital pore is located posterior to the level of the caecal origin and the vitelline glands are distributed all over the discoidal posterior body.

Homalogaster

These are intestinal flukes in which the body is divided into two, with a large anterior region and a small cylindrical posterior region.

Life cycle: The life cycle is presumed to be similar to other paramphistomes of the rumen.

Homalogaster species

| Species | Hosts | Site | Intermediate hosts |
|------------------------------|-----------------|-----------------|---|
| <i>Homalogaster paloniae</i> | Cattle, buffalo | Large intestine | Freshwater snails (<i>Hippeutis</i> spp., <i>Polypylis</i> spp.) |

Homalogaster paloniae

Description: Adult flukes are 8–15 mm long and 4.5–7.5 mm wide. The anterior body is large, flat, ellipsoidal and bluntly pointed anteriorly with large numbers of papillae present on the ventral tegument. The posterior body is small and spherical.

FAMILY GASTROTHYLACIDAE

Pouched amphistomes are similar in appearance to the paramphistomes, with a number of species belonging to the genera *Gastrothylax*, *Fischoederius* and *Carmyerius* parasitic in ruminants throughout Africa and Asia. These flukes differ in having an extremely large ventral pouch that opens anteriorly and which covers the ventral surface of the fluke as far as the large ventral sucker.

Gastrothylax

Gastrothylax species

| Species | Hosts | Site | Intermediate hosts |
|--------------------------------|--|------------------|--------------------|
| <i>Gastrothylax crumenifer</i> | Cattle, buffalo, zebu, sheep and other ruminants | Rumen, reticulum | Freshwater snails |

Gastrothylax crumenifer

Description: This is an elongated fluke, being circular in transverse section and reddish in colour when fresh. The body is 10–16 mm long and 5–8 mm wide. The ventral pouch is normally triangular in cross-section with a dorsally directed apex. The terminal genitalium opens into the ventral pouch about halfway between the intestinal bifurcation and the pharynx. The terminal oval sucker is small.

Fischoederius

Fischoederius species

| Species | Hosts | Site | Intermediate hosts |
|--------------------------------|--|-----------------|--------------------|
| <i>Fischoederius elongatus</i> | Cattle, buffalo, zebu, sheep and other ruminants; rarely human | Rumen, duodenum | Freshwater snails |
| <i>Fischoederius cobboldi</i> | Cattle, buffalo, zebu, sheep and other ruminants | Rumen, duodenum | Freshwater snails |

Fischoederius elongatus

Description: The flukes are reddish when fresh. The body is 10–20 mm long and 3–5 mm wide. The terminal genitalium is within the ventral pouch. The uterus is situated along the mid-line. The testes are lobed and one is sited dorsally to the other.

Fischoederius cobboldi

Description: The flukes are reddish in colour when fresh. The body measures 8–10 mm in length.

Carmyerius

Carmyerius species

| Species | Hosts | Site | Intermediate hosts |
|---|------------------------|-------|--------------------|
| <i>Carmyerius spatiosus</i> (syn. <i>Gastrothylax spatiosus</i>) | Cattle, zebu, antelope | Rumen | Freshwater snails |
| <i>Carmyerius gregarius</i> | Cattle, buffalo | Rumen | Freshwater snails |

Carmyerius spatiosus

Synonym: *Gastrothylax spatiosus*

Description: Flukes measure 8.5–12 mm in length and 2.5–3.0 mm in width. The posterior sucker is quite small and is spherical. The intestinal caeca extend down into the last quarter of the body. The ventral pouch is either circular or slightly triangular with blunt angles and the terminal genitalium lies within the pouch. The testes lie horizontally, one on each side of the median line, which differs from the position in *Fischoederius*.

Carmyerius gregarius

Description: The flukes are 7–10 mm in length. The intestinal caeca extend only a short distance below the middle of the body.

FAMILY ECHINOSTOMATIDAE

The family Echinostomatidae includes the genera *Echinostoma*, *Echinoparyphium* and *Hypoderaeum*, which are parasites of birds, and *Echinochasmus*, *Isthmiophora* and *Euparyphium*, which are parasites of fish-eating mammals.

Life cycle: The life cycle involves two intermediate hosts, namely freshwater snails and fish or frogs. Eggs passed in the faeces of infected birds hatch to produce a miracidium, which infects the first intermediate snail host. Subsequently, cercariae encyst within the snail or are shed and migrate to infect other snails. Cercariae can also encyst in the kidneys of tadpoles and adult frogs. The definitive host is infected through eating the second intermediate host containing encysted metacercariae (mesocercariae). The prepatent period is 1–2 weeks.

Echinostoma

Echinostoma species

| Species | Hosts | Site | Intermediate hosts |
|---|--|------------------------|--------------------|
| <i>Echinostoma revolutum</i> | Duck, goose, fowl, partridge, pigeon, occasionally human | Caecum, cloaca, rectum | Snails Frogs |
| <i>Echinostoma paraulum</i> (syn. <i>Echinoparyphium paraulum</i>) | Duck, pigeon, human | Small intestine | Snails Fish |

Echinostoma revolutum

Description: The fluke is about 10–20 mm long and up to 2 mm in width. The head-collar is armed with around 37 spines, some forming groups of ‘corner’ spines. The anterior of the cuticle is covered in spines. The ovary is anterior to the tandem testes.

Echinostoma paraulum

Synonym: *Echinoparyphium paraulum*

Description: The fluke measures 6.0–10.5 mm in length by 0.8–1.5 mm in width. The tegument is usually almost completely covered in spines, but in some instances these can be absent. The head-collar is armed with 37 spines, some forming a double dorsolateral row. The tandem testes are located in the third quarter of the body.

Echinoparyphium

Echinoparyphium species

| Species | Hosts | Site | Intermediate hosts |
|-----------------------------------|---|-----------------|-----------------------------------|
| <i>Echinoparyphium recurvatum</i> | Duck, goose, chicken, pigeon, wild birds, human | Small intestine | Snails, fish, shellfish, tadpoles |

Echinoparyphium recurvatum

Description: The fluke is about 4 mm long by 0.7 mm wide and curved ventrally. Spines are present anterior to the ventral sucker and the head-crown is armed with spines.

Hypoderaeum

Hypoderaeum species

| Species | Hosts | Site | Intermediate hosts |
|------------------------------|--|-----------------|-----------------------------------|
| <i>Hypoderaeum conoideum</i> | Chicken, turkey, duck, goose, swan, pigeon and other aquatic birds | Small intestine | Snails, fish, shellfish, tadpoles |

Hypoderaeum conoideum

Description: Adult fluke have an elongate body 5–12 mm long and tapering posteriorly. The anterior body is armed with about 50 small spines and bears a large ventral sucker. The testes are elongate and slightly lobed, and situated just beyond the midline.

Echinochasmus

Echinochasmus species

| Species | Hosts | Site | Intermediate hosts |
|----------------------------------|--------------------|-----------------|--------------------|
| <i>Echinochasmus perfoliatus</i> | Dog, cat, fox, pig | Small intestine | Snails, fish |

Echinochasmus perfoliatus

Description: Adult flukes are 2–4 mm long with a head-crown bearing 24 spines arranged in a single row. The testes are large and situated just beyond the midline, with the ovaries to the right and anterior to the testes.

Euparyphium

Euparyphium species

| Species | Hosts | Site | Intermediate hosts |
|-----------------------------|--|-----------------|----------------------------|
| <i>Euparyphium melis</i> | Cat, fox, polecat, mink, badger, otter, hedgehog | Small intestine | Snails, amphibian tadpoles |
| <i>Euparyphium ilocanum</i> | Human, dog, rat | Small intestine | Snails |

Euparyphium melis

Description: Adult flukes have an elongate body 3.5–12 mm long that bears a large ventral sucker and a dorsal head-collar with 27 spines. The whole ventral surface is covered with small spines. The testes are situated midline, with one lying posterior to the other. The ovary lies anterior to the testes and to the right of the midline.

FAMILY PHILOPHTHALMIDAE

Philophthalmus are eye flukes of birds.

Life cycle: Embryonated eggs are shed from the eyes, mouth and nostrils, and hatch immediately on contact with water. After penetrating a snail intermediate host, a single redia is released. The mother redia penetrates the heart of the snail, releasing daughter rediae that migrate to the digestive glands and after about 95 days produce cercariae, which are released from the snail and encyst on aquatic vegetation.

Following ingestion, metacercariae excyst in the mouth or crop and young flukes may be found in the oesophagus, nasal passages, orbit and lacrimal gland within a few hours following ingestion.

Philophthalmus

Philophthalmus gralli (the oriental avian eye fluke) are small flukes found in the conjunctival sac of many species of birds.

Philophthalmus species

| Species | Hosts | Site | Intermediate hosts |
|------------------------------|------------------------------|------------------|--------------------|
| <i>Philophthalmus gralli</i> | Ostrich, chicken, wild birds | Conjunctival sac | Freshwater snails |

Philophthalmus gralli

Description: Adult flukes are very small (2–3 mm) and fusiform shaped. The body surface is covered by small spines and the two suckers are orally and subterminally located. The pharynx is located immediately posterior to the oral sucker.

FAMILY CYCLOCOELIDAE

These are medium-sized to large slightly flattened flukes, parasites of aquatic birds in the body cavity, air sacs or nasal cavities. They do not possess an oral sucker and often the ventral sucker is absent. The intestinal caeca are joined together posteriorly and their structure is simple or branched. The lateral vitellaria similarly meet posteriorly. Genera include *Typhlocoelum* in the respiratory tract of ducks, and *Hyptiasmus* in the nasal and orbital sinuses of ducks and geese.

Typhlocoelum

Life cycle: Eggs are coughed up and swallowed in the faeces. A miracidium, containing a single redia, hatches from the egg. The redia, not the miracidium, enters a snail and after 11 days produces small numbers of cercariae. There is no sporocyst stage. The cercariae are retained within the snail and encyst. Birds are infected by eating infected snails. The larval fluke reaches the bronchi via the bloodstream.

Typhlocoelum species

| Species | Hosts | Site | Intermediate hosts |
|---|-------|-------------------------------|---|
| <i>Typhlocoelum cucumerinum</i> (syn. <i>Distoma cucumerinum</i> , <i>Typhlocoelum obovulae</i>) | Duck | Trachea, air sacs, oesophagus | Snails of the genera <i>Helisoma</i> and <i>Planorbis</i> |
| <i>Typhlocoelum cymbium</i> (syn. <i>Tracheophilus sisowi</i>) | Duck | Trachea, bronchi | Snails of the genera <i>Helisoma</i> and <i>Planorbis</i> |

Typhlocoelum cucumerinum

Synonyms: *Distoma cucumerinum*, *Typhlocoelum obovulae*

Description: Adult flukes are 6–12 mm long by 2–5 mm broad. The body is oval and blunter anteriorly than posteriorly. The testes are deeply lobed and lie diagonally one behind the other with the unlobed ovary situated in front of the posterior testis.

Typhlocoelum cymbium

Synonym: *Tracheophilus sisowi*

Description: Adult flukes are 6–11.5 mm long by 3 mm broad. The body has rounded ends and is wide in the middle. The testes are rounded, not lobed, and lie in a diagonal position in the posterior part of the body with the unlobed ovary situated in front of the anterior testis.

Hyptiasmus

Hyptiasmus species

| Species | Hosts | Site | Intermediate hosts |
|--|----------------|------------------------------|--------------------|
| <i>Hyptiasmus tumidus</i> (syn. <i>Hyptiasmus arcuatus</i> , <i>Cyclocoelum arcuatum</i>) | Duck, goose | Nasal and orbital sinuses | Water snails |

Hyptiasmus tumidus

Synonyms: *Hyptiasmus arcuatus*, *Cyclocoelum arcuatum*

Description: Adult flukes are 7–20 mm long by 2–5 mm wide. The body is pyriform and more rounded posteriorly. The gonads are arranged in a straight line.

FAMILY NOTOCOTYLIDAE

The family Notocotylidae includes the genera *Notocotylus*, *Paramonostomum* and *Catatropis*, which are parasites of birds, and *Cymbiforma*, which occur in sheep, goats and cattle. The small eggs are characterised by long filaments at the poles. The intermediate hosts are water snails.

Notocotylus

Notocotylus species

| Species | Hosts | Site | Intermediate hosts |
|-------------------------------|---|---------------|--------------------|
| <i>Notocotylus attenuatus</i> | Chicken, duck, goose, wild aquatic birds | Caeca, rectum | Snails |

Notocotylus attenuatus

Description: The adult flukes are 2–5 mm long by 0.7–1.5 mm wide, narrow anteriorly and have no ventral sucker. The testes are situated posteriorly and the ovary lies between them. The uterus forms regular transverse coils extending from the posterior ovary to the elongate cirrus sac, situated anteriorly.

Catatropis

Catatropis species

| Species | Hosts | Site | Intermediate hosts |
|-----------------------------|--|-------|--------------------|
| <i>Catatropis verrucosa</i> | Chicken, duck, goose, other aquatic birds | Caeca | Snails |

Catatropis verrucosa

Description: The fluke is 2–6 mm long and rounded anteriorly and posteriorly and has no ventral sucker. The testes are situated posteriorly and the ovary lies between them.

Cymbiforma

Cymbiforma species

| Species | Hosts | Site | Intermediate hosts |
|--|------------------------|-----------------|--------------------|
| <i>Cymbiforma indica</i> (syn. <i>Ogmocotyle indica</i>) | Sheep, goat, cattle | Small intestine | Snails |

Cymbiforma indica

Synonym: *Ogmocotyle indica*

Description: Adult flukes are pear-shaped, concave ventrally and measure 0.8–2.7 cm in length and 0.3–0.9 mm in width. There is no ventral sucker and the cuticle is armed with fine spines ventrally and anteriorly. The ovary has four demarcated lobes. The fluke lacks a pharynx and the oesophagus is short.

ORDER PLAGIORCHIDA

FAMILY DICROCOELIIDAE

These trematodes are small lancet-like flukes occurring in the biliary and pancreatic ducts of vertebrates. Miracidia are present in the eggs when they are passed in the faeces; there is no redial stage during development in the snail and two to three intermediate hosts may be involved in the life cycle. Members of this family are found in ruminants (*Dicrocoelium*, *Eurytrema*), cats and birds (*Platynosomum*).

Dicrocoelium

The single species of this genus is found in the bile ducts of the liver of ruminants. There is no possibility of confusion with other flukes in the bile ducts of ruminants due to their small size and distinct laceolate shape.

Life cycle: The egg does not hatch until ingested by the first intermediate host, a terrestrial snail, in which two generations of sporocysts develop which then produce cercariae. The latter are extruded in masses cemented together by slime and adhere to vegetation. This phase of development takes at least 3 months. The slime balls of cercariae are ingested by ants in which they develop to metacercariae mainly in the body cavity and occasionally the brain. The presence of a brain lesion in the ant, induced by metacercariae, impels the ant to climb up and remain on the tips of the herbage, thus increasing the chance of ingestion by the final host. This phase in the ant is completed in just over 1 month in summer temperatures. Infection of the final host is by passive ingestion of ants containing metacercariae. The metacercariae hatch in the small intestine and the young flukes migrate up the main bile duct and thence to the smaller ducts in the liver. There is no parenchymal migration and the prepatent period is 10–12 weeks. The total life cycle takes

approximately 6 months. The flukes are long-lived and can survive in the final host for several years.

Dicrocoelium species

| Species | Hosts | Site | Intermediate hosts |
|---|--|-------|--|
| <i>Dicrocoelium dendriticum</i> (syn. <i>Dicrocoelium lanceolatum</i>) | Sheep, goat, cattle, buffalo, deer, camel, rabbit, occasionally horse, pig, dog, human | Liver | Land snails of many genera: <i>Cionella</i> spp., <i>Zebrina</i> spp. Brown ants (<i>Formica</i> , frequently <i>F. fusca</i>) |
| <i>Dicrocoelium hospes</i> | Cattle, ox, occasionally sheep, goat | Liver | Land snails Ants |

Dicrocoelium dendriticum

Synonym: *Dicrocoelium lanceolatum*

Description: Adult flukes are 6–12 mm long and 1.5–2.5 mm wide, distinctly lanceolate and semi-transparent/translucent allowing the internal organs to be readily seen (Fig. 1.74). They are almost symmetrical in shape and the cuticle is smooth. The oral sucker is smaller than the ventral sucker and is located in close proximity. The gut is simple, consisting of two branches and resembles a tuning fork. Behind the ventral sucker the lobed testes lie in tandem with the ovary immediately posterior. The uterus is usually dark brown and convoluted, filling the space behind the genital gland. The cirrus is small. There are no spines on the cuticle (cf. *Fasciola*).

Dicrocoelium hospes

Description: Details are essentially similar to *D. dendriticum* and the flukes are usually found in the liver and gallbladder of cattle, ox and occasionally sheep and goats in parts of Africa.

Fig. 1.74 *Dicrocoelium dendriticum*.

Eurytrema

This genus inhabits the pancreatic ducts and sometimes the bile ducts of ruminants.

Eurytrema species

| Species | Hosts | Site | Intermediate hosts |
|---|---|--|---|
| <i>Eurytrema pancreaticum</i> (syn. <i>Distoma pancreaticum</i> , <i>Eurytrema ovis</i>) | Cattle, buffalo, sheep, goat, pig, camel, human, primates | Pancreas; rarely bile ducts Perirenal fat | Land snails, particularly of the genus <i>Bradybaena</i> Grasshoppers of the genus <i>Conocephalus</i> or tree crickets (<i>Oecanthus</i>) |
| <i>Eurytrema coelomaticum</i> (syn. <i>Distoma coelomaticum</i>) | Cattle, sheep | Pancreas; rarely bile ducts | Land snails, particularly of the genus <i>Bradybaena</i> Grasshoppers of the genus <i>Conocephalus</i> or tree crickets (<i>Oecanthus</i>) |
| <i>Eurytrema procyonis</i> | Cat, fox, raccoon | Pancreas | Snails of the genus <i>Mesodon</i> Grasshoppers |

Eurytrema pancreaticum

Synonyms: *Distoma pancreaticum*, *Eurytrema ovis*

Description: Oval, leaf-shaped, reddish-brown flukes measuring around 8–16 mm long by 5–8.5 mm wide (Fig. 1.75). The body is thick and the juvenile flukes are armed with spines which are often absent by the adult stage. The oral sucker is larger than the ventral sucker and the pharynx and oesophagus are short. The testes are positioned horizontally just behind the ventral sucker. A tubular cirrus sac is present. The uterus completely occupies the posterior body.

Life cycle: Eggs passed in faeces are ingested by a snail where two generations of sporocysts occur. Cercariae are released onto the herbage

Fig. 1.75 *Eurytrema pancreaticum*. (Redrawn from Soulsby, 1971. Reproduced with permission from Lord Soulsby of Swaffham Prior.)

about 5 months after initial infection and these are ingested by grasshoppers. Infective metacercariae are produced in about 3 weeks. The final host becomes infected by accidentally eating the second intermediate host. Metacercariae encyst in the duodenum and migrate to the pancreas via the pancreatic duct and reside in the small ducts of the pancreas. The prepatent period in cattle is 3–4 months.

Eurytrema coelomaticum

Synonym: *Distoma coelomaticum*

Description: A leaf-shaped reddish brown fluke with adults measuring around 8–12 by 6–7 mm.

Eurytrema procyonis

Description: The adult measures about 2.9 mm long by 1.2 mm wide. The oral sucker is subterminal with a dorsal lip-like projection.

Life cycle: The life cycle is unknown but is thought to involve snail intermediate hosts of the genus *Mesodon*. Animals are likely to become infected by ingestion of the snail intermediate host.

Platynosomum

Flukes of this genus are found in wild birds, but some species are also found in the liver of cats.

***Platynosomum* species**

| Species | Hosts | Site | Intermediate hosts |
|--|-------|---------------------------|--|
| <i>Platynosomum fastosum</i> (syn. <i>Eurytrema fastosum</i>) | Cat | Bile and pancreatic ducts | Land snail (<i>Sublima</i>) and woodlice Lizards are obligate paratenic hosts |
| <i>Platynosomum concinnum</i> | Cat | Bile and pancreatic ducts | Land snail (<i>Sublima</i>) and woodlice Lizards are obligate paratenic hosts |
| <i>Platynosomum illiciens</i> | Cat | Bile and pancreatic ducts | Land snail (<i>Sublima</i>) and woodlice Lizards are obligate paratenic hosts |

Platynosomum fastosum

Description: The adult fluke is lanceolate and measures 4–8 mm by 1.5–2.5 mm in size. The testes lie obliquely horizontal.

Life cycle: Eggs passed in the faeces develop in a land snail (*Sublima*) and a crustacean (woodlouse). Cercariae encyst when a lizard, gecko, skink or toad eats the woodlouse. The cat is infected by ingesting a lizard or other host containing metacercariae, which acts as an obligate paratenic host. The prepatent period is around 2–3 months.

FAMILY PARAGONIMIDAE

Trematodes in this family mainly have a flattened fleshy body and a tegument covered with spines. The oral sucker is subterminal and the ventral sucker is located around the middle of the body. The

genital pore is situated just below the ventral sucker. Several genera are of local veterinary interest. *Paragonimus*, commonly referred to as the 'lung fluke', is found in cats, dogs and other carnivores and in humans in North America and Asia. Pulmonary signs are comparatively rare in cats or dogs and the veterinary interest is in the potential reservoir of infection for humans.

Life cycle: The life cycle involves an amphibious or water snail, and a crayfish or freshwater crab. Snails of the genera *Melania*, *Ampullaria* or *Pomatiopsis* are infected by miracidia in which further development through sporocyst, redia and cercaria takes place. After escaping the snail, the cercariae swim about and, on contact with a freshwater crab or crayfish, penetrate it and encyst. Crabs and crayfish can also eat cercaria-infected snails. Infection of the final host occurs by ingestion of the metacercariae in the liver or muscles of the crustacean. Infection can also be acquired through consumption of paratenic hosts which have eaten infected crabs or crayfish. The young flukes migrate to the lungs where they are encapsulated by fibrous cysts connected by fistulae to the bronchioles to facilitate egg excretion. Eggs pass up from the lung in the sputum, which the animal usually swallows such that eggs are passed in the faeces. The prepatent period is 5–6 weeks.

Paragonimus

***Paragonimus* species**

| Species | Hosts | Site | Intermediate hosts |
|-------------------------------|--|------|--|
| <i>Paragonimus westermani</i> | Dog, cat, pig, goat, cattle, fox, other carnivores, human and primates | Lung | Snails of the genera <i>Melania</i> , <i>Ampullaria</i> , <i>Pomatiopsis</i> Crabs and crayfish |
| <i>Paragonimus kellicotti</i> | Cat, pig, dog | Lung | Snails of the genera <i>Melania</i> , <i>Ampullaria</i> , <i>Pomatiopsis</i> Crabs and crayfish |

Paragonimus westermani

Description: The parasite is rounded (lemon-shaped) and thick (7.5–16 mm by 4–8 mm), reddish-brown in colour, and covered in very small scale-like spines. The oral and ventral suckers are similar in size with the ventral sucker situated slightly anterior to the middle of the fluke (Fig. 1.76). The testes are located in the posterior half of the body. Species differentiation is based on the shape of the spines. Those in *P. westermani* are large and have bifid points.

Paragonimus kellicotti

Description: Adult flukes are usually located in pairs in cysts in the lungs of the final host. The spines in *P. kellicotti* are very large and have a number of points.

FAMILY NANOPHYETIDAE

The genus *Nanophyetus* is a fluke found mainly in the small intestine of dogs, mink and other fish-eating mammals. It occurs in the northwest USA and parts of Siberia and is of importance because the flukes are vectors of the rickettsial organism *Neorickettsia helminthoeca*, which causes severe haemorrhagic enteritis of dogs, so-called 'salmon poisoning'. This name is derived from the cycle of the

Fig. 1.76 *Paragonimus westermani*. (Redrawn from Mönnig, 1934.)

fluke, which involves a water snail and a fish that is often one of the salmonid type.

Life cycle: Undeveloped eggs are passed in the faeces of the host and after hatching, which takes about 3 months, infect the snail first intermediate host where cercariae develop in rediae. The liberated cercariae swim for a while before penetrating a fish and encysting in the kidneys, muscles and other organs. Infection of the final host occurs when the fish is eaten. The prepatent period is as short as 5 days in the dog.

Nanophyetus

Nanophyetus species

| Species | Hosts | Site | Intermediate hosts |
|--|--|-----------------|--|
| <i>Nanophyetus salmincola</i> (syn. <i>Trogloremma salmincola</i>) | Dog, fox, cat, raccoon, mink, bear, lynx, other fish-eating mammals and rarely human | Small intestine | Snails (<i>Oxytrema</i> , <i>Goniobasis</i> , <i>Semisulcospira</i> spp.) Salmonid fish, other fish, salamanders |

Nanophyetus salmincola

Synonym: *Trogloremma salmincola*

Description: These trematodes are generally very small, oval or elongate, and white or cream in colour. Adult flukes measure about 1–2.5 mm long by 0.3 mm wide. The oral sucker is well developed and is located terminally and the ventral sucker is usually found in the mid-third of the body.

FAMILY COLLYRICLIDAE

Parasites of the genus *Collyriclum* occur within subcutaneous cysts in chickens, turkeys and wild birds. Intermediate hosts are snails and dragonflies.

Life cycle: Cysts in the subcutaneous tissues usually contain a pair of flukes. Eggs are passed through an opening in the wall of the cyst and hatch in the environment to produce a miracidium, which penetrates a snail. These directly produce cercariae, there being no redial development, and the cercariae are shed from the snail and will enter dragonfly larvae, where they encyst to the metacercaria stage. Infection of the final host occurs through ingestion of the infected dragonfly. The immature trematodes then migrate to the subcutaneous tissues.

Collyriclum

Collyriclum species

| Species | Hosts | Site | Intermediate hosts |
|--|--------------------------------|----------------------------|----------------------------|
| <i>Collyriclum faba</i> (syn. <i>Monostoma faba</i>) | Chicken, turkey and wild birds | Skin, subcutaneous tissues | Snails Dragonfly nymphs |

Collyriclum faba

Synonym: *Monostoma faba*

Description: The flukes occur in pairs in a tissue cyst. The fluke has a spiny tegument, is dorsally convex and ventrally flattened, and measures about 4 by 5 mm. There is no ventral sucker and the oral sucker is small. The ovary is multilobular and the vitellaria are located in the anterior half of the body.

FAMILY PROSTHOGONIMIDAE

Prosthogonimus are parasites found in the cloaca and reproductive tract of birds.

Life cycle: Eggs passed in faeces hatch to produce a miracidium, which penetrates a snail to form a mother sporocyst, which produces daughter sporocysts. These directly produce cercariae, there being no redial development, and the cercariae are shed from the snail and will enter dragonfly larvae via the rectal respiratory chamber where they eventually encyst as the metacercaria stage in the haemocoel. Infection of the final host occurs through ingestion of the infected nymphal stage or the adult dragonfly. The immature trematodes then migrate to the cloaca and bursa of Fabricius or enter the oviduct. The fluke is mature after about a week.

Prosthogonimus

Prosthogonimus species

| Species | Hosts | Site | Intermediate hosts |
|--|--|--|--|
| <i>Prosthogonimus pellucidus</i> (syn. <i>Prosthogonimus intercalandus</i> , <i>Prosthogonimus cuneatus</i>) | Chicken, turkey, other fowl, goose, duck | Cloaca, oviduct, bursa of Fabricius | Water snails (<i>Bithynia</i>) Dragonfly nymphs |
| <i>Prosthogonimus macrorchis</i> | Chicken, turkey, other fowl, ducks | Lower gut, cloaca, oviduct, bursa of Fabricius | Water snails (<i>Bithynia</i>) Dragonfly nymphs |
| <i>Prosthogonimus ovatus</i> | Chicken, turkey, other fowl, geese | Cloaca, oviduct, bursa of Fabricius | Water snails (<i>Bithynia</i>) Dragonfly nymphs |

Prosthogonimus pellucidus

Synonyms: *Prosthogonimus intercalandus*, *Prosthogonimus cuneatus*

Description: Adult flukes are pear-shaped, semi-transparent, pale orange when fresh and measure around 9–12 mm in length, being broader towards the posterior. Two suckers are present. The irregular oval testes lie midline and horizontally. The lobed ovary lies dorsal and midline to the testes.

Prosthogonimus macrorchis

Description: These flukes are very similar to *P. pellucidus* but possess larger testes.

Prosthogonimus ovatus

Description: Adult flukes are smaller than the other two species, measuring 3–6 mm. The testes are slightly elongate and lie side by side midline.

FAMILY PLAGIORCHIIDAE

Plagiorchis are parasites of birds and are mainly located in the gut. One species, *P. arcuatus*, has a similar pathogenesis to *Prosthogonimus*, affecting the bursa of Fabricius in young birds and the oviduct in older birds.

Life cycle: The life cycle involves two intermediate hosts, namely freshwater snails and larvae of dragonflies. The definitive host is infected through eating the dragonflies or their nymphs containing encysted metacercariae.

Plagiorchis

Plagiorchis species

| Species | Hosts | Site | Intermediate hosts |
|-----------------------------|------------------------|--------------------------------|------------------------------|
| <i>Plagiorchis arcuatus</i> | Chicken, other poultry | Oviduct and bursa of Fabricius | Snails Crustacea, insects |

Plagiorchis arcuatus

Description: The fluke is oval, about 4–5 mm in length and 1.5 mm in breadth, and tapers to a point at both ends. The cuticle possesses small spines, which are more numerous in the anterior region. The testes are rounded or oval and lie obliquely behind each other. The ovary is rounded, situated near the end of the cirrus sac, and to the right of the ventral sucker.

FAMILY LECITHODENDRIIDAE

The Lecithodendriidae includes the genera *Novotrema*, *Odeningotrema*, *Phaneropsolus* and *Primatotrema*, which are intestinal flukes of primates.

ORDER OPISTHORCHIDA

FAMILY OPISTHORCHIIDAE

The members of this family require two intermediate hosts, the first being water snails and the second a wide variety of fish, in which the metacercariae are encysted. The final hosts are fish-eating mammals in which they inhabit the bile ducts. These oval or fusiform flukes are of medium size and possess suckers which are small and weak and located fairly close together. The ovary and uterus are anterior to the testes. This feature avoids confusion with the similarly sized and shaped microcoeliid flukes where they are positioned posteriorly to the testis.

Clonorchis is by far the most important genus, with *Opisthorchis*, *Metorchis*, *Parametorchis* and *Pseudamphistomum* being of lesser importance.

Clonorchis

Clonorchis species

| Species | Hosts | Site | Intermediate hosts |
|--|--|--|---|
| <i>Clonorchis sinensis</i> (syn. <i>Opisthorchis sinensis</i>) | Human, dog, cat, pig, mink, weasel, badger | Bile ducts, pancreatic ducts, occasionally small intestine | Operculated snails (<i>Parafossalurus</i> , <i>Bulimus</i> spp., <i>Bithynia</i> , <i>Melania</i> and <i>Vivipara</i>) Cyprinid fishes |

Clonorchis sinensis

Synonym: *Opisthorchis sinensis*

Description: The adult fluke is flat, transparent–pinkish, wide posteriorly and tapering anteriorly, and may reach a size of 25 mm long by 5 mm wide (Fig. 1.77). The cuticle bears spines in the young fluke but is smooth in the adult. The testes are multi-branched and lie posteriorly in the body. There is no cirrus sac.

Life cycle: The eggs normally hatch only after they have been swallowed by the snail first intermediate host. In the snails the miracidium develops into a sporocyst, which produces rediae and these in turn produce cercariae, which have fairly long tails and elongate bodies with pigmented eye-spots. After breaking out of the snail the cercaria swims about, and on meeting a suitable fish it penetrates partly or completely into the tissues of the fish and, losing its tail, becomes encysted in the fish. Infection of the final host occurs through eating raw infected fish. The metacercariae are liberated in the duodenum of the final host and reach the liver by way of the bile duct. The prepatent period is 16 days.

Opisthorchis

Opisthorchis species

| Species | Hosts | Site | Intermediate hosts |
|--|--------------------------------------|--|--|
| <i>Opisthorchis felineus</i> (syn. <i>Opisthorchis tenuicollis</i> , <i>Opisthorchis viverrini</i>) | Cat, dog, fox, pig, human, cetaceans | Liver, bile ducts, occasionally pancreatic ducts | Freshwater snails (<i>Bithynia</i> spp.) Freshwater fish |

Fig. 1.77 *Clonorchis sinensis*. (Redrawn from Soulsby, 1971. Reproduced with permission from Lord Soulsby of Swaffham Prior.)

Fig. 1.78 *Opisthorchis felineus*. (Redrawn from Mönning, 1934.)

Opisthorchis felineus

Synonyms: *Opisthorchis tenuicollis*, *Opisthorchis viverrini*

Description: Adult flukes are reddish in colour when fresh, with a smooth cuticle and measure 7–12 mm long by 1.5–2.5 mm broad (Fig. 1.78). The testes are lobed and not branched and a cirrus sac and cirrus are absent. The ovary is small. The intestinal caeca reach to almost the end of the body.

Life cycle: The prepatent period is 2–3 weeks and deposited eggs are ingested by a snail in which cercariae develop in rediae. The cercariae encyst in fish as metacercariae and infect the definitive host when ingested.

Metorchis

Metorchis species

| Species | Hosts | Site | Intermediate hosts |
|---|---|--------------------------------------|--|
| <i>Metorchis albidus</i> (syn. <i>Distoma albidum</i> , <i>Opisthorchis albidus</i>) | Dog, cat, fox, seal, some poultry, occasionally human | Liver, bile ducts, gallbladder | Freshwater snails Fishes (<i>Blicca</i>) |
| <i>Metorchis conjunctus</i> | Dog, cat, fox, mink, raccoon | Liver, bile ducts | Freshwater snails (<i>Amnicola</i>) Fishes (<i>Catostomus</i>) |

Metorchis albidus

Synonyms: *Distoma albidum*, *Opisthorchis albidus*

Description: The fluke is spatulate, pointed anteriorly, rounded and flat posteriorly, 2.5–6.5 mm long by 1.0–1.6 mm broad with

a spinous cuticle in the young fluke. The genital pore is in front of the ventral sucker. The testes are located diagonally in the posterior region of the body and they are lobed. The ovary is fairly circular and lies just in front of the anterior testis.

Metorchis conjunctus

Description: Adults measure 1–6.5 mm long by 0.6–2.6 mm broad. The suckers are equal in diameter. The genital pore lies at the anterior margin of the acetabulum. The cuticle of the young fluke possesses spines.

Parametorchis

Parametorchis species

| Species | Hosts | Site | Intermediate hosts |
|--------------------------------|----------|-------------------|---|
| <i>Parametorchis complexus</i> | Cat, dog | Liver, bile ducts | Not known, but probably freshwater snails |

Parametorchis complexus

Description: The fluke is 5–10 mm long by 1.5–2 mm broad. The uterus forms a rosette around the ventral sucker. The testes are lobed and lie together in the posterior part of the body. The vitelline glands are restricted to the anterior third of the fluke.

Fig. 1.79 *Pseudamphistomum truncatum*. (Redrawn from Mönnig, 1934.)

Pseudamphistomum

Pseudamphistomum species

| Species | Hosts | Site | Intermediate hosts |
|-----------------------------------|-----------------------------|-------------------|--------------------|
| <i>Pseudamphistomum truncatum</i> | Dog, cat, fox, rarely human | Liver, bile ducts | Snails Fish |

Pseudamphistomum truncatum

Description: Adult flukes are small, measuring 2–2.5 mm, with a spiny body that is truncate posteriorly. The testes are spherical and lie horizontally at the posterior end of the body (Fig. 1.79).

FAMILY BRACHYLAEMIDAE

Members of this family are parasites of birds (*Brachylaemus*), sheep (*Skrjabinotrema*) and pigs (*Postharmostomum*). The intermediate hosts are snails. They are of only minor veterinary importance.

Skrjabinotrema

Skrjabinotrema species

| Species | Hosts | Site | Intermediate hosts |
|----------------------------|-------|-----------------|--------------------|
| <i>Skrjabinotrema ovis</i> | Sheep | Small intestine | Snails |

Skrjabinotrema ovis

Description: Adult flukes are small with smooth bodies and measure about 1 mm long by 0.3–0.7 mm wide.

Postharmostomum

Postharmostomum species

| Species | Hosts | Site | Intermediate hosts |
|-----------------------------|-------|-----------------|--------------------|
| <i>Postharmostomum suis</i> | Pig | Small intestine | Snails |

Postharmostomum suis

Description: The body is smooth, elongate and around 4–8 mm in length.

FAMILY HETEROPHYIDAE

These are small trematodes found in the intestines of mammals and birds. The genital pore and the ventral sucker are located in a ventro-genital sac. More than 10 species of the family Heterophyidae have been reported in humans and fish-eating mammals. The life cycle generally involves two intermediate hosts, namely freshwater snails and fishes or frogs. Genera of veterinary interest are *Heterophyes* found in dogs, cats, foxes and humans; *Metagonimus* in the small intestines of dogs, cats, pigs and humans; *Cryptocotyle* of seabirds, reported in dogs and cats; and *Apophallus* (*Rossicotrema*) normally found in seabirds or seals but also reported in cats, dogs and foxes.

Heterophyes

Heterophyes species

| Species | Hosts | Site | Intermediate hosts |
|--------------------------------|----------------------|-----------------|--|
| <i>Heterophyes heterophyes</i> | Dog, cat, fox, human | Small intestine | Snails (<i>Pirenella</i> spp., <i>Cerithida</i> spp.) Fish |
| <i>Heterophyes nocens</i> | Dog, cat, fox, human | Small intestine | Snails (<i>Pirenella</i> spp.) Fish |

Heterophyes heterophyes

Description: This is a small pear-shaped fluke that is wider posteriorly than anteriorly and measuring 1–1.7 mm by 0.3–0.7 mm. The ventral sucker is anterior to the middle of the body and the genital sucker lies immediately behind it and to one side and bears an incomplete circle of 70–80 small rods. The testes are located horizontally and are oval in shape (Fig. 1.80).

Heterophyes nocens

Description: Small ovoid fluke measuring 0.8–1 mm in length by 0.5–0.6 mm in width. The genital sucker is armed with 50–60 small rods and is located close to the ventral sucker.

Metagonimus

Metagonimus species

| Species | Hosts | Site | Intermediate hosts |
|------------------------------|----------------------|-----------------|--|
| <i>Metagonimus yokagawai</i> | Dog, cat, pig, human | Small intestine | Snails (<i>Semisulcospira</i> spp.) Cyprinid fish, mullet, trout |

Fig. 1.80 *Heterophyes heterophyes*. (Redrawn from Neveu-Lemaire, 1936. Reproduced with permission from Editions Vigot.)

Metagonimus yokagawai

Description: Small flukes that are wider posteriorly than anteriorly and measuring 1–2.5 mm by 0.4–0.7 mm. The cuticle bears spines over its whole surface. The ventral sucker is right of the median line and close to the genital pore, which opens anteriorly. The testes are slightly oblique and the ovary is median in position.

Apophallus

Apophallus species

| Species | Hosts | Site | Intermediate hosts |
|---|--------------------------------|--------------------|--------------------|
| <i>Apophallus muhlingi</i> (syn. <i>Cotylophallus muhlingi</i>) | Gulls, cormorants, dog, cat | Small intestine | Unknown Fish |
| <i>Apophallus donicum</i> (syn. <i>Rossicotrema donicum</i>) | Cat, dog, fox, seal | Small intestine | Unknown Fish |

Apophallus muhlingi

Synonym: *Cotylophallus muhlingi*

Description: Adult flukes are small and measure 1.2–1.6 mm by 0.2 mm. The cuticle is covered in fine spines. The suckers are small, equal in size and located in the mid-body. The testes are rounded and lie diagonally one behind the other. The ovary is rounded and is opposite the anterior testis.

Apophallus donicum

Synonym: *Rossicotrema donicum*

Description: Flukes are small, measuring 0.5–1.15 mm by 0.2–0.4 mm. The cuticle is covered in spines and the testes are round and large and located in the posterior section of the body.

Cryptocotyle

Cryptocotyle species

| Species | Hosts | Site | Intermediate hosts |
|----------------------------|---|--------------------|---------------------------|
| <i>Cryptocotyle lingua</i> | Gulls, terns, kittiwake, seal, mink, dog, cat, human | Small intestine | Shellfish, snails Fish |

Cryptocotyle lingua

Description: Spatula-shaped body, 0.5–2 mm long by 0.2–0.9 mm wide. The cuticle is armed with spines and the suckers are small, with the anterior larger than the ventral sucker. The testes are slightly lobed and lie side by side or diagonally at the posterior end of the body. The ovary is trilobed and lies in front of the testes.

ORDER STRIGEIDIDA

FAMILY SCHISTOSOMATIDAE

This family is primarily parasitic in the blood vessels of the alimentary tract and bladder. In humans, schistosomes are often responsible for severe and debilitating disease and veterinary interest lies in the fact that they can cause a similar disease in animals, some of which may act as reservoirs of infection for humans. The schistosomes differ from other flukes in that the sexes are separate, the small adult female lying permanently in a longitudinal groove, the gynaecophoric canal, in the body of the male (Fig. 1.81). The most important genus is *Schistosoma*, with *Bilharziella*, *Trichobilharzia*, *Orientobilharzia*, *Ornithobilharzia*, *Heterobilharzia* and *Austrobilharzia* other genera of lesser importance.

Schistosoma

The sexes are separate, with the male, which is broad and flat and about 2.0 cm long, carrying the slender female in the hollow of its inwardly curved body. This characteristic and the vascular predilection site are sufficient for generic identification. Suckers are either absent or weak and there is no pharynx. The genus, as currently defined, is paraphyletic so revisions are likely. The genus has been divided into four groups: *haematobium*, *indicum*, *mansoni* and

Fig. 1.81 Male and female *Schistosoma* in copula.

Fig. 1.82 *Schistosoma* egg morphology: (a) *mansoni* group; (b) *haematobium* group.

japonicum. Species found in Africa are divided into two groups: those with a lateral spine on the egg (*mansoni* group) and those with a terminal spine (*haematobium* group) (Fig. 1.82).

Schistosoma species

| Species | Hosts | Site | Intermediate hosts |
|---|---|--|---|
| Haematobium group | | | |
| <i>Schistosoma bovis</i> | Cattle, sheep, goat, camel | Portal, mesenteric, and urogenital veins | Snails (<i>Bulinus</i> spp., <i>Physopsis</i> spp.) |
| <i>Schistosoma haematobium</i> | Human, primates | Bladder veins and urethra | Snails (<i>Bulinus</i> spp.) |
| <i>Schistosoma mattheei</i> | Cattle, sheep, goat, camel, human, primates | Portal, mesenteric and bladder veins | Snails (<i>Physopsis</i> spp.) |
| <i>Schistosoma leiperi</i> | Cattle, antelope | Mesenteric veins | Snails (<i>Bulinus</i> spp.) |
| Indicum group | | | |
| <i>Schistosoma indicum</i> | Cattle, buffalo, sheep, goat, horse, donkey, camel | Portal, pancreatic, hepatic and mesenteric veins | Snails (<i>Indoplanorbis</i>) |
| <i>Schistosoma nasalis</i> (syn. <i>Schistosoma nasale</i>) | Cattle, goat, sheep, buffalo, horse | Nasal mucosa veins | Snails (<i>Lymnaea</i> spp., <i>Indoplanorbis</i> spp.) |
| <i>Schistosoma spindale</i> | Cattle, buffalo, horse, pig and rarely dog | Mesenteric veins | Snails (<i>Planorbis</i> , <i>Indoplanorbis</i> spp., <i>Lymnaea</i> spp.) |
| Mansoni group | | | |
| <i>Schistosoma mansoni</i> | Human, primates, wild animals | Mesenteric veins | Snails (<i>Biomphalaria</i> spp.) |
| Japonicum group | | | |
| <i>Schistosoma japonicum</i> | Cattle, horse, sheep, goat, dog, cat, rabbit, rodents, pig, human | Portal and mesenteric veins | Snails (<i>Oncomelania</i> spp.) |
| Others | | | |
| <i>Schistosoma incognitum</i> (syn. <i>Schistosoma suis</i>) | Pig, dog | Mesenteric veins | Snails (<i>Radix</i> spp.) |
| <i>Schistosoma turkestanica</i> (syn. <i>Orientobilharzia turkestanicum</i>) | Cattle, buffalo, sheep, goat, camel, horse, donkey, cat | Mesenteric veins and small veins of the pancreas and liver | Snails (<i>Lymnaea</i> spp.) |

Schistosoma bovis

Description: The male is 9–22 mm long and 1–2 mm wide, and the female 12–28 mm long. In the male the suckers and the tegument behind the suckers are armed with minute spines, while the dorsal

surface of the tegument bears small cuticular tubercles. The slender female worm lies permanently in a ventral groove in the broad flat body of the male.

Life cycle: The ovigerous female penetrates deeply into the small vessels of the mucosa or submucosa of the intestine and inserts her tail into a small venule. Since the genital pore is terminal, the eggs are deposited, or even pushed, into the venule. There, aided by their spines and by proteolytic enzymes secreted by the unhatched miracidia, they penetrate the endothelium to enter the intestinal submucosa and ultimately the gut lumen; they are then passed out in the faeces. Worms present in the vesical veins penetrate the endothelial lining of the bladder where eggs may be passed in the urine. Some eggs are carried away in the bloodstream and locate in other organs such as the liver. The eggs hatch in water and the miracidia penetrate appropriate snails. Cercariae develop from daughter sporocysts, which replace the redia stage and there is no metacercarial phase; penetration of the final host by the motile cercariae occurs via the skin or by ingestion in drinking water. After penetration or ingestion the cercariae lose their forked tails, transform to schistosomula or young flukes, and travel via the bloodstream through the heart and lungs to the systemic circulation. In the liver they locate in the portal veins and become sexually mature before migrating to their final site, the mesenteric veins. The prepatent period is 6–7 weeks.

Schistosoma mattheei

Description: The male flukes measure around 9–22 mm in length and about 1–2 mm wide. Females range from 12 to 28 mm in length. The body of the male behind the suckers is armed with very long spines, as are the suckers. The dorsal surface possesses small cuticular tubercles.

Schistosoma indicum

Description: The sexes are separate; the males are 5–19 mm and the females 6–22 mm in length.

Schistosoma spindale

Description: The male measures 5–16 mm and the female 7.2–16.2 mm long.

Schistosoma nasalis

Synonym: *Schistosoma nasale*

Description: The male is 6.3–11 mm and the female 5–11 mm long.

Life cycle: Details of the life cycle are not completely known. The female in the veins of the nasal mucosa lays her eggs, which presumably enter the nasal sinuses and are sneezed out. The eggs hatch in minutes in water and the miracidia penetrate appropriate snails. Development to the cercarial stage occurs without a redial form and there is no metacercarial phase. After penetration or ingestion the cercariae transform to schistosomula, or young flukes, and travel to their final site, the nasal veins.

Schistosoma mansoni

Description: The male *S. mansoni* is approximately 1 cm long with a funnel-shaped oral sucker at its anterior end followed by a second pediculated sucker. The female worm has a cylindrical body that is darker, longer and thinner than that of the male (12–16 mm long).

Schistosoma japonicum

Description: The male is broad and flat and 9.5–20 mm long, carrying the female (12–26 mm long) in the hollow of the inwardly curved body. The suckers lie close together near the anterior end. The cuticle is spiny on the suckers and in the gynaecophoric canal. This characteristic and the vascular predilection site are sufficient for generic identification.

Life cycle: This is similar to that of *S. bovis*. Development to the cercarial stage occurs through two generations of sporocyst without a redial form and there is no metacercarial phase, penetration of the final host by the motile cercariae occurring via the skin. The developmental period in the snail can be as short as 5 weeks. Schistosomula, or young flukes, that reach the abdominal vessels and pass to the portal veins become sexually mature in about 4 weeks.

Schistosoma turkestanica

Synonym: *Orientobilharzia turkstanicum*

Description: This is a small species; the male is 4.2–8 mm and the female 3.4–8 mm in length. The female uterus contains only one egg at a time.

Other schistosomes

Other schistosome species

| Species | Hosts | Site | Intermediate hosts |
|------------------------------|-------|-----------------------------|--------------------------------------|
| <i>Bilharziella polonica</i> | Duck | Mesenteric and pelvic veins | Snails of the genus <i>Planorbis</i> |

Bilharziella polonica

Description: The body is lancet-shaped posteriorly and the sexes are separate. Males are about 4 mm and females 2 mm in size. The female genital pore is just behind the ventral sucker and the short uterus contains one egg at a time.

Life cycle: Eggs are laid in the small vessels of the intestinal wall through which they penetrate and are passed out in the faeces. Development takes place in the snail intermediate host and leads to the release of cercariae, which infect the intermediate host either percutaneously or following ingestion.

FAMILY DIPLOSTOMATIDAE

The family Diplostomatidae includes the genera *Alaria* and *Diplostomum*, which are flukes of mammals and birds. Only the former genus is of veterinary significance. The life cycle involves two

intermediate hosts, namely freshwater snails and frogs. The definitive host is infected through eating frogs containing encysted metacercariae (mesocercariae).

Alaria

Alaria are found in the small intestine of dogs, cats, foxes and mink. The anterior forebody of the fluke is flattened or spoon-shaped, and the posterior hindbody is conical and contains the reproductive organs. The oral and ventral suckers are located in the forebody. The life cycle involves freshwater snails as first intermediate hosts, and amphibian or reptile second intermediate hosts.

Life cycle: Unembryonated eggs are passed in the faeces from which miracidia eventually hatch and enter freshwater snails (*Planorbis*). Sporocysts produce cercariae with bifurcated tails. These leave the snail and infect tadpoles or frogs where the cercariae encyst in the muscles forming mesocercariae. If a frog, snake or mouse eats the tadpole, the mesocercariae become encysted, these animals acting as paratenic hosts. Dogs and foxes may be infected by eating rodents infected with mesocercariae. Once infected the mesocercariae migrate extensively, including passage through the lungs and diaphragm, becoming metacercariae before returning to the small intestine and maturing into flukes. The prepatent period is 2–4 weeks.

Alaria species

| Species | Hosts | Site | Intermediate hosts |
|-----------------------------|---|-----------------|---|
| <i>Alaria alata</i> | Dog, cat, fox, mink, wild carnivores and rarely human | Small intestine | Snails (<i>Planorbis</i> spp.) Frogs, toads Paratenic: snakes, rodents |
| <i>Alaria americana</i> | Dog, fox and other canids | Small intestine | Snails (<i>Planorbis</i> spp.) Frogs, toads |
| <i>Alaria canis</i> | Dog, fox | Small intestine | Snails (<i>Heliosoma</i> spp.) Frogs, toads |
| <i>Alaria marcianae</i> | Cat, raccoon | Small intestine | Snails (<i>Heliosoma</i> spp.) Frogs, toads Paratenic: snakes, rodents |
| <i>Alaria michiganensis</i> | Dog, fox, coyote | Small intestine | Snails (<i>Planorbis</i> spp.) Frogs, toads |

Alaria alata

Description: Adult flukes are 2–6 mm in length and the flat spatulate forebody is much longer than the posterior cylindrical hindbody. At the anterior lateral corners of the anterior section there are two tentacle-like processes (Fig. 1.83). The suckers are very small and the adhesive organ comprises two long tubular folds with lateral margins that are distinct.

Alaria americana

Description: Adult flukes range from 2.5 to 4.0 mm in length. The genital pore is located posteriorly on the mid-hindbody. This species is additionally characterised by the presence of pointed processes flanking the oral sucker.

Fig. 1.83 *Alaria alata*. (Adapted from Baylis, 1929.)

Alaria canis

Description: Adult flukes are 2.5–4.2 mm long. There is a conical tentacle-like appendage on each side of the oral sucker. There is an oval holdfast organ with a longitudinal median depression extending from the ventral sucker to the constriction between the anterior and posterior parts of the body. Testes are lobed, with the posterior one much larger.

FAMILY STRIGEIDAE

These flukes are characterised by a constriction dividing the body into an anterior flattened adhesive organ and a posterior cylindrical or oval part, which contains the reproductive system. A cup-shaped adhesive organ is present in the anterior region. They are parasites of the alimentary tract of birds. The life cycle involves two intermediate hosts, freshwater snails of many genera and a second host that may be a fish or leech. Genera include *Apatemon* and *Cotylurus* in the intestine of pigeons and ducks, and *Parastrigea* in ducks.

Apatemon

Apatemon species

| Species | Hosts | Site | Intermediate hosts |
|--------------------------|--------------------------|-----------|--------------------|
| <i>Apatemon gracilis</i> | Duck, pigeon, wild birds | Intestine | Snails Leeches |

Apatemon gracilis

Description: Adult flukes have a cup-like anterior region, containing an adhesive organ, and a posterior cylindrical region and measure 1.5–2.5 mm by 0.4 mm. The suckers are fairly well developed

and the testes and ovary are arranged one behind the other with the ovary foremost. Vitellaria are limited to the posterior region of the body.

Parastrigea

Parastrigea species

| Species | Hosts | Site | Intermediate hosts |
|----------------------------|-------|-----------|--------------------|
| <i>Parastrigea robusta</i> | Duck | Intestine | Unknown |

Parastrigea robusta

Description: The flukes are 2–2.5 mm long and broader in the anterior region (1.5 mm) than the posterior region (1 mm). The genital papilla is large and oviform and the testes are compact and only slightly lobed. The vitellaria are mainly located in the adhesive organ and the lateral expansions, although some extend into the posterior part of the body.

Cotylurus

Cotylurus species

| Species | Hosts | Site | Intermediate hosts |
|---------------------------|--------------------------|-----------|--------------------|
| <i>Cotylurus cornutus</i> | Duck, pigeon, wild birds | Intestine | Snails |

Cotylurus cornutus

Description: The adult flukes are around 1.2–1.5 mm long and 0.5 mm wide with a rounded anterior region and an ovoid posterior region. The oral sucker is smaller than the ventral sucker and the testes and ovary are arranged one behind the other. They are similar to *Apatemon* species but a strong copulatory organ is located in the bursa.

CLASS CESTODA

This class differs from the Trematoda in having a tape-like body with no body cavity or alimentary canal. There is a wide variation in length, ranging from a few millimetres to several metres. The body is segmented, each segment containing one and sometimes two sets of male and female reproductive organs. Almost all the tapeworms of veterinary importance are in the order Cyclophyllidea, the two exceptions being in the order Pseudophyllidea (Table 1.9).

ORDER CYCLOPHYLLIDEA

STRUCTURE AND FUNCTION

The adult cestode (Fig. 1.84) consists of a globular head or **scolex** bearing attachment organs, a short unsegmented neck and a chain of segments. The chain is known as a **strobila** and each segment as a **proglottid**.

The organs of attachment are four suckers on the sides of the scolex and these may bear hooks. The scolex usually bears anteriorly a

Table 1.9 Classification of cestodes of veterinary importance.

| Kingdom | Phylum | Class Subclass | Order | Family | Genus | |
|----------|-----------------|-------------------|----------------|------------------|--|--|

mobile protrusible cone or rostellum and in some species this may be also armed with one or more concentric rows of hooks, which aid in attachment.

The proglottids are continuously budded from the neck region and become sexually mature as they pass down the strobila to the distal end of the tapeworm. Each proglottid is hermaphrodite with one or two sets of reproductive organs, the genital pores usually opening on the lateral margin or margins of the segment (Fig. 1.85);

Fig. 1.84 Structure of a typical cyclophyllidean cestode.

both self-fertilisation and cross-fertilisation between proglottids may occur. The structure of the genital system is generally similar to that of the trematodes. As the segment matures, its internal structure largely disappears and the fully ripe or gravid proglottid eventually contains only remnants of the branched uterus packed with

Fig. 1.85 Mature segment illustrating the reproductive organs.

eggs. The gravid segments are usually shed intact from the strobila and pass out with the faeces, either singly or occasionally in chains. Outside the body the eggs are liberated by disintegration of the segment or are shed through the genital pore.

The fully embryonated egg consists of:

- 1 the hexacanth (six-hooked) embryo or **oncosphere**;
- 2 a thick, dark, radially striated 'shell' called the **embryophore** (in the Mesocostoididae it is apparent as a thin cellular membrane);
- 3 a true shell, which is a delicate membrane and is often lost while still in the uterus.

The tegument of the adult tapeworm is highly absorptive, the worm deriving all its nourishment through this structure. Below the tegument are muscle cells and the parenchyma, the latter a syncytium of cells, which fills the space between the organs. The nervous system consists of ganglia in the scolex from which nerves run posteriorly and enter the strobila. The excretory system, as in the Trematoda, is composed of flame cells leading to efferent canals that run through the strobila to discharge at the terminal segment.

LIFE CYCLE

The typical life cycle of these cestodes is indirect with one or more intermediate hosts. With few exceptions, the adult tapeworm is found in the small intestine of the final host, the segments and eggs reaching the exterior in the faeces.

When the egg is ingested by the intermediate host, the gastric and intestinal secretions digest the embryophore and activate the oncosphere. Using its hooks, it tears through the mucosa to reach the blood or lymph stream or, in the case of invertebrates, the body cavity. Once in its predilection site the oncosphere loses its hooks and develops, depending on the species, into one of the following larval stages, often known as **metacestodes** (Fig. 1.86).

- **Cysticercus**: Single fluid-filled cyst or bladder containing an attached single invaginated scolex, sometimes called a protoscolex.
- **Coenurus**: This large cyst is similar to a cysticercus, but with numerous invaginated scolices attached to the cyst wall.
- **Strobilocercus**: The scolex is evaginated and is connected to the cyst by a chain of segmented asexual proglottids. The latter are digested away after ingestion by the final host, leaving only the scolex.
- **Hydatid**: This is a large, fluid-filled, complex cyst lined with germinal epithelium from which are produced invaginated scolices which lie free or in bunches, surrounded by germinal epithelium (brood capsules). The contents of the cysts other than the fluid (i.e. scolices and brood capsules) are frequently described as 'hydatid sand'. Occasionally also, daughter cysts complete with cuticle and germinal layer are formed endogenously or, if the cyst wall ruptures, exogenously.
- **Cysticercoid**: A single evaginated scolex embedded in a small solid cyst. Typically found in very small intermediate hosts such as arthropods.
- **Tetrathyridium**: Worm-like, flattened and elongate larva with an invaginated acetabular scolex; found only in Mesocostoididae.

When the metacestode is ingested by the final host the scolex attaches to the mucosa, the remainder of the structure is digested off, and a chain of proglottids begins to grow from the base of the scolex.

Fig. 1.86 Larval stages of cyclophyllidean cestodes.

The seven main families of veterinary interest in the order Cyclophyllidea are the Taeniidae, Anoplocephalidae, Dilepididae, Davaineidae, Hymenolepididae, Mesocostoididae and Paruterinidae.

FAMILY TAENIIDAE

The adults are, in most cases, large tapeworms and are found in domestic carnivores and humans in the small intestine. Genera of importance are *Taenia* (syn. *Multiceps*) and *Echinococcus*. The scolex has an armed rostellum with a concentric double row of hooks (the important exception is *Taenia saginata* whose scolex is unarmed). The gravid segments are longer than they are wide.

The intermediate stage is a cysticercus, strobilocercus, coenurus or hydatid cyst and these occur only in mammals. Historically, the intermediate stage has been named according to the type of metacestode stage present in the intermediate host. Thus *Cysticercus tenuicollis* found in the ruminant host is the metacestode stage of *Taenia hydatigena* in the dog. The correct nomenclature now is for the intermediate host stage to be referred to as the 'metacestode stage' of the adult *Taenia* species.

Taenia

Members of the genus *Taenia* are large tapeworms comprising a number of species. Differentiation is usually based on the size of the scolex, the size of the rostellum and number of hooks, and on the morphology of the genital system within the mature proglottids. The adults of *Taenia* are usually of minor importance in domesticated animals, and it is the larval stages which are of veterinary interest.

Taenia species

| Species | Final hosts | Intermediate hosts (larval stage) | Site |
|--|----------------------------------|--|-----------------------------------|
| <i>Taenia asiatica</i> (syn. <i>Taenia saginata asiatica</i>) | Human | Cattle | Muscle |
| <i>Taenia crassiceps</i> | Fox, coyote | Rodents | Abdominal cavity, various tissues |
| <i>Taenia hydatigena</i> (syn. <i>Taenia marginata</i>) | Dog, fox, wild canids, mustelids | Cattle, sheep, goat, pig (<i>Cysticercus tenuicollis</i>) | Abdominal cavity, liver |
| <i>Taenia multiceps</i> (syn. <i>Multiceps multiceps</i>) | Dog, fox, wild canids | Sheep, cattle, goat, pig, horse, deer, camel, human (<i>Coenurus cerebralis</i>) | Brain, spinal cord |
| <i>Taenia skrjabini</i> | | Sheep (<i>Coenurus skrjabini</i>) | Muscle, subcutaneous tissue |
| <i>Taenia (Multiceps) gaigeri</i> | | Goat (<i>Coenurus gaigeri</i>) | |
| <i>Taenia ovis</i> (syn. <i>Taenia cervi</i> , <i>Taenia krabbei</i> , <i>Taenia hyaenae</i>) | Dog, fox, wild canids | Sheep, goat (<i>Cysticercus ovis</i>) Deer (<i>Cysticercus cervi</i>) Reindeer (<i>Cysticercus tarandi</i>) Camel (<i>Cysticercus dromedarii</i> , <i>Cysticercus cameli</i>) | Muscle |
| <i>Taenia pisiformis</i> | Dog, fox, wild canids | Rabbit, hare (<i>Cysticercus pisiformis</i>) | Peritoneum, liver |
| <i>Taenia saginata</i> (syn. <i>Taeniarrhynchus saginata</i>) | Human | Cattle, occasionally other ruminants (<i>Cysticercus bovis</i>) | Muscle |
| <i>Taenia serialis</i> (syn. <i>Multiceps serialis</i>) | Dog | Rabbit, hare (<i>Coenurus serialis</i>) | Connective tissue |
| <i>Taenia solium</i> | Human | Pig, wild boar (<i>Cysticercus cellulosae</i>) | Muscle |
| <i>Taenia taeniaeformis</i> (syn. <i>Hydatigera taeniaeformis</i> , <i>Taenia crassicolis</i>) | Cat, wild felids | Small rodents (<i>Strobilocercus fasciolaris</i> ; syn. <i>Strobilocercus crassicolis</i>) | Liver |

Taenia asiatica

Synonym: *Taenia saginata asiatica*

Description: Similar to *T. saginata*. The adult tapeworm is about 3.5 m long with a scolex bearing four simple suckers and the rostellum is usually surrounded by two rows of rudimentary hooklets. It is unique in having posterior protruberances in the gravid proglottid, which are absent in other taeniids including *T. saginata*. The metacestode differs morphologically from that of *T. saginata* in having wart-like formations on the external surface of the bladder wall.

Taenia hydatigena

Synonyms: *Taenia marginata*, *Cysticercus tenuicollis*

Description: *Taenia hydatigena* is a large tapeworm measuring up to 5 m in length. The scolex is large and has two rows of 26 and 46

rostellar hooks. Gravid proglottids measure 12 by 6 mm and the uterus has 5–10 lateral branches. The semi-transparent cysticercus may be up to 5–7 cm in size (see Fig. 9.54) and contains a watery fluid and invaginated scolex with a long neck.

Life cycle: Dogs and wild canids are infested by consuming the cysticercus in the intermediate host. The intermediate host is infected through the ingestion of tapeworm eggs that hatch in the intestine. The oncospheres, infective to sheep, goats, cattle and pigs, are carried in the blood to the liver in which they migrate for about 4 weeks before they emerge on the surface of this organ and attach to the peritoneum. Within a further 4 weeks each develops into the characteristically large metacestode, *Cysticercus tenuicollis*. The complete life cycle of this tapeworm is around 7–8 months.

Taenia multiceps

Synonyms: *Multiceps multiceps*, *Coenurus cerebralis*, *Taenia skrjabini*, *Coenurus skrjabini*, *Taenia (Multiceps) gaigeri*, *Coenurus gaigeri*

Description: Adult tapeworms are 40–100 cm in length and have a small head about 0.8 mm in diameter with four suckers. There is a double ring of 22–32 rostellar hooks (Fig. 1.87). The gravid segments measure 8–12 mm by 3–4 mm and the uterus has 18–26 lateral branches which contain taeniid eggs. The metacestode larval stage (*Coenurus cerebralis*) is readily recognised when mature as a large fluid-filled cyst up to 5.0 cm or more in diameter bearing random clusters of invaginated scolices, sometimes up to several hundred, on its internal wall (Fig. 1.88).

Life cycle: The intermediate host is infected through the ingestion of *T. multiceps* eggs. Each egg contains an oncosphere that hatches and is activated in the small intestine. The oncosphere then penetrates the intestinal mucosa and is carried via the blood to the brain or spinal cord where each oncosphere develops into the metacestode larval stage (*Coenurus cerebralis*). In goats, the cysts can also mature in subcutaneous and intramuscular sites. The cysts in sheep and goats often persist throughout the life of the animal. The life cycle is completed when the final host, dog or wild canid, eats an infected sheep brain or spinal cord.

Fig. 1.87 Rostellar hooks of *Taenia (Multiceps) multiceps*.

Fig. 1.88 *Coenurus cerebralis* metacestode stage of *Taenia multiceps*.

Fig. 1.90 Scolex of *Taenia pisiformis* showing the four suckers and armed rostellum.

Taenia ovis

Synonyms: *Cysticercus ovis*, *Taenia cervi* (*Cysticercus cervi*), *Taenia krabbei* (*Cysticercus tarandi*), *Taenia hyaenae* (*Cysticercus dromedarii*), *Cysticercus cameli*

Description: The adult tapeworm is large, measuring 0.5–1.5 m in length. The rostellum bears 24–36 hooks. The strobila has a scalloped edge and is often coiled into a spiral. The mature proglottids have a vaginal sphincter and the ovary and vagina cross each other. The uterus of the gravid proglottids has 20–25 lateral branches on either side. Each cysticercus occurs within a small cyst measuring about 4 mm or less in length (Fig. 1.89).

Life cycle: Dogs and wild canids are infested by consuming the cysticercus in the intermediate host. The intermediate host is infected through the ingestion of tapeworm eggs that hatch in the intestine. The metacestode stage (*Cysticercus ovis*) infects the musculature and cysts are usually located in the skeletal muscle, heart, diaphragm and intermuscular connective tissue. The cyst becomes infective around 2–3 months after infection of the host. The prepatent period in dogs is around 6–9 weeks.

Fig. 1.89 *Cysticercus ovis* metacestode stage of *Taenia ovis* in sheep heart (arrowed).

Taenia pisiformis

Synonym: *Cysticercus pisiformis*

Description: The adult tapeworm can measure up to 2 m in length. It has a large scolex with narrow strobila and the rostellum has 34–48 hooks in two rows (Fig. 1.90). Gravid segments have a uterus with 8–14 lateral branches on either side. The cysticercus is a small pea-like transparent cyst and usually occurs in bunches.

Life cycle: Infection of the intermediate host is through ingestion of tapeworm eggs shed by dogs. Ingested eggs hatch in the small intestine of the intermediate host and penetrate the intestinal wall and pass via the portal system to the liver. Juvenile stages migrate through the liver parenchyma and locate in the abdominal cavity after 2–4 weeks, where they develop into cysts (*Cysticercus pisiformis*) attached to the wall of the mesentery and omentum. Cysts can survive the life of the host. The final host is infected by ingesting the cysticercus. The prepatent period in the dog is around 6–8 weeks.

Taenia saginata

Synonyms: *Taeniarhynchus saginata*, *Cysticercus bovis*

Description: The adult tapeworm is usually 5–8 m long, rarely up to 15 m. The scolex has neither a rostellum nor hooks. Gravid segments are 16–20 mm long by 4–7 mm wide and the uterus has 15–35 lateral branches on either side. In cattle, the mature cysticercus, *C. bovis*, is greyish-white, oval, about 0.5–1.0 by 0.5 cm long, and filled with fluid in which the scolex is usually clearly visible. As in the adult tapeworm, it has neither rostellum nor hooks.

Life cycle: An infected human may pass millions of eggs daily, either free in the faeces or as intact segments each containing about 250,000 eggs, and these can survive on pasture for several months. After ingestion by a susceptible bovine, the oncosphere travels via the blood to striated muscle. It is first grossly visible about 2 weeks later as a pale semi-transparent spot about 1.0 mm in diameter, but is not infective to humans until about 12 weeks later when it has reached its full size of around 1.0 cm. By then it is enclosed

Fig. 1.91 Scolex of *Taenia solium*.

by the host in a thin fibrous capsule but despite this the scolex can usually still be seen. The longevity of the cysts ranges from weeks to years. When they die they are usually replaced by a caseous crumbly mass, which may become calcified. Both living and dead cysts are frequently present in the same carcass. Humans become infected by ingesting raw or inadequately cooked meat. Development to patency takes 2–3 months.

Taenia serialis

Synonyms: *Multiceps serialis*, *Coenurus serialis*

Description: The adult tapeworm is of medium length, around 0.5–0.7 m long. The scolex is armed with two rows of 26–32 hooks (Fig. 1.92). The gravid uterus possesses 20–25 lateral branches on either side. The metacestode cysts may be 4–6 cm in size and the scolices are distributed in packed rows within the cyst.

Fig. 1.92 Scolex of *Taenia serialis*.

Life cycle: Infection of the intermediate host is through ingestion of tapeworm eggs shed by dogs. The intermediate stage, *Coenurus serialis*, is found in the rabbit, usually subcutaneously or in the intermuscular connective tissue. The final host is infected by ingesting the metacestode stage.

Taenia solium

Synonym: *Cysticercus solium*

Description: The adult tapeworm is 3–5 m long, rarely up to 8 m. The rostellum has four radially arranged suckers and bears four suckers and 22–32 hooks in two rows (Fig 1.91), one row of large hooks measuring 0.14–0.18 mm and one row of smaller hooks measuring 0.11–0.14 mm. Gravid segments are 10–12 mm long and 5–6 mm wide. The ovary is in the posterior third of the proglottid and has two lobes with an accessory third lobe. The uterus has 7–12 lateral branches on either side.

The cysticerci have morphologically distinct types. The commonest is the ‘cellulose’ cysticercus which has a fluid-filled bladder that is 0.5–1.5 cm in length with an invaginated scolex. The ‘racemose’ form has no evident scolex, but are larger and up to 20 cm in length.

Life cycle: Gravid segments passed in the faeces, frequently in chains, each contain around 40,000 eggs and because they are non-motile they tend to be concentrated over a small area. Eggs can also resist destruction for a relatively long period. After ingestion by a susceptible pig the oncosphere travels via the blood to striated muscle. The principal location is the striated muscles, but cysticerci may also develop in other organs, such as the lungs, liver, kidney and brain. Humans become infected by ingesting raw or inadequately cooked pork containing viable cysticerci. The human final host may also act as an intermediate host and become infected with cysticerci. This is most likely to occur from the accidental ingestion of *T. solium* eggs via unwashed hands or contaminated food. There is also, apparently, a minor route of autoinfection in a person with an adult tapeworm, from the liberation of oncospheres after the digestion of a gravid segment that has entered the stomach from the duodenum by reverse peristalsis. The prepatent period is 2–3 months.

Taenia taeniaeformis

Synonyms: *Hydatigera taeniaeformis*, *Taenia crassicollis*, *Strobilocercus fasciolaris*, *Strobilocercus crassicollis*

Description: The adult tapeworm is of medium size, up to 70 cm in length. The scolex is large with a double row of rostellar hooks and there is absence of a neck region (Fig. 1.93). The uterus has five to nine lateral branches and the posterior proglottids are bell-shaped. The metacestode stage is a strobilocercus (*Strobilocercus fasciolaris*), which is a small cyst connected with an evaginated scolex by a segmented juvenile strobila.

Life cycle: The metacestode (*Cysticercus fasciolaris*) develops in the liver of rodents and is infective to cats after about 9 weeks. When a cat ingests the metacestode the scolex attaches to the wall of the intestine. Tapeworms in cats become patent around 6 weeks and eggs are ingested by the intermediate host. Cats can remain infected for up to about 2 years.

Fig. 1.93 Scolex of *Taenia taeniaeformis*.

Echinococcus

The genus *Echinococcus* is composed of several species that exploit predator-prey systems between carnivores (mainly canids) as principal hosts and intermediate hosts that range from rodents to livestock depending on the species. Six species are currently recognised in the genus *Echinococcus* with a seventh, *Echinococcus shiquicus*, recently described. Considerable phenotypic and genetic variability has been observed within the species *E. granulosus* and several strains have been identified based on molecular genotyping. New data demonstrate that '*E. granulosus*' is an assembly of several rather diverse strains and genotypes (designated G1–G10) that show fundamental differences, not only in their epidemiology but also in their pathogenicity to humans. *Echinococcus equinus* was formerly known as the horse strain (G4) of *E. granulosus*. *Echinococcus ortelevi*, the former cattle strain (G5), is adapted to transmission by cattle. *Echinococcus oligarthus* and *E. vogeli* exist in wildlife cycles and are morphologically similar to *E. multilocularis* and cause polycystic echinococcosis in humans.

Echinococcus species

| Species | Hosts | Intermediate hosts | Site |
|------------------------------------|-----------------------------------|---|--------------|
| <i>Echinococcus granulosus</i> | Dog, fox, wild canids | Sheep, cattle, camel, pig, buffalo, deer, human | Liver, lungs |
| <i>Echinococcus equinus</i> (G4) | Dog | Horse, donkey | Liver |
| <i>Echinococcus ortelevi</i> (G5) | Dog | Cattle | Liver |
| <i>Echinococcus multilocularis</i> | Dog, fox, cat, wild canids, human | Rodents, pig | Liver |
| <i>Echinococcus vogeli</i> | Wild canids | Rodents | Liver |
| <i>Echinococcus oligarthus</i> | Wild felids | Rodents | Liver |

Echinococcus granulosus (*Echinococcus equinus*, *Echinococcus ortelevi*)

Description: The entire cestode is only about 6.0 mm long, and is therefore difficult to find in the freshly opened intestine. It consists of a scolex and usually three or four segments, the terminal gravid one occupying about half the length of the complete tapeworm (Fig. 1.94). The scolex is typically taeniid and the rostellum has two rows of hooks, varying from in number from 30 to 60. Each segment has a single genital opening, with the penultimate segment sexually mature and the last segment gravid. The genital pores alternate irregularly. The gravid proglottid normally disintegrates in the alimentary tract and only eggs are expelled in faeces.

Hydatid cysts are large fluid-filled vesicles, 5–10 cm in diameter, with a thick concentrically laminated cuticle and an internal germinal layer. The germinal layer produces numerous small vesicles or brood capsules each containing up to 40 scolices, invaginated into their neck portions and attached to the wall by stalks. Brood capsules may become detached from the wall of the vesicle and float freely in the vesicular fluid and form 'hydatid sand'.

Life cycle: The prepatent period in the final host is around 40–50 days, after which only one gravid segment is shed per week. The oncospheres are capable of prolonged survival outside the host, being viable on the ground for about 2 years. After ingestion by the intermediate host, the oncosphere penetrates the gut wall and travels in the blood to the liver or in the lymph to the lungs. These are the two commonest sites for larval development, but occasionally oncospheres escape into the general systemic circulation and develop in other organs and tissues. Growth of the hydatid is slow, maturity being reached in 6–12 months. In the liver and lungs the cyst may have a diameter of up to 20 cm, but in the rarer sites, such as the abdominal cavity, where unrestricted growth is possible, it may be very large and contain several litres of fluid. The cyst capsule consists of an outer membrane and an inner germinal epithelium from which, when cyst growth is almost complete, brood capsules each containing a number of scolices are budded off. Many of these brood capsules become detached and exist free in the hydatid fluid; collectively these and the scolices are often referred to as 'hydatid sand'. Sometimes, complete daughter cysts are formed either inside the mother cyst or externally; in the latter case they may be carried to other parts of the body to form new hydatids.

Fig. 1.94 *Echinococcus granulosus* showing the scolices, and the large gravid posterior proglottids.

Echinococcus multilocularis

Description: *Echinococcus multilocularis* is a very small tapeworm (2–4 mm) and is generally similar to *E. granulosus*, but usually with three to five segments, the terminal one measuring less than half the length of the whole worm (Fig. 1.95). The scolex has four suckers and possesses a double row of large and small hooks (about 14–34). The third segment of the adult tapeworm is sexually mature and the genital pores are in front of the middle of each segment. The uterus is sac-like with no lateral sacculations in the terminal proglottid. Gravid segments contain around 200–300 spherical eggs. Eggs that are shed have a diameter of about 30–40 µm. The structure of the metacestode consists of a germinative gelatinous matrix forming a cystic structure with internal brood capsules and protoscolices which form racemose proliferative masses of metacestodes within infected livers of the intermediate hosts.

Life cycle: *Echinococcus multilocularis* is typically maintained in a sylvatic (wildlife) cycle, although in some rural communities a synanthropic cycle occurs with the domestic dog acting as definitive host. The intermediate host is infected by ingestion of the oncosphere and subsequent passage, via the circulatory system, to the liver where it develops into a multilocular or alveolar cyst (metacestode stage). The cycle is completed when the definitive host consumes an infected intermediate host, the mature tapeworm developing in about 5 weeks. Adult tapeworms are relatively short-lived, about 6 months.

Echinococcus vogeli

Description: *Echinococcus vogeli* is a very small tapeworm (4–6 mm) and usually has three segments, the terminal gravid segment being very long in comparison to the rest of the tapeworm. The uterus is sac-like, long and tubular in shape. The metacestode has a polycystic structure.

Fig. 1.95 *Echinococcus multilocularis*.

Echinococcus oligarthus

Description: *Echinococcus oligarthus* is an extremely small tapeworm (2.5–3.0 mm) and usually has three segments.

FAMILY ANOPLOCEPHALIDAE

These are essentially tapeworms of horses (*Anoplocephala*, *Paranoplocephala*) and ruminants (*Moniezia*, *Stilesia*, *Thysanosoma*, *Thysaniezia* and *Avitellina*). Species of *Cittotaenia* are found in lagomorphs. The scolex has neither rostellum nor hooks and the gravid segments are wider than they are long. The intermediate stage is a cysticercoid present in forage mites of the family Oribatidae.

Life cycle: Mature segments are passed in the faeces and disintegrate, releasing the eggs. These are ingested by forage mites in which they develop to the cysticercoid stage in 2–4 months. The adult tapeworms are found in the intestine of horses 1 or 2 months after the ingestion of infected mites in the herbage.

Anoplocephala

Anoplocephala species

| Species | Hosts | Site | Intermediate hosts |
|---------------------------------|-----------------------------|-------------------------------|---------------------------|
| <i>Anoplocephala perfoliata</i> | Horse, donkey, other equids | Terminal ileum, rarely caecum | Forage mites (Oribatidae) |
| <i>Anoplocephala magna</i> | Horse, donkey, other equids | Small intestine | Forage mites (Oribatidae) |

Anoplocephala perfoliata

Description: Adult tapeworms measure 4–8 cm in length and 1.2 cm in width. There is a small rounded scolex, 2–3 mm in diameter, with a pair of 'lappets' just behind the four suckers, but there is neither rostellum nor hooks. It has a very short neck and the strobila widens rapidly, individual proglottids being much wider than they are long and containing only a single set of reproductive organs. The large gravid uterus is lobed and shaped like a sac.

Anoplocephala magna

Description: *Anoplocephala magna* is similar morphologically to *A. perfoliata* but much longer, up to 80 cm long by 2.5 cm wide and is similar to a broad ribbon. The scolex is large, 4–6 mm wide, with suckers opening anteriorly, and there are no lappets on the scolex. The neck is short as are the segments. The genital organs are single and the pores are unilateral.

Paranoplocephala

Paranoplocephala species

| Species | Hosts | Site | Intermediate hosts |
|--|---------------|-----------------|---------------------------|
| <i>Paranoplocephala mamillana</i> (syn. <i>Anoplocephaloides mamillana</i>) | Horse, donkey | Small intestine | Forage mites (Oribatidae) |
| <i>Paranoplocephala cuniculi</i> | Rabbit | Small intestine | Forage mites (Oribatidae) |

Paranoplocephala mamillana

Synonym: *Anoplocephaloides mamillana*

Description: *Paranoplocephala mamillana* is only 10–50 mm long by 4–6 mm wide and is often referred to as the equine ‘dwarf tapeworm’. There are no lappets on the narrow scolex and the suckers are slit-like and located ventrally and dorsally. The scolex is large and without rostellum and hooks. The gravid segments are wider than they are long.

Life cycle: Mature proglottids or eggs are passed in the faeces and on to pasture where the oncospheres are ingested by forage mites. The oncospheres are only infective for mites for about 3 months. The embryos migrate into the body cavity of the mite where they develop to cysticercoids in 1–4 months and infection of the final host is by ingestion of infected mites during grazing. The prepatent period is approximately 6 weeks, but the adult worms appear to be short-lived, patent infections persisting for only about 3 months.

Moniezia

Moniezia species

| Species | Hosts | Site | Intermediate hosts |
|--------------------------|-----------------|-----------------|---------------------------|
| <i>Moniezia expansa</i> | Sheep, goat | Small intestine | Forage mites (Oribatidae) |
| <i>Moniezia benedeni</i> | Cattle, buffalo | Small intestine | Forage mites (Oribatidae) |

Moniezia expansa

Description: These are long tapeworms, up to 600 cm or more, which possess unarmed scolices and have four prominent suckers (Fig. 1.96). Segments are broader than they are long (up to 1.5 cm wide) and contain two sets of genital organs grossly visible along the lateral margin of each segment (Table 1.10 and Fig. 1.97). There is a row of inter-proglottid glands extending along the whole breadth of the posterior border of each segment, which may be used in species differentiation.

Fig. 1.96 Scolex of *Moniezia expansa* with four prominent suckers.

Table 1.10 Tapeworms of ruminants.

| Tapeworm | Description |
|----------------------------------|--|
| <i>Moniezia</i> | Long wide tapeworms up to 600 cm long. Segments broader than long with two sets of genital organs |
| <i>M. expansa</i> | Row of inter-proglottid glands along whole breadth of posterior border |
| <i>M. benedeni</i> | Inter-proglottid glands confined to short row close to the middle of the posterior margin |
| <i>Thyasanosoma actinoides</i> | Short tapeworms up to 30 cm long. Segments short and fringed posteriorly containing two sets of genital organs |
| <i>Thyasaniezia ovilla</i> | Long tapeworms up to 200 cm long. Segments wider than long with single genital pore alternating irregularly |
| <i>Stilesia globipunctata</i> | Short thin tapeworms up to 60 cm long. Single genital pore alternating irregularly. Two distinct set of testes present |
| <i>Avitellina centripunctata</i> | Long thin tapeworms up to 300 cm in length. Segments wider than long and indistinct except for last few. Single genital pore alternating irregularly |

Source: Drawings reproduced from Ransom (1911) and Soulsby (1971). Reproduced with permission from Lord Soulsby of Swaffham Prior.

Moniezia benedeni

Description: Grossly similar to *M. expansa*. Segments are broader than they are long (up to 2.5 cm wide). In *M. benedeni*, the inter-proglottid glands are confined to a short row close to the middle of the posterior margin of the segment (Table 1.10).

Thyasanosoma

Thyasanosoma species

| Species | Hosts | Site | Intermediate hosts |
|--------------------------------|---------------------|--|--|
| <i>Thyasanosoma actinoides</i> | Sheep, cattle, deer | Small intestine, bile and pancreatic ducts | Oribatid mites (<i>Galuma</i> , <i>Scheloribatates</i>) and psocids (bark lice, dust lice) |

Fig. 1.97 Proglottids of *Moniezia expansa* containing two sets of genital organs.

Thysanosoma actinoides

Description: The adult ‘fringed’ tapeworms measure 15–30 cm in length by 8 mm in width. The scolex is up to 1.5 mm in breadth; segments are short and fringed posteriorly. In the distal regions of the tapeworm the ‘fringes’ are as long as the proglottid (Table 1.10 and Fig. 1.98). Each proglottid contains two sets of genital organs with the testes lying medially. Several paruterine organs are present in each proglottid.

Life cycle: Mature segments are passed in the faeces of the infected host on to pasture, where forage mites ingest the oncospheres. Cysticercoids develop within the oribatid intermediate hosts and infection of the final host is by ingestion of infected mites during grazing.

Fig. 1.98 *Thysanosoma actinoides* showing ‘fringed’ proglottids.

Thysaniezia

Thysaniezia species

| Species | Hosts | Site | Intermediate hosts |
|---|---|-----------------|--|
| <i>Thysaniezia ovilla</i> (syn. <i>Thysaniezia giardia</i> , <i>Helictometra giardi</i>) | Cattle, sheep, goat, camel and wild ruminants, occasionally pig | Small intestine | Oribatid mites (<i>Galuma</i> , <i>Scheloribates</i>) and psocids (bark lice, dust lice) |

Thysaniezia ovilla

Synonyms: *Thysaniezia giardia*, *Helictometra giardi*

Description: Adults reach 200 cm in length, varying in width up to 12 mm. The scolex is small, measuring up to 1 mm in diameter, and the suckers are slit-like in appearance. Segments are short, bulge outwards giving the margin of the worm an irregular appearance, and contain a single set of genital organs, rarely two, with genital pores alternating irregularly. Mature segments have an undulating uterus (Table 1.10).

Stilesia

Stilesia species

| Species | Hosts | Site | Intermediate hosts |
|-------------------------------|--------------------------------------|-------------------|--------------------------------|
| <i>Stilesia globipunctata</i> | Sheep, goat, cattle, other ruminants | Small intestine | Oribatid mites and psocid lice |
| <i>Stilesia hepatica</i> | Sheep, goat, cattle, wild ruminants | Liver, bile ducts | Oribatid mites? |
| <i>Stilesia vittata</i> | Camel | Small intestine | Oribatid mites? |

Stilesia globipunctata

Description: Adults measure 45–60 cm in length by 3–4 mm in width. The narrow scolex has four large suckers, but no hooks. Strobila is broader than long. A single set of genital organs is present and genital pores alternate irregularly (Table 1.10). Two distinct sets of testes are present in each segment, one on each side, but no testes in the median line.

Stilesia hepatica

Description: The adult tapeworm measures 20–50 cm in length and 2–3 mm in width. The neck is narrow and the scolex is large with prominent suckers. The genital organs are single and the opening pores alternate irregularly. There are 10–12 testes on either side lying dorsal to the ventral canal. The proglottids are short.

Life cycle: The life cycle is not known but probably involves oribatid mites.

Stilesia vittata

Description: Adults are 18–23 cm long. Mature proglottids contain five to seven testes lying lateral to the ventral canal.

Avitellina

Species of this genus occur in the small intestine of ruminants in parts of Africa, Europe and India.

Life cycle: The life cycle is similar to that of *Moniezia*.

Avitellina species

| Species | Hosts | Site | Intermediate hosts |
|--|--|-----------------|-------------------------------|
| <i>Avitellina centripunctata</i> (syn. <i>Avitellina woodlandi</i>) | Sheep, goat, camel and other ruminants | Small intestine | Oribatid mites or psocid lice |
| <i>Avitellina goughi</i> | Sheep | Small intestine | Oribatid mites or psocid lice |
| <i>Avitellina chalmersi</i> | Sheep | Small intestine | Oribatid mites or psocid lice |
| <i>Avitellina tatia</i> | Goat | Small intestine | Oribatid mites or psocid lice |

Avitellina centripunctata

Synonym: *Avitellina woodlandi*

Description: This tapeworm resembles *Moniezia* on gross inspection except that the segmentation is so poorly marked that it appears somewhat ribbon-like. It can reach 3 m in length and about 3–4 mm in width and the posterior end is almost cylindrical in appearance. Proglottids are short with indistinct segmentation and single genitalia present with the pores alternating irregularly (Table 1.10).

Cittotaenia

Parasites of this genus are found in rabbits and hares.

Life cycle: Mature proglottids or eggs are passed in the faeces and on to pasture where the oncospheres are ingested by forage mites. The embryos migrate into the body cavity of the mite where they develop to cysticercoids. Infection of the final host is by ingestion of infected mites during grazing.

Cittotaenia species

| Species | Hosts | Site | Intermediate hosts |
|--------------------------------|--------------|-----------------|--------------------|
| <i>Cittotaenia ctenoides</i> | Rabbit | Small intestine | Oribatid mites |
| <i>Cittotaenia denticulata</i> | Rabbit | Small intestine | Oribatid mites |
| <i>Cittotaenia pectinata</i> | Rabbit, hare | Small intestine | Oribatid mites |

Cittotaenia ctenoides

Description: Mature tapeworms grow up to 80 cm long and 1 cm wide. The scolex is about 0.5 mm wide and bears a short neck. The proglottids are much wider than they are long and each contains two sets of genital organs containing 60–80 testes behind an ovary on each side.

Cittotaenia denticulata

Description: Differs from *C. ctenoides* by having a wider scolex (0.8 mm) and no neck.

Cittotaenia pectinata

Description: Very similar to *C. ctenoides* but with a smaller scolex (0.25 mm) but also bears a short neck.

FAMILY DILEPIDIDAE

These are small to medium-sized tapeworms of the dog, cat (*Dipylidium*) and fowl (*Amoebotaenia*, *Choanotaenia*). The scolex usually has an armed rostellum with several rows of hooks. The suckers may also possess fine hooks. The gravid uterus is retained as a transverse sac. The intermediate stage is a cysticercoid.

Dipylidium

This is the commonest tapeworm genus of the domestic dog and cat. *Dipylidium* is a much shorter tapeworm than *Taenia*, the maximum length being about 50 cm.

Life cycle: The newly passed segments are active, and can crawl about on the tail region of the animal. The oncospheres are contained in egg packets or capsules, each with about 20 eggs, and these are either expelled by the active segment or released by its disintegration.

After ingestion by the intermediate host, the oncospheres travel to the abdominal cavity where they develop into cysticercoids. All stages of the biting louse can ingest oncospheres, but the adult flea, with its mouthparts adapted for piercing, cannot do so and infection is only acquired during the larval stage, which has chewing mouthparts. Development in the louse, which is permanently parasitic and therefore enjoys a warm habitat, takes about 30 days, but in the flea larva and the developing adult in the cocoon, both of which are on the ground, development may extend over several months. The final host is infected by ingestion of the flea or louse containing the cysticercoids, usually while grooming. Development to patency, when the first gravid segments are shed, takes about 3 weeks.

Dipylidium species

| Species | Hosts | Site | Intermediate hosts |
|---------------------------|--------------------------------|-----------------|---|
| <i>Dipylidium caninum</i> | Dog, fox and cat; rarely human | Small intestine | Fleas (<i>Ctenocephalides</i> spp., <i>Pulex irritans</i>) and lice (<i>Trichodectes canis</i>) |

Dipylidium caninum

Description: This medium-sized tapeworm can be up to 50 cm in length. The small scolex has four suckers and a protrusible rostellum, which is armed with three or four rows of small rose-thorn shaped hooks (Fig. 1.99). The mature gravid proglottids are easily recognised, being oval/elongate like a large rice grain, and have two sets of genital organs, with a pore opening on each margin (Fig. 1.100). Each egg capsule can contain 5–30 eggs (see Fig. 12.8).

Amoebotaenia

Small tapeworms found in the duodenum of chickens with earthworms as intermediate hosts.

Fig. 1.99 Scolex of *Dipylidium caninum* with four suckers and protrusible rostellum.

Fig. 1.100 Proglottids of *Dipylidium caninum* with two sets of genital organs.

Life cycle: See *Raillietina cesticillus*. The prepatent period is around 4–5 weeks.

Amoebotaenia species

| Species | Hosts | Site | Intermediate hosts |
|---|---------|-----------------|--------------------|
| <i>Amoebotaenia sphenoides</i> (syn. <i>Amoebotaenia cuneata</i>) | Chicken | Small intestine | Earthworms |

Amoebotaenia sphenoides

Synonym: *Amoebotaenia cuneata*

Description: A very small tapeworm, up to about 4.0 mm long by 1 mm wide, with up to 20 proglottids, each wider than long.

These proglottids are approximately triangular in shape, although the last few segments decrease in size. Its overall appearance is slightly fluke-like. The rostellum bears a single circular row of 12–14 hooks. In the single reproductive organ the genital pores alternate regularly.

Choanotaenia

These are large robust tapeworms, up to 20 cm in length, found in chickens, turkeys and other gallinaceous birds.

Choanotaenia species

| Species | Hosts | Site | Intermediate hosts |
|----------------------------------|----------------------------|-----------------|--|
| <i>Choanotaenia infundibulum</i> | Chicken, turkey, gamebirds | Small intestine | House fly (<i>Musca domestica</i>), beetles (<i>Aphodius</i> , <i>Calathus</i> , <i>Geotrupes</i> , <i>Tribolium</i>) and grasshoppers |

Choanotaenia infundibulum

Description: A relatively large tapeworm up to 20 cm in length and 1.5–3 mm in width. Each segment is wider posteriorly, giving the margin of the tapeworm a ‘saw-edge’ appearance. The scolex is triangular, pointed anteriorly with a distinctive rostellum, ringed with about 18 slender hooks. A single set of reproductive organs is present in each proglottid and the genital pores alternate regularly.

Joyeuxiella and *Diplopylidium*

These two genera contain a couple of species of restricted veterinary importance. In these tapeworms the genital apertures are sited anterior to the middle of the proglottid. Each egg capsule contains only one egg.

Joyeuxiella pasquale has been found in the cat and the dog in Africa and the Middle East and Australia. It is very similar to *Dipylidium*. It requires two intermediate hosts: firstly, various beetles and secondly, a lizard or small mammals.

Diplopylidium nolleri and *D. trinchesi* occur in the cat and the dog in the Middle East. Two intermediate hosts are involved: firstly, various beetles and secondly, a reptile or small mammals.

FAMILY PARUTERINIDAE

Members of this family, which are parasites of birds, are closely related to the Dilepididae but possess a paruterine organ.

Metroliasthes

Metroliasthes species

| Species | Hosts | Site | Intermediate hosts |
|---|-----------------|-----------------|---|
| <i>Metroliasthes lucida</i> (syn. <i>Hexaparuterins lucida</i>) | Turkey, chicken | Small intestine | Grasshoppers (<i>Chorthippus</i> , <i>Paroxya</i> , <i>Melanopus</i>) |

Metroliaesthes lucida

Synonym: *Hexaparuterins lucida*

Description: The tapeworm is about 20 cm long and 1.5–2.0 mm wide. The scolex has no rostellum or hooks and the suckers are devoid of spines. The single genital pores are irregularly alternating and can be prominent. Each gravid proglottid possesses a single paruterine organ containing one egg.

FAMILY DAVAINIIDAE

These are mainly parasites of birds (*Davainea*, *Raillietina*, *Cotugnia*, *Houttuynia*). These tapeworms usually have rows of hooks on both rostellum and suckers. Egg capsules replace the uterus in this family. The intermediate stage is a cysticeroid.

Davainea

This genus contains *Davainea proglottina*, the most pathogenic cestode of poultry.

Life cycle: Gravid proglottids are shed in faeces and eggs are ingested by various gastropod molluscs, in which they develop to the cysticeroid stage after about 3 weeks. Following ingestion of the mollusc by the final host, the cysticeroids develop into adult tapeworms in about 2 weeks.

Davainea species

| Species | Hosts | Site | Intermediate hosts |
|-----------------------------|--|-----------------|---|
| <i>Davainea proglottina</i> | Chicken, turkey, pigeon and other gallinaceous birds | Small intestine | Slugs (<i>Agriolimax</i> , <i>Arion</i> , <i>Cepaea</i> and <i>Limax</i>) and land snails |

Davainea proglottina

Description: *Davainea proglottina* is an extremely small cestode up to 1–4 mm long, and usually possesses only four to nine segments. The rostellum bears 80–94 hooks, arranged in a double row, and the suckers bear a few rows of small hooks. Each segment contains a single set of reproductive organs. The genital pores alternate regularly. Eggs are located singly in capsules in the gravid segment.

Raillietina

Species of this genus are found in the small intestine of chickens and turkeys and other fowl with the cysticeroid intermediate stage, depending on the species, in ants or beetles.

Life cycle: Gravid proglottids are passed in faeces and eggs are ingested by various intermediate hosts. The embryo hatches from the egg in the intestine and then changes into a cysticeroid in the body cavity. Following ingestion by the final host the activated cysticeroid attaches to the mucosa of the anterior or mid small intestine. The prepatent period is around 2–3 weeks.

Raillietina species

| Species | Hosts | Site | Intermediate Hosts |
|--|--|-----------------|--|
| <i>Raillietina cesticillus</i> (syn. <i>Skrjabinia cesticillus</i>) | Chicken, turkey, guinea fowl | Small intestine | Various genera of beetles, cockroaches, <i>Musca domestica</i> |
| <i>Raillietina echinobothrida</i> | Chicken, turkey | Small intestine | Ants of the genera <i>Pheidole</i> and <i>Tetramorium</i> |
| <i>Raillietina tetragona</i> | Chicken, guinea fowl, peafowl and pigeon | Small intestine | Houseflies (<i>Musca domestica</i>) and ants of the genera <i>Pheidole</i> , <i>Tetramorium</i> and <i>Onthophagus</i> |
| <i>Raillietina georgiensis</i> | Turkey | Small intestine | Ants of the genera <i>Pheidole</i> and <i>Tetramorium</i> |

Raillietina cesticillus

Description: A small tapeworm that can reach around 10–14 cm in length, but is often much shorter at about 4–5 cm long. The broad scolex is large and the rostellum wide. The unarmed suckers are not prominent and the rostellum is armed with several hundred small hammer-shaped hooks arranged in a double row. The gravid proglottids contain several thin-walled egg capsules, each housing a single egg.

Raillietina echinobothrida

Description: Tapeworms of this species may be up to 20–25 cm in length, and similar in shape to *R. tetragona*. The suckers are circular and armed with several rows of small hooklets and the rostellum is well endowed with two rows of around 200 hooks (these features enable it to be distinguished from *R. tetragona*). A 'neck' is absent behind the scolex. The gravid proglottids contain multiple fibrous-walled egg capsules, each housing several eggs (around 6–12).

Raillietina tetragona

Description: Often the largest tapeworm of fowl reaching around 20–25 cm in length. The scolex is smaller than that of *R. echinobothrida* and the 'neck' is quite prominent. The oval suckers are lightly armed with several rows of fine hooklets and the rostellum bears one or sometimes two rows of around 100 hooks. The gravid proglottids contain multiple fibrous-walled egg capsules, each housing many eggs (about 8–14).

Raillietina georgiensis

Description: The length of this tapeworm is around 15–35 cm. The rostellum is covered with about 100 hooks.

Cotugnia

Cotugnia species

| Species | Hosts | Site | Intermediate hosts |
|----------------------------|-------------|-----------------|--------------------|
| <i>Cotugnia digonopora</i> | Chicken | Small intestine | Ants, beetles? |
| <i>Cotugnia fastigata</i> | Duck, goose | Small intestine | Unknown |
| <i>Cotugnia cuneata</i> | Pigeon | Small intestine | Unknown |

Cotugnia digonopora

Description: The tapeworm is up to 10 cm long. The head is large with a small rudimentary retractile rostellum, which is armed with two rows of small hooklets. The suckers are large and unarmed and the proglottids are wider than long. Segments possess a double set of genital organs.

Life cycle: The life cycle is unknown but is thought to involve ants or beetles.

Houttuynia

Houttuynia species

| Species | Hosts | Site | Intermediate hosts |
|-------------------------------|---------------|-----------------|--------------------|
| <i>Houttuynia struthionis</i> | Ostrich, rhea | Small intestine | Unknown |

Houttuynia struthionis

Description: These are large, long, flat, white segmented tapeworms (60–120 cm long by 9 mm wide). The scolex is 1–2 mm wide and bears a double row of about 160 large and small hooks. The eggs are contained within parenchymatous capsules in the gravid proglottid. There are around 15–25 eggs in each capsule. Genital pores are unilateral.

Life cycle: The life cycle is unknown.

FAMILY HYMENOLEPIDIDAE

These small to medium-sized parasites are of minor veterinary importance. Members of this family, which have a characteristically slender strobila with a conical rostellum, infect birds, humans and rodents (*Hymenolepis*, *Rodentolepis*, *Fimbriaria*). The intermediate stage is a cysticercoid present in an arthropod host.

Hymenolepis

This genus contains a large number of species occurring mainly in domestic and wild birds. The tapeworms are usually narrow and thread-like in appearance with three testes in each segment.

Hymenolepis species

| Species | Hosts | Site | Intermediate hosts |
|--|---|-----------------|---|
| <i>Hymenolepis cantaniana</i> (syn. <i>Stephylepis cantaniana</i>) | Chicken, turkey, pheasant, quail and other fowl | Small intestine | Beetles (Scarabaeidae) |
| <i>Hymenolepis carioca</i> (syn. <i>Echinolepis carioca</i>) | Chicken, turkey and other fowl | Small intestine | Dung and flour beetles; occasionally <i>Stomoxys</i> spp. |
| <i>Hymenolepis lanceolata</i> (syn. <i>Drepanidotaenia lanceolatum</i>) | Duck, goose | Small intestine | Freshwater crustaceans (copepods) |

Hymenolepis cantaniana

Synonym: *Stephylepis cantaniana*

Description: A slender tapeworm, reaching a length of up to 2 cm. The rostellum is rudimentary and the suckers are unarmed.

Hymenolepis carioca

Synonym: *Echinolepis carioca*

Description: This is a slender thread-like tapeworm reaching a length of up to 8 cm. The scolex is unarmed. The proglottids number 500–1100 and are broader than they are long.

Hymenolepis lanceolata

Synonym: *Drepanidotaenia lanceolatum*

Description: A slender tapeworm reaching up to 15–20 cm in length. The proglottids are much wider than they are long.

Fimbriaria

Fimbriaria species

| Species | Hosts | Site | Intermediate hosts |
|-------------------------------|--|-----------------|---|
| <i>Fimbriaria fasciolaris</i> | Chicken, duck, goose and wild anseriform birds | Small intestine | Copepods (<i>Cyclops</i> spp. and <i>Diaptomus</i> spp.) |

Fimbriaria fasciolaris

Description: This is not a common cestode. The adult tapeworms vary in length from 2.5 cm up to about 40 cm. The scolex is small with 10 hooks but the anterior part of the body possesses a 'pseudoscolex' (a folded body expansion) for attachment to the host. The presence of this expansion aids diagnosis. The uterus is a continuous tube which separates into small tubules in the posterior of the worm. These tubules contain eggs which retain the outer spindle-shaped shell and they contain the oval embryophores. The genital pores are unilateral with three testes to each set of genital organs.

Rodentolepis

Parasites of rats and mice (formerly *Hymenolepis*) and includes the dwarf tapeworm (*Rodentolepis nana*) and the rat tapeworm (*Rodentolepis diminuta*), which can infect humans.

Rodentolepis species

| Species | Hosts | Site | Intermediate hosts |
|---|-------------------|-----------------|--|
| <i>Rodentolepis nana</i> (syn. <i>Hymenolepis nana</i> , <i>Hymenolepis fraterna</i> , <i>Vampirolepis nana</i>) | Rat, mouse, human | Small intestine | Flour beetles (<i>Tenebrio</i>) or fleas |
| <i>Rodentolepis diminuta</i> (syn. <i>Hymenolepis diminuta</i>) | Rat, mouse, human | Small intestine | Moths, cockroaches, fleas, beetles, millipedes |

Rodentolepis nana

Synonyms: *Hymenolepis nana*, *Hymenolepis fraterna*, *Vampirolepis nana*

Description: The tapeworm is small, 2.5–4 cm in length, and has a characteristically slender strobila with about 200 segments. The scolex has four suckers and is armed with a retractable rostellum

bearing a single row of 20–30 hooks. The genitalia are single and the segments are wider than they are long.

Life cycle: The life cycle can be direct, the cysticercoids developing in the villi of the small intestine of the final host and then emerging to develop to the adult tapeworm in the intestinal lumen. Otherwise flour beetles or fleas can serve as intermediate hosts.

Rodentolepis diminuta

Synonym: *Hymenolepis diminuta*

Description: A small tapeworm, about 20–60 mm in length. The rostellum does not possess hooks.

FAMILY MESOCESTOIDIDAE

Also of minor veterinary importance, these cestodes of carnivorous animals and birds have two metacestode stages. The first is a cysticercoid in an insect or mite, and the second a solid larval form, a tetrathyridium, in a vertebrate. Genera include *Mesocestoides* found in dogs, cats and wild mammals, and *Dithyridium* in chickens, turkeys and wild birds.

Mesocestoides

Adult tapeworms are found in the small intestine of dogs, cats and wild carnivores. The second intermediate stages (tetrathyridia) occur in the peritoneal and pleural cavities or subcutaneous tissue of a wide variety of vertebrate hosts (*Dithyridium*, *Tetrathyridium*).

Life cycle: The life cycle requires two intermediate hosts. A cysticercoid is produced in the first intermediate host which, when eaten by the second intermediate host, forms a tetrathyridium; this may remain as an encapsulated form for some time. The tetrathyridium is located in the peritoneal cavity in reptiles and mammals and in the lungs in birds. Dogs and cats can start to shed tapeworm segments in faeces as early as 3 weeks after infection.

***Mesocestoides* species**

| Species | Hosts | Site | Intermediate hosts |
|-------------------------------|---|-----------------|---|
| <i>Mesocestoides lineatus</i> | Dog, cat, fox, mink and wild carnivores, occasionally human | Small intestine | Oribatid mites (cysticercoid) Coprophagus beetles Birds, amphibians, reptiles, mammals (tetrathyridium) |

Mesocestoides lineatus

Synonyms: *Dithyridium variable*, *Tetrathyridium bailetti*, *Tetrathyridium elongatum*

Description: The adult tapeworm ranges from 30 to 250 cm in length and up to 3 mm wide. The scolex is large, unarmed and without a rostellum, and the four suckers are elongate and oval. The strobila is thin and narrow, up to 1.5 cm in length. Mature segments are longer than wide and each contains a single set of central reproductive organs, the central genital pore opening on the dorsal surface (Fig. 1.101). The ovary and vitelline glands are bilobed and there are numerous testes. Oncospheres in gravid segments progress from the uterus into a paruterine organ.

Fig. 1.101 Proglottid of *Mesocestoides lineatus* with single set of central genital organs opening dorsally.

ORDER PSEUDOPHYLLIDEA

The morphology of the Pseudophyllidea is generally similar to that of the Cyclophyllidea, but there are three distinct features. First, the unarmed scolex has no suckers and instead has two weakly muscular, shallow longitudinal grooves or **bothria**, which become flattened to form organs of attachment. Secondly, the proglottids possess a uterine pore that enables eggs to be discharged from a large length of the strobila. The terminal proglottids are not gravid and usually are exhausted and may become detached in short chains. Thirdly, the eggshell is thick, brownish-yellow and operculate, and the **coracidium**, which emerges after hatching, is an oncosphere with an embryophore which is ciliated for mobility in water.

The pseudophyllidean life cycle utilises two intermediate hosts. The coracidium must first be ingested by a crustacean in whose body cavity a larval **proceroid** develops. Subsequently, if the crustacean is eaten by a freshwater fish, amphibian or reptile, the proceroid is liberated and in the muscles of the new host develops into a second larval stage, a **plerocercoid**, which possesses the characteristic scolex; it is only this stage which is infective to the final host.

This order contains only two genera of veterinary importance, *Diphyllobothrium* and *Spirometra*.

FAMILY DIPHYLLOBOTHRIIDAE

Parasites of cetaceans, fish-eating mammals and other vertebrates with well-developed bothria.

Diphyllobothrium

The genus *Diphyllobothrium* is an important cestode of humans and fish-eating mammals. They are long tapeworms with an unarmed scolex, with two muscular bothria.

Fig. 1.102 Egg of *Diphyllbothrium latum*.

Life cycle: Eggs are continuously discharged from the genital pores of the attached gravid segments of the strobila and pass to the exterior in the faeces. They resemble *F. hepatica* eggs, being yellow and operculate, but are approximately half the size (Fig. 1.102). The eggs must develop in water and within a few weeks each hatches to liberate a motile ciliated coracidium which, if ingested by a copepod, develops into the first parasitic larval stage, a worm-like procercoïd. When the copepod is ingested by a freshwater fish, the procercoïd migrates to the muscles or viscera to form the second larval stage, the plerocercoid; this solid larval metacestode is about 5.0 mm long and possesses the characteristic scolex. The life cycle is completed when the infected fish is eaten raw, or insufficiently cooked, by the final host. Development to patency is rapid, occurring within 3–4 weeks of ingestion of the plerocercoid. However, if the infected fish is eaten by a larger fish, the plerocercoid has the ability to establish itself in its new host.

Diphyllbothrium species

| Species | Hosts | Site | Intermediate hosts |
|--|---|-----------------|---|
| <i>Diphyllbothrium latum</i> | Human and fish-eating | Small intestine | Copepods: <i>Cyclops</i> spp. and <i>Diaptomum</i> spp. (procercoïd) |
| (syn. <i>Dibothriocephalus latus</i>) | mammals such as dog, cat, pig, polar bear | | Freshwater fish: pike, trout, perch (plerocercoid) |

Diphyllbothrium latum

Synonym: *Dibothriocephalus latus*

Description: A very long, ivory-coloured tapeworm measuring up to 10–15 m in length or longer, with several hundred, or in some cases a few thousand, proglottids. The scolex is unarmed with two weak muscular longitudinal grooves or bothria as organs of attachment. Anterior proglottids are broader than long while the mature and gravid segments are rectangular-shaped with a central genital pore. The uterus is situated centrally and is rosette-shaped.

Spirometra

Spirometra are small to medium-sized tapeworms of dogs, cats and wild carnivores and an occasional human zoonosis (sparganosis). A couple of features enable differentiation from the very similar genus *Diphyllbothrium*: the vagina and uterus exit separately onto the ventral surface of the proglottid; and the uterus has a spiral form whereas in *Diphyllbothrium* it has a rosette shape.

Life cycle: The morphology and life cycle of these tapeworms is similar to that of *D. latum*, the procercoïds being found in crustaceans, such as *Cyclops*, and the plerocercoids in a wide variety of hosts. These can also act as paratenic hosts. The plerocercoids can also transfer between intermediate hosts. The prepatent period is around 20–30 days.

Spirometra species

| Species | Hosts | Site | Intermediate hosts |
|--|---|-----------------|--|
| <i>Spirometra mansoni</i> | Dog, cat, wild carnivores, occasionally human | Small intestine | Copepods: <i>Cyclops</i> spp. (procercoïd) Amphibia, reptiles, birds (plerocercoid) |
| <i>Spirometra mansonioides</i> (syn. <i>Diphyllbothrium mansonioides</i>) | Cat, bobcat, raccoon, occasionally dog | Small intestine | Crustacea (procercoïd) Rats, snakes, mice (plerocercoid or spargana) |
| <i>Spirometra erinacei</i> (syn. <i>Spirometra erinacei-europaei</i>) | Cat, dog, fox | Small intestine | Crustacea (procercoïd) Frogs (plerocercoid) |

Spirometra mansoni

Description: The adult tapeworms are very similar to *Diphyllbothrium*, measuring around 6–35 cm in length. Proglottids possess both a uterine and a vaginal pore and the uterus is spiral in shape.

Spirometra mansonioides

Synonym: *Diphyllbothrium mansonioides*

Description: The adult worms are pinkish in color and gravid proglottids have a tightly coiled uterus full of brown eggs.

Spirometra erinacei

Synonym: *Spirometra erinacei-europaei*

Description: Adult tapeworms can reach 1.5 m in length and possess a finger-like scolex with the bothria fading into the strobila. The proglottids contain a spiral uterus with two to three coils and a dumbbell-shaped ovary that is transversely long.

KINGDOM PROTOZOA

Protozoa are unicellular organisms that are more primitive than animals, and no matter how complex their bodies may be all the different structures are contained in a single cell.

Protozoa, like most organisms, are **eukaryotic**, in that their genetic information is stored in chromosomes contained in a nuclear envelope. In this way they differ from bacteria which do not have a nucleus and whose single chromosome is coiled like a skein of wool in the cytoplasm. This primitive arrangement, found only in bacteria, rickettsia and certain algae, is called prokaryotic and such organisms may be regarded as neither animal nor plant, but as a separate kingdom of prokaryotic organisms, the Monera.

STRUCTURE AND FUNCTION OF PROTOZOA

Protozoa, like other eukaryotic cells, have a nucleus, an endoplasmic reticulum, mitochondria and a Golgi body and lysosomes. In

Fig. 2.1 *Trypanosoma brucei* showing the flagellum and undulating membrane.

addition, because they lead an independent existence, they possess a variety of other subcellular structures or organelles with distinct organisational features and functions.

Thus locomotion in, for example, the genus *Trypanosoma* (Fig. 2.1) is facilitated by a single **flagellum**, and in some other protozoa by several flagella. A flagellum is a contractile fibre, arising from a structure called a basal body, and in some species is attached to the body of the protozoan along its length, so that when the flagellum beats, the cell membrane (pellicle) is pulled up to form an **undulating membrane**. Sometimes, also, it projects beyond the protozoan body as a free flagellum. During movement the shape of these organisms is maintained by microtubules in the pellicle.

Other protozoa, such as *Balantidium* (Fig. 2.2), move by means of **cilia** which are fine short hairs, each arising from a basal body; these cover much of the body surface and beat in unison to effect movement. In such species a mouth or **cytostome** is present and the ciliary movement is also used to waft food towards this opening.

A third means of locomotion, used by protozoa such as *Entamoeba* (Fig. 2.3), are **pseudopodia**, which are prolongations of cytoplasm. Movement occurs as the rest of the cytoplasm flows into this prolongation. The pseudopodium also possesses a phagocytic capacity and can function as a cup, which closes, enveloping particulate food material in a vacuole.

Fig. 2.2 The morphology of the intestinal protozoan *Balantidium*.

Fig. 2.3 *Entamoeba histolytica* has an amoeboid trophozoite stage and a non-motile cystic stage with four nuclei.

Finally some protozoa, such as the extracellular stages of *Eimeria*, have no obvious means of locomotion, but are nevertheless capable of gliding movements.

The nutrition of parasitic protozoa usually occurs by pinocytosis or phagocytosis, depending on whether tiny droplets of fluid or small objects of macromolecular dimension are taken into the cell. In both cases, the process is the same, the cell membrane gradually enveloping the droplet or object which has become adherent to its outer surface. When this is complete, the particle is carried into the cell where fusion with lysosomes effects digestion. Finally, undigested material is extruded from the cell. As noted above, some ciliated protozoa and also some stages of the organisms causing malaria obtain food through a cytostome. At the base of the cytostome the food enters a vacuole for digestion within the cell. Metabolic products are excreted by diffusion through the cell membrane.

The infective stage of some protozoa is called a **sporozoite**, while the term **trophozoite** is applied to that stage of the protozoa in the host, which feeds and grows until division commences. In most protozoa, reproduction is asexual and is accomplished by binary fission or, in the case of *Babesia* within erythrocytes, by budding. Another form of asexual reproduction, which occurs in the subphylum Sporozoa, is **merogony (schizogony)**. In the latter process, the trophozoite grows to a large size while the nucleus divides repeatedly. This structure is called a **meront (schizont)** and, when mature, each nucleus has acquired a portion of the cytoplasm so that the meront is filled with a large number of elongated separate organisms called **merozoites**. The meront eventually ruptures, liberating the individual merozoites.

Protozoa that only divide asexually generally have a short generation time, and since they cannot exchange genetic material, rely on mutants to provide the variants necessary for natural selection. However, most Sporozoa at certain stages in their life cycle also have a sexual phase of reproduction, called **gametogony**, which may be followed by a free-living maturation phase, or **sporogony**. Sometimes, as in *Eimeria*, both asexual and sexual phases occur in the same host while in others, such as *Plasmodium*, the asexual phase occurs in the vertebrate host and the sexual phase in the arthropod vector.

Finally, it should be noted that although this section deals with pathogenic protozoa of veterinary importance, there are many other species, particularly in the rumen, which are purely commensal or even symbiotic. These protozoa assist in the digestion of cellulose, and on being passed to the abomasum act as a source of protein for the host.

CLASSIFICATION

Classification of the kingdom Protozoa is extremely complex and undergoing constant revision. The classification given below is intended to give an outline of the basic differences in the structure and life cycles of the main groups.

The most recent classification of the protozoa now recognises 13 phyla. Under the older system of classification, as described in most veterinary textbooks, there were four phyla containing parasites of veterinary interest: Sarcomastigophora (containing Sarcodina and Mastigophora), Apicomplexa, Microspora and Ciliophora.

Under the new classification system listed in Table 2.1, there are now nine phyla containing the genera of veterinary importance. The old phylum Microspora has been moved to the kingdom Fungi, as the phylum Microsporidia.

PHYLUM AMOEBOZOA

Members of the phylum Amoebozoa move by means of pseudopods, which are also used for feeding. Their cytoplasm is divided into endoplasm, containing food vacuoles and nucleus, and relatively clear ectoplasm. Reproduction is asexual by binary fission. Only a few species of the Sarcodina are pathogenic.

ORDER AMOEBIDA

FAMILY ENDAMOEBIDAE

Members of this family are parasitic in the digestive tract of vertebrates and invertebrates. Three genera contain parasites of animals and humans (*Entamoeba*, *Iodamoeba*, *Endolimax*) but only *Entamoeba* contains pathogenic species of veterinary significance. Genera are differentiated on the basis of their nuclear structure. The only species known to be pathogenic to mammals is *Entamoeba histolytica*.

Entamoeba

Members of the genus can be divided into distinct types based on the trophozoite and cyst structures and species within the groups are differentiated on the basis of size and hosts infected. Many species are probably synonymous.

Life cycle: Trophozoites divide by binary fission. Before encysting the amoebae round up, become smaller and lay down a cyst wall. Amoebae emerge from the cysts and grow into trophozoites.

The genus *Entamoeba* found in humans and animals has been arbitrarily divided into four groups based on trophozoite and cyst structure.

- 1 Histolytica group (*E. histolytica*, *E. hartmanni*, *E. equi*, *E. anatis*) in which the nucleus has a small central endosome, with a few scattered chromatin granules. Cysts when mature have four nuclei.
- 2 Coli group (*E. coli*, *E. wenyoni*, *E. muris*, *E. caviae*, *E. cuniculi*, *E. gallinarum*) in which there is a larger and eccentric nucleus with a ring of coarse peripheral granules and scattered chromatin granules between them. Cysts have eight nuclei.
- 3 Bovis group (*E. bovis*, *E. ovis*, *E. suis*, *E. chattoni*) in which the endosome of the nucleus varies in size and the ring of peripheral granules are fine or coarse. Cysts have one nucleus when mature.

Table 2.1 Classification of the Protozoa.

| Kingdom | Phylum | Class | Order | Family | Genus | | | | | | | |
|----------|-------------------|--|-----------------------|------------------|---|--|-----------------|---|---|---------------------------------------|----------------|--------------------|
| Protozoa | Amoebozoa | Archamoeba | Amoebida | Entamoebidae | <i>Entamoeba</i> <i>Iodamoeba</i> <i>Endolimax</i> | | | | | | | |
| | | | | Acanthamoebidae | <i>Acanthamoeba</i> | | | | | | | |
| | Percolozoa | Heterolobosea | Schizopyrenida | Vahlkampfiidae | <i>Naegleria</i> | | | | | | | |
| | Euglenozoa | Kinetoplasta | Trypanosomatida | Trypanosomatidae | <i>Leishmania</i> <i>Trypanosoma</i> | | | | | | | |
| | Parabasalia | Trichomonadea | Trichomonadida | Trichomonadidae | <i>Trichomonas</i> <i>Trichomonas</i> <i>Tetratrichomonas</i> <i>Trichomitus</i> <i>Pentatrichomonas</i> <i>Cochlosoma</i> | | | | | | | |
| | | | | | Dientamoebidae | <i>Histomonas</i> | | | | | | |
| | | | | | Monocercomonadidae | <i>Monocercomonas</i> <i>Chilomitus</i> <i>Dientamoeba</i> | | | | | | |
| | | | | | | Honigbergiellida | Hexamastigidae | <i>Hexamastix</i> | | | | |
| | | | | | Fornicata | Retortamonadea | Retortamonadida | Retortamonadorididae | <i>Retortamonas</i> <i>Chilomastix</i> | | | |
| | | | | Hexamitidae | | | | | <i>Spironucleus</i> <i>Caviomonas</i> | | | |
| | | | | | | | | Enteromonadidae | <i>Enteromonas</i> | | | |
| | | | | Metamonada | Trepomanadea | Giardiida | Giardiidae | <i>Giardia</i> | | | | |
| | | | | Preaxostyla | Anaeromonadea | Oxymonadida | Polymastigidae | <i>Monocercomonoides</i> | | | | |
| | | | | Apicomplexa | Conoidasida | Eucoccidiorida | Eimeriidae | <i>Eimeria</i> <i>Isospora</i> <i>Cyclospora</i> <i>Tyzzeria</i> <i>Wenyonella</i> <i>Caryospora</i> <i>Hoarella</i> <i>Octosporella</i> <i>Pythonella</i> <i>Atxoplasma</i> | | | | |
| | Cryptosporidiidae | <i>Cryptosporidium</i> | | | | | | | | | | |
| | Sarcocystiidae | <i>Besnoitia</i> <i>Hammondia</i> <i>Sarcocystis</i> <i>Neospora</i> <i>Frankelia</i> <i>Toxoplasma</i> | | | | | | | | | | |
| | | Lankesterellidae | <i>Lankesterella</i> | | | | | | | | | |
| | | Klossiellidae | <i>Klossiella</i> | | | | | | | | | |
| | | Hepatozoidae | <i>Hepatozoon</i> | | | | | | | | | |
| | | Haemogregarinidae | <i>Haemogregarina</i> | | | | | | | | | |
| | Aconoidasida | Haemospororida | Plasmodiidae | | | | | <i>Haemoproteus</i> <i>Hepatocystis</i> <i>Leucocytozoon</i> <i>Plasmodium</i> | | | | |
| | | | | | | | | Piroplasmorida | Babesiidae | <i>Babesia</i> | | |
| | | | | | | | | | Theileridae | <i>Theileria</i> <i>Cytauxzoon</i> | | |
| | | | | | | | | Ciliophora | Litostomatea | Trichostomatorida | Balantiidae | <i>Balantidium</i> |
| | | | | | | | | | | | Pycnotrichidae | <i>Buxtonella</i> |
| | Nyctotheridae | <i>Nyctotherus</i> | | | | | | | | | | |

- 4 Gingivalis group (*E. gingivalis*, *E. equibuccalis*, *E. suigingivalis*) in which the nucleus has a small central endosome and a ring of small peripheral granules. There are no cysts.
- 5 Others (*E. dedoelsti*, *E. invadens*).

Entamoeba species

| Species | Hosts | Site |
|---|---|---|
| Histolytica group | | |
| <i>Entamoeba histolytica</i> (syn. <i>Entamoeba dysenteriae</i> , <i>Endamoeba histolytica</i>) | Human, apes, monkeys, dog, cat, pig, rat | Large intestine, liver, lungs; rarely brain, spleen |
| <i>Entamoeba hartmanni</i> | Human, apes, monkeys | Caecum, colon |
| <i>Entamoeba equi</i> | Horse | Caecum, colon |
| <i>Entamoeba anatis</i> | Duck | Caeca |
| Coli group | | |
| <i>Entamoeba coli</i> (syn. <i>Amoeba coli</i> , <i>Endamoeba hominis</i> , <i>Entamoeba cynocephalusae</i>) | Human, apes, monkeys; reported in pig and deer (white-tailed) | Caecum, colon |
| <i>Entamoeba wenyoni</i> | Goat | Caecum, colon |
| <i>Entamoeba muris</i> | Rat, mouse | Caecum, colon |
| <i>Entamoeba caviae</i> | Guinea pig | Caecum |
| <i>Entamoeba cuniculi</i> | Rabbit | Caecum |
| <i>Entamoeba gallinarum</i> | Chicken, turkey, duck, goose, guinea fowl | Caeca |
| Bovis group | | |
| <i>Entamoeba bovis</i> | Cattle, deer | Rumen |
| <i>Entamoeba ovis</i> | Sheep, goat | Large intestine |
| <i>Entamoeba suis</i> | Pig | Caecum, colon |
| <i>Entamoeba chattoni</i> | Monkeys; rarely human | Caecum, colon |
| Gingivalis group | | |
| <i>Entamoeba gingivalis</i> (syn. <i>Amoeba gingivalis</i> , <i>Amoeba buccalis</i> , <i>Amoeba dentalis</i> , <i>Entamoeba buccalis</i> , <i>Entamoeba maxillaris</i> , <i>Entamoeba canibuccalis</i>) | Human, chimpanzee, macaques, baboons | Mouth |
| <i>Entamoeba equibuccalis</i> | Horse | Mouth |
| <i>Entamoeba suigingivalis</i> | Pig | Mouth, teeth |
| Others | | |
| <i>Entamoeba gedoelsti</i> | Horse | Caecum, colon |
| <i>Entamoeba invadens</i> | Reptiles | Intestines |

Entamoeba histolytica

Description: Two forms of the parasite exist. Trophozoites of the large form are 20–30 µm in diameter; those of the small form are 12–15 µm. The nucleus, when stained, has a small central endosome with a ring of small peripheral granules. The cysts of both forms are 10–12 µm in size and contain four nuclei when mature and often contain rod-like chromatin bodies with rounded ends.

Entamoeba bovis, Entamoeba ovis, Entamoeba suis

Description: Trophozoites vary in size from 5 to 25 µm in diameter. The endosome of the nucleus varies in size with a ring of peripheral

granules of varying sizes around its periphery. The cysts are 4–17 µm in diameter and contain a single nucleus when mature. A large glycogen granule may or may not be present.

Entamoeba coli, Entamoeba muris, Entamoeba caviae, Entamoeba cuniculi

Description: The nucleus is large and eccentric and has a ring of coarse peripheral granules with scattered chromatin granules. The cysts have eight nuclei and splinter-like chromatin granules. Glycogen granules, when present, are fairly well defined.

Entamoeba gingivalis, Entamoeba equibuccalis, Entamoeba suigingivalis

Description: Trophozoites vary in size (10–20 µm long) and have no cysts. The nucleus has a small central endosome and a ring of small peripheral granules.

Entamoeba gedoelsti

Description: Trophozoites are 7–13 µm in diameter. The nucleus has an eccentric endosome and a row of relatively coarse chromatin granules around its periphery. Cysts have not been reported.

Entamoeba invadens

Description: Trophozoites are 11–20 µm and cysts approximately 16 µm.

Iodamoeba

A single species is recognised with a large nuclear endosome rich in chromatin surrounded by a layer of globules. The cysts each contain a large glycogen body.

Iodamoeba species

| Species | Hosts | Site |
|-----------------------------|---------------------------|------------------|
| <i>Iodamoeba buetschlii</i> | Pig, human, apes, monkeys | Caecum and colon |

Iodamoeba buetschlii

Description: Trophozoites are 4–20 µm with blunt pseudopods that form slowly. The nucleus is large and contains a large nuclear endosome rich in chromatin surrounded by a layer of globules. The cysts are irregular in form, ranging from 5 to 14 µm and contain a single nucleus and a large glycogen body.

Endolimax

Small amoebae 6–15 µm in diameter with a vesicular nucleus containing a large irregular-shaped endosome composed of chromatin granules. Mature cysts are generally oval and contain four nuclei.

Endolimax species

| Species | Hosts | Site |
|---|---|---------------|
| <i>Endolimax nana</i> (syn. <i>Amoeba limax</i> , <i>Entamoeba nana</i> , <i>Endolimax intestinalis</i> , <i>Endolimax suis</i> , <i>Endolimax ratti</i>) | Human, pig, apes, monkeys, rat | Caecum, colon |
| <i>Endolimax caviae</i> | Guinea pig | Caecum |
| <i>Endolimax gregariniformis</i> | Chicken, turkey, guinea fowl, pheasant, goose, duck, wild birds | Caeca |

Endolimax nana

Description: Trophozoites are 6–15 µm with granular vacuolated cytoplasm and a nucleus which contains an irregular endosome composed of chromatin granules. Mature cysts are oval, 8–10 µm long, and contain four nuclei.

FAMILY ACANTHAMOEBIDAE

Members of this family are found in soil and water and have a specific form of pseudopodia (acanthopodia) that are continuously formed and resorbed to induce locomotion. Most species are free-living, but some *Acanthamoeba* species are opportunistic pathogens in animals and humans.

PHYLUM PERCOLOZOA

Members of this phylum are free-living amoebae in soil, water and faeces and can exist in either amoeboid or flagellate forms.

ORDER SCHIZOPYRENIDA**FAMILY VAHLKAMPFIDAE**

Includes the genus *Naegleria*, which is an opportunist pathogen of animals and humans.

Naegleria

Description: The trophozoites are characterised by a nucleus and a surrounding halo. They travel by pseudopodia, temporary round processes which fill with granular cytoplasm. The pseudopodia form at different points along the cell, thus allowing the trophozoite to change directions.

Naegleria species

| Species | Hosts | Site |
|--------------------------|--|-------------------|
| <i>Naegleria fowleri</i> | Human, various animals including cattle, monkeys, reptiles | Nasal mucosa, CNS |

PHYLUM EUGLENOZOA

These are flagellate protozoa having one or more flagella. Multiplication is mainly asexual by binary fission with some species producing cysts.

CLASS KINETOPLASTA**ORDER TRYPANOSOMATIDA**

The haemoflagellates all belong to the family Trypanosomatidae, and include the trypanosomes and leishmanias.

FAMILY TRYPANOSOMATIDAE

Members of the genus *Trypanosoma* are found in the bloodstream and tissues of vertebrates throughout the world. However, a few species are of overwhelming importance as a serious cause of morbidity and mortality in animals and humans in tropical regions. With one exception – *T. equiperdum*, which is transmitted venereally – all have an arthropod vector. Trypanosomosis is one of the world's most important diseases of animals and humans. Most African species are transmitted by the tsetse fly (*Glossina*).

MORPHOLOGY

Trypanosomes have a leaf-like or rounded body containing a vesicular nucleus, and a varying number of sub-pellicular microtubules lying beneath the outer membrane. There is a single flagellum arising from a **kinetosome** or basal granule. An undulating membrane is present in some genera and the flagellum lies on its outer border. Posterior to the kinetosome is a rod-shaped or spherical **kinetoplast** containing DNA. Members of this family were originally parasites of the intestinal tract of insects, and many are still found in insects. Others are heteroxenous, spending part of their life cycle in a vertebrate host and part in an invertebrate host.

Members of the genus *Trypanosoma* are heteroxenous and pass through amastigote, promastigote, epimastigote and trypomastigote stages in their life cycle. In some species only trypomastigote forms are found in the vertebrate host; in others, presumably more primitive species, both amastigote and trypomastigote forms are present.

- In the **trypomastigote** form, the kinetoplast and kinetosome are near the posterior end and the flagellum forms the border of an undulating membrane that extends along the side of the body to the anterior end.
- In the **epimastigote** form, the kinetoplast and kinetosome are just posterior to the nucleus and the undulating membrane runs forward from there.
- In the **promastigote** form, the kinetoplast and kinetosome are still further anterior in the body and there is no undulating membrane.
- In the **amastigote** form, the body is rounded and the flagellum emerges from the body through a wide funnel-shaped reservoir.

THE TRANSMISSION OF TRYPANOSOME INFECTION IN ANIMALS

With one exception, all trypanosomes have arthropod vectors in which transmission is either cyclical or non-cyclical.

In **cyclical transmission** the arthropod is a necessary intermediate host in which the trypanosomes multiply, undergoing a series of morphological transformations before forms infective for the next mammalian host are produced. When multiplication occurs in the digestive tract and proboscis, so that the new infection is transmitted when feeding, the process is known as **anterior station**

development; the various species of trypanosomes which use this process are often considered as a group, the **Salivaria**. All are trypanosomes transmitted by tsetse flies, the main species being *Trypanosoma congolense* (subgenus *Nanomonas*), *T. vivax* (subgenus *Duttonella*) and *T. brucei* (subgenus *Trypanozoon*).

In other trypanosomes, multiplication and transformation occur in the gut and the infective forms migrate to the rectum and are passed with the faeces; this is **posterior station development** and the trypanosome species are grouped together as the **Stercoraria**. In domestic animals, these are all relatively non-pathogenic trypanosomes such as *T. theileri* and *T. melophagium* transmitted by tabanid flies and sheep keds, respectively. This is certainly not the case in humans, in which *T. cruzi*, the cause of the serious Chagas' disease in South America, is transmitted in the faeces of reduviid bugs.

Non-cyclical transmission is essentially mechanical transmission in which the trypanosomes are transferred from one mammalian host to another by the interrupted feeding of biting insects, notably tabanids and *Stomoxys*. The trypanosomes in or on the contaminated proboscis do not multiply and die quickly so that cross-transmission is only possible for a few hours. *Trypanosoma evansi*, widely distributed in livestock in Africa and Asia, is transmitted mechanically by biting flies. However, in Central and South America, *T. evansi* is also transmitted by the bites of vampire bats in which the parasites are capable of multiplying and surviving for a long period. Strictly speaking, this is more than mere mechanical transmission, since the bat is also a host, although it is certainly non-cyclical, since the multiplying trypanosomes in the bat's blood do not undergo any morphological transformation before they migrate into the buccal cavity.

It is important to note that the salivarian trypanosomes, normally transmitted cyclically in tsetse flies, may on occasions be transmitted mechanically. Thus, in South America, *T. vivax* has established itself, presumably by the importation of infected cattle, and is thought to be transmitted mechanically by biting flies.

Finally, apart from classical cyclical and non-cyclical transmission, dogs, cats and wild carnivores may become infected by eating fresh carcasses or organs of animals that have died of trypanosomosis, the parasites penetrating oral abrasions.

The important trypanosome infections of domestic animals differ considerably in many respects and are best treated separately. The African species responsible for the 'tsetse-transmitted trypanosomoses' (i.e. Salivaria) are generally considered to be the most significant.

Trypanosoma

A number of species of *Trypanosoma*, found in domestic and wild animals, are all transmitted cyclically by *Glossina* in much of sub-Saharan Africa. Reproduction in the mammalian host is continuous, taking place in the trypomastigote stage. Salivarian trypanosomes are highly pathogenic for certain mammals, such that the presence of trypanosomosis precludes the rearing of livestock in many areas, while in others, where the vectors are not so numerous, trypanosomosis is often a serious problem, particularly in cattle. The disease, sometimes known as nagana, is characterised by lymphadenopathy and anaemia accompanied by progressive emaciation and, often, death.

Salivarian trypanosomes are elongated spindle-shaped protozoa ranging from 8.0 to 39 µm long and the posterior end of the body is usually blunt. All possess a flagellum, which arises at the posterior end of the trypanosome from a basal body at the foot of a flagellar pocket. The flagellum runs to the anterior end of the body and is attached

along its length to the pellicle to form an undulating membrane. Thereafter the flagellum may continue forward as a free flagellum. Within a stained specimen, a single centrally placed nucleus can be seen, and adjacent to the flagellar pocket is a small structure, the kinetoplast, which contains the DNA of the single mitochondrion.

In stercorarian trypanosomes, the free flagellum is always present in the trypomastigote and the kinetoplast is large and not terminal. The posterior end of the body is pointed. Multiplication in the mammalian host is discontinuous, typically taking place in the epimastigote or amastigote stages with the trypomastigotes typically not pathogenic.

Trypanosoma species

| Species | Subgenus | Hosts | Vector |
|---|-----------------------|---|---|
| Salivarian | | | |
| <i>Trypanosoma vivax</i> | <i>Duttonella</i> | Cattle, sheep, goat, horse, camel, wild ruminants | Tsetse flies |
| <i>Trypanosoma congolense</i> | <i>Nanomonas</i> | Cattle, sheep, goat, horse, camel, pig, wild ruminants | Tsetse flies |
| <i>Trypanosoma simiae</i> | <i>Nanomonas</i> | Pig, camel, sheep, goat | Tsetse flies |
| <i>Trypanosoma brucei</i> <i>T. brucei brucei</i> <i>T. brucei evansi</i> | <i>Trypanozoon</i> | Cattle, sheep, goat, horse, donkey, camel, pig, dog, cat, wild game animals | Tsetse flies (<i>T. b. evansi</i> : <i>Tabanus</i> , <i>Stomoxys</i> , <i>Haematopota</i> , <i>Stomoxys</i>) |
| <i>T. brucei gambiense</i> <i>T. brucei rhodesiense</i> <i>T. brucei equiperdum</i> | | Human Horse | Tsetse flies None (coitus) |
| <i>Trypanosoma suis</i> | <i>Pycnomonas</i> | Pig | Tsetse flies |
| <i>Trypanosoma avium</i> | <i>Trypanomorpha</i> | Birds | Biting insects, red mites |
| <i>Trypanosoma gallinarum</i> | <i>Trypanomorpha</i> | Chicken | Biting insects |
| Stercorarian | | | |
| <i>Trypanosoma theileri</i> | <i>Megatrypanum</i> | Cattle, wild ruminants | Tabanid, hippoboscids flies |
| <i>Trypanosoma melophagium</i> | <i>Megatrypanum</i> | Sheep | Sheep ked |
| <i>Trypanosoma cervi</i> | <i>Megatrypanum</i> | Deer | Tabanid, hippoboscids flies |
| <i>Trypanosoma lewsi</i> | <i>Herpetosoma</i> | Rat | Fleas |
| <i>Trypanosoma musculi</i> | <i>Herpetosoma</i> | Mouse | Fleas |
| <i>Trypanosoma cruzi</i> | <i>Schizotrypanum</i> | Human, primates, dogs, cats | Reduviid bugs |

SALIVARIAN TRYPANOSOMES

SUBGENUS DUTTONELLA

These are monomorphic trypanosomes with a free flagellum and large kinetoplast, which is usually terminal. Development in the tsetse fly vector occurs only in the proboscis.

Trypanosoma vivax

Description: *Trypanosoma vivax* is monomorphic, ranging in size from 20 to 27 µm. The undulating membrane is inconspicuous, the

Fig. 2.4 *Trypanosoma vivax* is monomorphic and has a short flagellum and terminal kinetoplast.

large kinetoplast is terminal and the posterior end is broad and rounded. A short free flagellum is present (Fig. 2.4). In fresh blood films, *T. vivax* moves rapidly across the microscope field.

Life cycle: Development in the insect vector takes place only in the proboscis. The trypanosomes turn first into the epimastigote form and then the metacyclic infective trypanosomes, which pass to the hypopharynx and infect new hosts when the tsetse flies bite and feed.

SUBGENUS NANNOMONAS

These are small forms usually without a free flagellum and a typically marginal medium-sized kinetoplast. Development in the tsetse fly vector occurs in the midgut and proboscis.

Trypanosoma congolense

Description: *Trypanosoma congolense* is small, monomorphic in form and 8–20 μm long. The undulating membrane is inconspicuous, the medium-sized kinetoplast is marginal and the posterior end is blunt. There is no free flagellum (Fig. 2.5). In fresh blood films the organism moves sluggishly, often apparently attached to red cells.

Life cycle: The trypanosomes divide by longitudinal binary fission in the vertebrate host. After ingestion by the tsetse fly they develop in the midgut as long tryptomastigotes without a free flagellum. They attach first to the wall of the proboscis and multiply there for a time before passing to the hypopharynx where they develop into metacyclic infective tryptomastigotes similar in appearance to the blood forms. These are injected into the vertebrate when the fly bites. Development to the infective stage in *Glossina* takes from 15 to well over 20 days at 23–34°C.

SUBGENUS TRYPANOZOON

These are pleomorphic (slender to stumpy) forms with or without a free flagellum and with a small subterminal kinetoplast. Development occurs in the midgut and salivary glands of the tsetse fly

Fig. 2.5 *Trypanosoma congolense* is monomorphic and possesses a marginal kinetoplast.

vector. Some forms are transmitted mechanically by tabanid vectors or by contact.

Trypanosoma brucei

Description: *Trypanosoma brucei* is pleomorphic in form and ranges from long and slender, up to 42 μm (average 29 μm), to short and stumpy, 12–26 μm (mean 18 μm), the two forms often being present in the same blood sample. The undulating membrane is conspicuous, the kinetoplast is small and subterminal and the posterior end is pointed. In the slender form the kinetoplast is up to 4 μm from the posterior end, which is usually drawn out, tapering almost to a point, and has a well-developed free flagellum; in the stumpy form the flagellum is either short or absent and the posterior end is broad and rounded with the kinetoplast almost terminal. Intermediate forms average 23 μm long and have a blunt posterior end and moderately long flagellum (Fig. 2.6). A fourth form with a posterior nucleus may be seen in laboratory animals. In fresh unfixed blood films, the organism moves rapidly within small areas of the microscope field.

Fig. 2.6 *Trypanosoma brucei* is pleomorphic, showing (a) long slender, (b) short stumpy and (c) intermediate forms.

Life cycle: Tsetse flies ingest trypanosomes in the blood or lymph while feeding on an infected host. Thereafter the trypanosomes lose their glycoprotein surface coat, and become elongated and multiply in the midgut before migrating forward to the salivary glands. There they undergo a transformation, losing their typical trypanosome, or trypomastigote, form and acquire an epimastigote form, characterised by the fact that the kinetoplast lies just in front of the nucleus. After further multiplication of the epimastigotes, they transform again into small typically trypomastigote forms with a glycoprotein surface coat. These are the infective forms for the next host and are called **metacyclic** trypanosomes. The entire process takes at least 2–3 weeks and the metacyclic trypanosomes are inoculated into the new host when the tsetse fly feeds. At the site of inoculation the metacyclic forms multiply locally as the typical blood forms, producing within a few days a raised cutaneous inflammatory swelling called a **chancre**. Thereafter they enter the bloodstream and multiply; a parasitaemia, detectable in the peripheral blood, usually becomes apparent 1–3 weeks later. Subsequently, the parasitaemia may persist for many months, although its level may wax and wane due to the immune response of the host.

Trypanosoma equiperdum

Description: The organism is identical to, and structurally indistinguishable in appearance from, *T. brucei evansi*. The organism is polymorphic, with slender, intermediate and stumpy forms. The mean length varies considerably, with typical forms 15–34 μm long (mean 24 μm). The undulating membrane is conspicuous and the kinetoplast small and subterminal. Strains that lack a kinetoplast, visible with the light microscope, have occasionally arisen spontaneously or can be produced by treatment with certain dyes, drugs or frozen storage.

Life cycle: The trypanosome is transmitted at coitus. The organism divides by longitudinal binary fission in various tissue fluids, particularly in subcutaneous urticarial plaques and in the reproductive system.

SUBGENUS PYCNOMONAS

These are stout monomorphic forms with short free flagellum and small subterminal kinetoplast. Development in the tsetse fly vector occurs in the midgut and salivary glands.

Trypanosoma suis

Description: Trypomastigotes are monomorphic, stout, 14–19 μm long with a small marginal kinetoplast and a short free flagellum.

SUBGENUS TRYPANOMORPHA

These are pleomorphic, often large trypanosomes, with a long flagellum. Development occurs in biting flies.

Trypanosoma gallinarum

Description: Pleomorphic organisms, 26–29 μm long, or even longer, with a free flagellum.

Life cycle: Multiplication occurs in the avian host by longitudinal binary fission of the epimastigote form in various tissues. Following ingestion by the invertebrate host, they multiply in the midgut before migrating forward to the salivary glands, forming trypomastigotes. Metacyclic trypanosomes are inoculated into the new host when the arthropod feeds.

STERCORARIAN TRYPANOSOMES

SUBGENUS MEGATRYPANUM

These are large mammalian trypanosomes with the kinetoplast typically situated near the nucleus and far from the posterior end of the body. Known vectors are hippoboscids or tabanid flies.

Trypanosoma theileri

Description: Large trypanosome, 60–70 μm in length, although they may be up to 120 μm with the posterior end long and pointed (Fig. 2.7). There is a medium-sized kinetoplast with a prominent undulating membrane and a free flagellum. Both trypomastigote and epimastigote forms may appear in the blood.

Life cycle: Multiplication occurs in the vertebrate host by longitudinal binary fission of the epimastigote form in the lymph nodes and various tissues. The trypanosomes develop into small metacyclic trypomastigotes in the hindgut of tabanid flies (stercorarian development). Transmission back to the vertebrate host occurs through fly faeces, containing the parasite, deposited on mucous membranes.

Fig. 2.7 *Trypanosoma theileri* is a large trypanosome with a prominent undulating membrane.

SUBGENUS HERPETOSOMA

These trypanosomes are of medium size with a subterminal kinetoplast lying at some distance from the pointed end of the body. Reproduction in the mammalian host is in the amastigote and/or epimastigote stages. Fleas are the main vectors.

SUBGENUS SCHIZOTRYPANUM

These are relatively small, typically 'C'-shaped trypanosomes with a large kinetoplast close to the short, pointed posterior end of the

body. Multiplication in the mammalian host is typically intracellular, primarily in the amastigote form and secondarily in the epimastigote form. Known vectors are reduviid bugs.

Trypanosoma cruzi

Description: Trypanosomes are monomorphic, 16–20 µm long, with a pointed posterior end and a curved stumpy body and a narrow undulating membrane with a trailing flagellum. The kinetoplast is large and subterminal, causing the body to bulge around it. Amastigotes are 1.5–4 µm in diameter and occur in groups.

Life cycle: Tryptomastigote forms enter cells of the reticuloendothelial system, muscles and especially the heart, where they form rounded amastigotes. These multiply by binary fission, forming groups of parasites that turn into trypomastigote forms and which re-enter the blood. The vectors of *T. cruzi* are kissing bugs (Reduviidae) and, once ingested, the trypomastigotes pass to the midgut where they turn into amastigote forms. These multiply by binary fission and turn into either metacyclic trypomastigote or epimastigote forms. Epimastigote forms multiply further and extend into the rectum, where they turn into metacyclic trypomastigotes, which pass out in the faeces. Infective trypomastigotes can actively penetrate the mucous membrane or skin of the final host.

Leishmania

Leishmania are ovoid organisms within the macrophage and possess a rod-shaped kinetoplast associated with a rudimentary flagellum. The parasites are found as the amastigote stage in cells of the vertebrate host and as the promastigote stage in the intestine of the sandfly.

In the vertebrate host *Leishmania* is found in the macrophages and other cells of the reticuloendothelial system in the skin, spleen, liver, bone marrow, lymph nodes and mucosa. It may also be found in leucocytes in the blood.

Life cycle: After ingestion by a sandfly, the leishmanial, or amastigote, form transforms in the insect gut into a promastigote form in which the kinetoplast is situated at the posterior end of the body (Fig. 2.8a). These divide repeatedly by binary fission, migrate to the proboscis, and when the insect subsequently feeds are inoculated into a new host. Once within a macrophage the promastigote reverts to the amastigote form (Fig. 2.8b) and again starts to divide.

Leishmania occur primarily in mammals, although 10 species have been described in Old World lizards. They cause disease in human, dogs and various rodents. *Leishmania* have a heteroxenous life cycle, and are transmitted by sandflies of the genus *Phlebotomus* in the Old World and *Lutzomyia* in the New World.

Hypopylaria are primitive species found in Old World lizards, which become infected following ingestion of sandflies. Development occurs in the sandfly hindgut.

Peripylaria develop in both the hindgut and foregut of sandflies and infect both lizards and mammals. Transmission in mammals is by bite of sandflies.

Suprapylaria develop in the sandfly midgut and foregut and occur only in mammals, with transmission by sandfly bite.

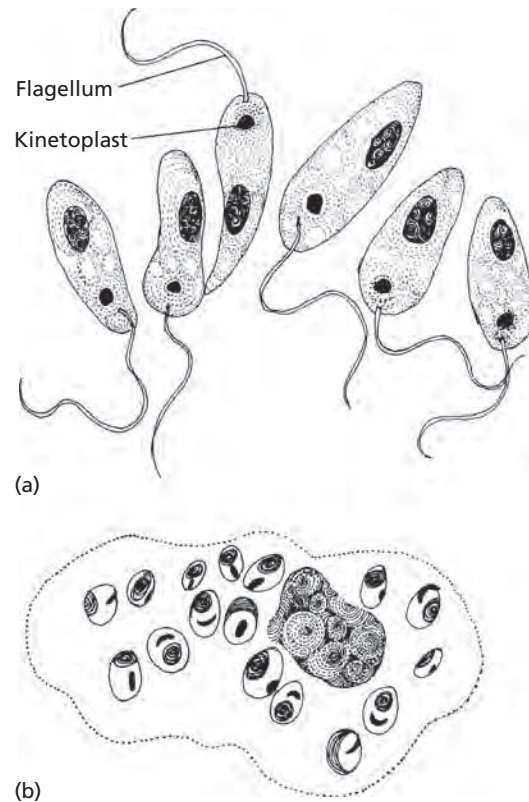

Fig. 2.8 *Leishmania*: (a) promastigote form; (b) amastigote form.

***Leishmania* species**

| Species | Hosts | Site | Vector |
|---|------------------------------|--------------|--|
| <i>Leishmania donovani</i> complex | Human, dog, | Skin, liver, | Sandflies |

PHYLUM PARABASALIA

CLASS TRICHOMONADEA

ORDER

Members of the families Trichomonadidae, Dientamoebidae and Monocercomonadidae occur predominantly in the gastrointestinal tract of vertebrates. While many are considered to be commensals, some may be important causes of enteritis and diarrhoea.

FAMILY TRICHOMONADIDAE

The family Trichomonadidae ('trichomonads') includes a number of genera of medical and veterinary interest: *Tritrichomonas*, *Trichomonas*, *Tetratrichomonas*, *Trichomitus* and *Pentatrichomonas*. Trichomonads have three to five flagella, of which one is usually recurrent and attached to an undulating membrane, and have been

found in the caecum and colon of virtually every species of mammals and birds, and also in reptiles, amphibians, fish and invertebrates. Specific identification and host–parasite relationships of many species remains unclear and several species are thought to be synonymous.

Tritrichomonas in cattle is an important venereal disease causing infertility and abortion.

Tritrichomonas

Members of this genus have three anterior flagella and a posterior flagellum and lack a pelta.

Life cycle: The trichomonads reproduce by longitudinal binary fission. No sexual stages are known and there are no cysts.

Tritrichomonas species

| Species | Hosts | Site |
|---|--------------------------------|--|
| <i>Tritrichomonas eberthi</i> (syn. <i>Trichomonas eberthi</i>) | Chicken, turkey | Caeca |
| <i>Tritrichomonas foetus</i> (syn. <i>Trichomonas foetus</i>) | Cattle Cat | Prepuce, uterus Small intestine |
| <i>Tritrichomonas muris</i> (syn. <i>Trichomonas criceti</i>) | Mouse, rat, vole | Large intestine |
| <i>Tritrichomonas suis</i> (syn. <i>Trichomonas suis</i>) (considered synonymous with <i>T. foetus</i>) | Pig | Nasal passages, stomach, caecum, colon |
| <i>Tritrichomonas enteris</i> (syn. <i>Trichomonas enteris</i>) | Cattle, zebu | Caecum, colon |
| <i>Tritrichomonas minuta</i> | Rat, mouse, hamster | Large intestine |
| <i>Tritrichomonas wenyoni</i> (syn. <i>Trichomitus wenyoni</i>) | Rat, mouse, hamster, monkey | Large intestine |
| <i>Tritrichomonas caviae</i> | Guinea pig | Caecum |

Tritrichomonas eberthi

Description: The body is elongate, 8–14 by 4–7 μm , with vacuolated cytoplasm and three anterior flagella. The undulating membrane is prominent and extends the full length of the body. The posterior flagellum extends about half the length of the body beyond the undulating membrane (Fig. 2.9). An accessory filament is present. The blepharoplast is composed of four granules; the axostyle is massive and hyaline, and its anterior end is broadened to form a capitulum and a ring of chromatin granules is present at the point that the axostyle emerges from the body. The parabasal body is shaped like a flattened rod and is of variable length.

Tritrichomonas foetus

Description: The organism is pear-shaped, approximately 10–25 μm long and 3–15 μm wide and has a single nucleus and four flagella, each arising from a basal body situated at the anterior rounded end. Three of the flagella are free anteriorly, while the fourth extends backwards to form an undulating membrane along the length of the organism and then continues posteriorly as a free flagellum (Fig. 2.10). The axostyle, a hyaline rod with a skeletal function, extends the length of the cell and usually projects posteriorly. The costa is prominent but there is no pelta.

Fig. 2.9 *Tritrichomonas eberthi*.

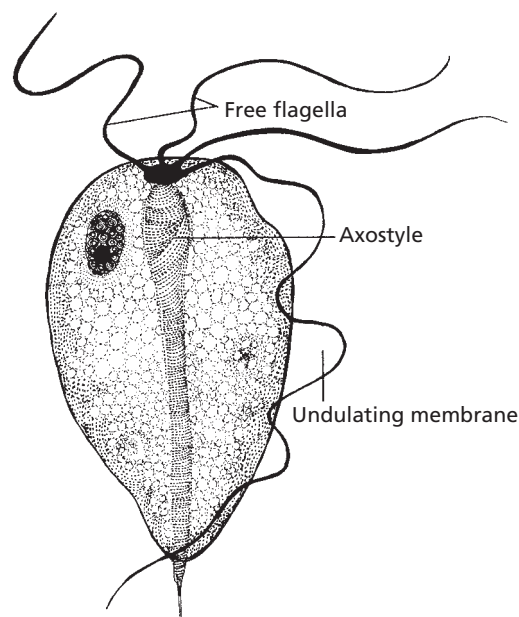

Fig. 2.10 *Tritrichomonas foetus*.

Tritrichomonas muris

Description: The body is pyriform, 12–20 μm long, and there are three anterior flagella, which arise from a conspicuous blepharoplast. The undulating membrane is prominent and extends the length of the body in ribbon-like folds bounded by a thick marginal filament, which extends beyond the body as a free trailing

Fig. 2.11 *Tritrichomonas suis*.

flagellum. The costa is well developed and the axostyle is present as a thick tubular structure and has a short posterior extension.

Tritrichomonas suis

Description: The body is characteristically elongate or spindle-shaped, but may occasionally be piriform or rotund, 9–16 by 2–6 μm (mean $11 \times 3 \mu\text{m}$), with three anterior flagella, which are approximately equal in length and each ending in a round or spatulate knob. The undulating membrane runs the full length of the body and has four to six folds and its marginal filament continues as a posterior free flagellum (Fig. 2.11). An accessory filament is present. The costa runs the full length of the body, and fine subcostal granules are present. The axostyle is a hyaline rod with a bulbous capitulum and extends beyond the body as a cone-shaped projection narrowing abruptly to a short tip. There is a chromatic ring around its point of exit. The parabasal body is usually a single, slender, tube-like structure, and the nucleus is ovoid or elongated and has a large conspicuous endosome surrounded by a relatively clear halo.

Tritrichomonas enteris

Description: The body measures 6–12 by 5–6 μm and there are three anterior flagella of equal length, which arise from a single blepharoplast. The flagellum at the edge of the undulating membrane is single and lacks an accessory filament. The undulating membrane extends three-quarters of the body length and a free flagellum extends beyond the undulating membrane. The axostyle is straight and slender, bending around the nucleus to give a spoon-shape and extending at most one-quarter of the body length beyond the body.

Tritrichomonas minuta

Description: The body measures 4–9 μm long and there are three anterior flagella. The undulating membrane extends almost the length of the body and there is a trailing posterior flagellum.

Tritrichomonas wenyoni

Description: The body measures 4–16 μm long and there are three anterior flagella. The undulating membrane extends the length of the body and has a long trailing posterior flagellum. The axostyle is broad and hyaline.

Tritrichomonas caviae

Description: The body is 10–22 μm long with a flat cylindrical nucleus, three anterior flagella and a prominent undulating membrane extending the length of the body (Fig. 2.12). The axostyle is well defined with a prominent costa.

Trichomonas

Members of this genus have four anterior flagella, an undulating membrane but no trailing flagellum.

Trichomonas species

| Species | Hosts | Site |
|--|---|--|
| <i>Trichomonas gallinae</i> (syn. <i>Cercomonas gallinae</i> , <i>Trichomonas columbae</i>) | Pigeon, turkey, raptors (hawks, falcons, eagles) | Pharynx, oesophagus, crop, proventriculus |

Fig. 2.12 *Tritrichomonas caviae*.

Trichomonas gallinae

Description: The body is elongate, ellipsoidal or pyriform, 5–19 by 2–9 μm , with four anterior flagella that arise from the blepharoplast. The undulating membrane does not reach the posterior end of the body and a free posterior flagellum is absent (Fig. 2.13). An accessory filament is present. The axostyle is narrow, protrudes 2–8 μm from the body and its anterior portion is flattened into a spatulate capitulum. There is a crescent-shaped pelta anterior to the axostyle and there is no chromatic ring at its point of emergence. The parabasal body is hook-shaped and has a parabasal filament and the costa is a very fine rod running three-quarters the length of the body.

Tetratrichomonas

Members of this genus have four flagella, a posterior (trailing) flagellum, an undulating membrane and a pelta.

Life cycle: Reproduction is by longitudinal binary fission. No sexual stages are known and there are no cysts.

Tetratrichomonas species

| Species | Hosts | Site |
|--|---|---------------------------|
| <i>Tetratrichomonas anatis</i> (syn. <i>Trichomonas anatis</i>) | Duck | Small and large intestine |
| <i>Tetratrichomonas anseris</i> (syn. <i>Trichomonas anseris</i>) | Goose | Caeca |
| <i>Tetratrichomonas buttrei</i> (syn. <i>Trichomonas buttrei</i>) | Cattle, pig | Caecum, colon |
| <i>Tetratrichomonas canistomae</i> | Dog | Mouth |
| <i>Tetratrichomonas felistomae</i> | Cat | Mouth |
| <i>Tetratrichomonas gallinarum</i> (syn. <i>Trichomonas gallinarum</i> , <i>Trichomonas pullorum</i>) | Chicken, turkey, guinea fowl, quail, pheasant | Caeca |
| <i>Tetratrichomonas microti</i> (syn. <i>Trichomonas microti</i>) | Rat, mouse, hamster, vole | Large intestine |
| <i>Tetratrichomonas ovis</i> (syn. <i>Trichomonas ovis</i> , <i>Ditrichomonas ovis</i>) | Sheep | Caecum, rumen |
| <i>Tetratrichomonas pavlovi</i> (syn. <i>Trichomonas pavlovi</i> , <i>Trichomonas bovis</i>) | Cattle | Large intestine |

Tetratrichomonas anatis

Description: The body is broadly beet-shaped, 13–27 by 8–18 μm , with four anterior flagella, and an undulating membrane that extends most of the length of the body and terminates in a free posterior flagellum. There is a costa and a slender fibrillar axostyle.

Tetratrichomonas anseris

Description: The body is elongate, 8–14 by 4–7 μm , with vacuolated cytoplasm and three anterior flagella. The undulating membrane is prominent and extends the full length of the body. The posterior flagellum extends about half the length of the body beyond the undulating membrane. An accessory filament is

Fig. 2.13 *Trichomonas gallinae*.

present. The blepharoplast is composed of four granules; the axostyle is massive and hyaline, and its anterior end is broadened to form a capitulum. A ring of chromatin granules is present at the point that the axostyle emerges from the body. The parabasal body is shaped like a flattened rod and is of variable length.

Tetratrichomonas buttrei

Description: The body is ovoid or ellipsoidal, and 4–7 by 2–5 μm (mean 6 \times 3 μm) in size. Cytoplasmic inclusions are frequently present. There are three or four anterior flagella, which vary in length from a short stub to more than twice the length of the body, and each ends in a knob or spatulate structure. The undulating membrane runs the full length of the body and has three to five undulations ending in a free posterior flagellum. The accessory filament is prominent, and the costa relatively delicate. The axostyle is relatively narrow, has a spatulate capitulum and extends 3–6 μm beyond the body. There is no chromatic ring at its point of exit. A pelta is present. The nucleus is frequently ovoid (2–3 \times 1–2 μm) but is variable in shape and has a small endosome.

Tetratrichomonas canistomae

Description: The body is pyriform, 7–12 by 3–4 μm . The four anterior flagella are about as long as the body and arise in pairs from a large blepharoplast. The undulating membrane extends almost the length of the body, and terminates in a free posterior flagellum, which is about half the length of the body (Fig. 2.14). The axostyle is thread-like and extends a considerable length beyond the body.

Fig. 2.14 *Tetratrichomonas canistomae*.

Tetratrichomonas felistomae

Description: The body is piriform, 6–11 by 3–4 μm (mean $8 \times 3 \mu\text{m}$). There are four anterior flagella, which are longer than the body. The undulating membrane extends most of the body length and terminates in a free posterior flagellum and the axostyle extends a considerable distance beyond the body.

Tetratrichomonas gallinarum

Description: The body is piriform and is 7–15 by 3–9 μm . There are four anterior flagella, and a posterior flagellum that runs along the undulating membrane and extends beyond it. An accessory filament is present. The axostyle is long, pointed and slender, and lacks a chromatic ring at its point of emergence. Supracostal granules are present, but there are no subcostal or endoaxostylar granules. The pelta is elaborate and terminates in a short ventral extension which is more or less free from the ventral edge of the axostyle. The parabasal body usually consists of a ring of variously spaced granules plus one or two fibrils or rami.

Tetratrichomonas microti

Description: The body is 4–9 μm long and there are four anterior flagella. The undulating membrane extends almost the length of the body and there is a trailing posterior flagellum (Fig. 2.15). The axostyle is slender.

Tetratrichomonas ovis

Description: The body is pyriform, 6–9 by 4–8 μm (mean $7 \times 6 \mu\text{m}$) and the four anterior flagella are of unequal length. There is

Fig. 2.15 *Tetratrichomonas microti*.

a slender hyaline axostyle which extends approximately 5 μm beyond the body and gradually tapers to a point. There is no chromatic ring at the point at which the axostyle leaves the body. There is an anterior nucleus, and a prominent pelta at the anterior end. There is a prominent undulating membrane which extends 75–100% the length of the body, and which continues as a free posterior flagellum. The costa is prominent and there are several irregular rows of paracostal granules, and an ovoid or club-shaped parabasal body containing an intensely chromophilic body, and a parabasal filament.

Tetratrichomonas pavlovi

Description: The body is pyriform and is usually 11–12 by 6–7 μm . It has four anterior flagella, which are about the same length as the body. The undulating membrane is well developed and has two to four waves that extend almost to the posterior end of the body. There is a free posterior flagellum, an accessory filament and a costa. The nucleus is round or ovoid. The axostyle is slender, broadening to form a capitulum at the anterior end.

Trichomitus

Members of this genus have three anterior flagella, an undulating membrane, a pelta and posterior (trailing) flagellum.

Trichomitus species

| Species | Hosts | Site |
|----------------------------|-------|---------------|
| <i>Trichomitus rotunda</i> | Pig | Caecum, colon |

Trichomitus rotunda

Description: The body is typically broadly piriform, but may occasionally be ovoid or ellipsoidal. It measures 7–11 by 5–7 μm (mean $9 \times 6 \mu\text{m}$). Cytoplasmic inclusions are frequently present. The three anterior flagella are approximately equal in length and each terminates in a knob or spatulate structure. The blepharoplast appears to consist of a single granule. The undulating membrane together with the costa extends about 50–75% the length of the body. The free posterior flagellum is generally shorter than the body. The axostyle is a narrow, straight, non-hyaline rod with a crescent or sickle-shaped capitulum extending about 4 μm beyond the body.

Pentatrichomonas

Members of this genus have five anterior flagella, an undulating membrane, a pelta and a sixth trailing flagellum.

Life cycle: The trichomonads reproduce by longitudinal binary fission. No sexual stages are known and there are no cysts.

Pentatrichomonas species

| Species | Hosts | Site |
|---|--|-----------------|
| <i>Pentatrichomonas hominis</i> (syn. <i>Pentatrichomonas felis</i> , <i>Cercomonas hominis</i> , <i>Monocercomonas hominis</i> , <i>Trichomonas intestinalis</i> , <i>Trichomonas felis</i>) | Human, monkey, dog, cat, rat, mouse, hamster, guinea pig | Large intestine |
| <i>Pentatrichomonas gallinarum</i> | Chicken, turkey, guinea fowl | Caeca, liver |

Pentatrichomonas hominis

Synonyms: *Pentatrichomonas felis*, *Cercomonas hominis*, *Monocercomonas hominis*, *Trichomonas intestinalis*, *Trichomonas felis*

Description: The body is pyriform, 8 by 20 μm and there are usually five anterior flagella. Four of the anterior flagella are grouped together, and the fifth is separate and directed posteriorly. A sixth flagellum runs along the undulating membrane and extends beyond the body as a free trailing flagellum. The undulating membrane extends the length of the body. The axostyle is thick and hyaline with a sharply pointed tip. The pelta is crescent-shaped.

Pentatrichomonas gallinarum

Description: The body is usually spherical, measuring 7 by 5 μm with five anterior flagella, and an undulating membrane extends the length of the body with a free flagellum at its end. The axostyle is slender, projecting from the posterior end (Fig. 2.16).

Cochlosoma

Cochlosoma species

| Species | Hosts | Site |
|---|-------|--------------------------------|
| <i>Cochlosoma anatis</i> (syn. <i>Cochlosoma rostratum</i>) | Duck | Large intestine, cloaca, caeca |

Fig. 2.16 *Pentatrichomonas gallinarum*.

Cochlosoma anatis

Synonym: *Cochlosoma rostratum*

Description: The body is beet-shaped, 6–12 by 4–7 μm with a nucleus in the middle of the body. There are six flagella of unequal length arising from a blepharoplast at the anterior end, and two trailing flagella lying in a longitudinal groove. A sucker covers one-third to half of the body length.

FAMILY DIENTAMOEBIDAE

Histomonas

A single species, *Histomonas meleagridis*, is recognised. The body is actively amoeboid with a single flagellum arising from a basal granule close to the nucleus.

Life cycle: Birds become infected by ingestion of the embryonated egg of the caecal worm, *Heterakis gallinarum*, the flagellate being carried in the unhatched larva. When the egg hatches, the histomonads are released from the larva and enter the caecal mucosa where they cause ulceration and necrosis. They reach the liver in the portal stream and colonise the liver parenchyma, producing circular necrotic foci, which increase in size as the parasites multiply in the periphery of the lesion. The next phase of the life cycle is not clear, but it is presumed that the *Heterakis* worms become infected with the caecal histomonads, possibly by ingestion, and that these subsequently reach the ovary of the worm. It is certainly established that the histomonads become incorporated in a proportion of the *Heterakis* eggs, and thus reach the exterior. Infection of birds may also result from the ingestion of earthworms, which are transport hosts for *Heterakis* eggs and larvae.

Histomonas species

| Species | Hosts | Site |
|-------------------------------|--------------------------------------|--------------|
| <i>Histomonas meleagridis</i> | Turkey, pheasant, partridge, chicken | Caeca, liver |

Histomonas meleagridis

Description: A pleomorphic organism, the morphology depending on organ location and the stage of disease. In the caecum, the organism is round or oval, amoeboid, with clear ectoplasm and granular endoplasm, 6.0–20 µm in diameter, and bears a single flagellum (Fig. 2.17), although this appears to be lost when in the mucosal tissue or the liver. The nucleus is vesicular and a flagellum arises from a small blepharoplast near the nucleus. In the caecal mucosa and liver, the organism is found singly or in clusters and is amoeboid, 8–15 µm in diameter, with no flagellum.

FAMILY MONOCERCOMONADIDAE

These are similar in appearance to the trichomonads except there is no undulating membrane. The genus *Histomonas* is of veterinary importance, causing major losses in turkeys and gamebirds. *Monocercomonas* occurs in a wide range of mammals, birds, reptiles, amphibians and fish and is generally considered non-pathogenic. Organisms in the single species of the genus *Dientamoeba* were originally thought to be amoebae but are now classed as trichomonads.

Monocercomonas

Members of this genus have three anterior flagella, a trailing flagellum with no undulating membrane and the axostyle usually projects beyond the posterior end of the body.

Fig. 2.17 *Histomonas meleagridis*.

Life cycle: The life cycle is simple, with trophozoites dividing by binary fission. No sexual stages are known and there are no cysts.

Monocercomonas species

| Species | Hosts | Site |
|--|---------------|--------|
| <i>Monocercomonas ruminantium</i> (syn. <i>Trichomonas ruminantium</i> , <i>Tritrichomonas ruminantium</i>) | Cattle, sheep | Rumen |
| <i>Monocercomonas cuniculi</i> (syn. <i>Trichomastix cuniculi</i>) | Rabbit | Caecum |

Monocercomonas ruminantium

Synonyms: *Trichomonas ruminantium*, *Tritrichomonas ruminantium*

Description: The trophozoite is subspherical (3–8 × 3–7 µm) with a rounded anterior end. The axostyle is curved and may or may not extend beyond the body. A pelta and parabasal body are present. The cytostome and anterior nucleus are anterior. There are three anterior flagella and a trailing flagellum (Fig. 2.18).

Monocercomonas cuniculi

Synonym: *Trichomastix cuniculi*

Description: The body is pyriform, 5–14 µm long, with a slender hyaline axostyle projecting from the body.

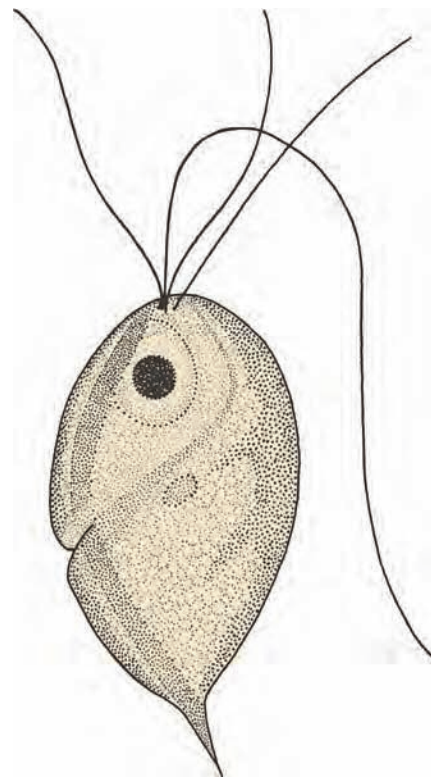

Fig. 2.18 *Monocercomonas ruminantium* trophozoite.

Chilomitus

Trophozoites have an elongate body, an anterior nucleus, a rudimentary axostyle and a cup-like cytostome at the anterior end from which arise four flagella.

Chilomitus species

| Species | Hosts | Site |
|---------------------------|------------|--------|
| <i>Chilomitus caviae</i> | Guinea pig | Caecum |
| <i>Chilomitus conexus</i> | Guinea pig | Caecum |

Chilomitus caviae

Description: Trophozoites are 6–14 µm long and 3–5 µm wide.

Chilomitus conexus

Description: Trophozoites are 4–7 µm long by 1–2 µm wide.

Dientamoeba

There is a single species, *D. fragilis*, which occurs in the caecum and colon of humans and some species of monkeys. Only trophozoites have been described, and these are 3–22 µm in diameter and contain one or two vesicular nuclei connected by a filament or desmose.

Dientamoeba species

| Species | Hosts | Site |
|-----------------------------|----------------|---------------|
| <i>Dientamoeba fragilis</i> | Human, monkeys | Caecum, colon |

ORDER HONIGBERGIELLIDA**FAMILY HEXAMASTIGIDAE****Hexamastix**

Hexamastix has a pyriform body with an anterior nucleus and cytostome, a pelta, conspicuous axostyle and five anterior flagella and a trailing flagellum.

Hexamastix species

| Species | Hosts | Site |
|---|------------|--------|
| <i>Hexamastix caviae</i> (syn. <i>Pentatrachomastix caviae</i>) | Guinea pig | Caecum |
| <i>Hexamastix robustus</i> (syn. <i>Pentatrachomastix robustus</i>) | Guinea pig | Caecum |
| <i>Hexamastix muris</i> (syn. <i>Pentatrachomastix muris</i>) | Rat | Caecum |

Hexamastix caviae

Synonym: *Pentatrachomastix caviae*

Description: Trophozoites are 4–10 µm long by 3–5 µm wide.

Hexamastix robustus

Synonym: *Pentatrachomastix robustus*

Description: Trophozoites are 7–14 µm long by 3–8 µm wide.

Hexamastix muris

Synonym: *Pentatrachomastix robustus*

Description: Trophozoites are 5–12 µm long.

ORDER PROTEROMONADIDA**FAMILY PROTEROMONADIDAE****Proteromonas**

Trophozoites are spindle-shaped with an anterior and free-trailing posterior flagellum. The nucleus is anterior to the body and lies next to a paranuclear body of similar size.

Proteromonas species

| Species | Hosts | Site |
|--------------------------------|------------|--------|
| <i>Proteromonas brevifilia</i> | Guinea pig | Caecum |

Proteromonas brevifilia

Description: Trophozoites are 4–9 µm long by 2–4 µm wide.

PHYLUM FORNICATA**CLASS RETORTAMONADEA****ORDER RETORTAMONADIDA****FAMILY RETORTAMONADIDAE**

These protozoa are predominantly inhabitants of stagnant water but occur in a wide range of mammals, birds, reptiles and insects and are generally considered non-pathogenic. Species of *Retortamonas* and *Chilomastix* are found in humans, monkeys, cattle, sheep, rabbits, guinea pigs and in amphibians, reptiles and insects.

Retortamonas

Retortamonas has a pyriform body with large cytostome and two flagella.

Retortamonas species

| Species | Hosts | Site |
|---|-------------------------------|--------|
| <i>Retortamonas ovis</i> (syn. <i>Embadomonas ovis</i> , <i>Embadomonas ruminantium</i>) | Sheep, cattle | Caecum |
| <i>Retortamonas cuniculi</i> (syn. <i>Embadomonas cuniculi</i>) | Rabbit | Caecum |
| <i>Retortamonas caviae</i> | Guinea pig | Caecum |
| <i>Retortamonas intestinalis</i> (syn. <i>Embadomonas intestinalis</i> , <i>Waskia intestinalis</i>) | Human, chimpanzee, monkeys | Caecum |

Retortamonas ovis

Synonyms: *Embadomonas ovis*, *Embadomonas ruminantium*

Description: Trophozoites are pyriform and average 5.2 by 3.4 μm . There is a large cytostome near the anterior end containing a cytostomal fibril that extends across the anterior end and posteriorly along each side. An anterior flagellum and a posterior trailing flagellum emerge from the cytostomal groove. Cysts are pyriform and ovoid, containing one or two nuclei and retain the cytostomal fibril.

Retortamonas cuniculi

Synonyms: *Embadomonas cuniculi*

Description: Trophozoites are ovoid, 7–13 by 5–10 μm , with an anterior flagellum and a posterior trailing flagellum emerging from the cytostomal groove. Cysts are pyriform or ovoid, 5–7 by 3–4 μm .

Retortamonas caviae

Description: Trophozoites are 4–8 μm long by 4 μm wide with cysts 4–6 μm by 3–4 μm wide.

Retortamonas intestinalis

Synonyms: *Embadomonas intestinalis*, *Waskia intestinalis*

Description: The trophozoite is small, measuring 4–9 μm long by 4–7 μm wide, with two anterior flagella and a prominent cytostome. It has a relatively large nucleus at the anterior end with a small compact karyosome.

Chilomastix

Trophozoites are pyriform with a large cytostomal groove near the anterior end. There are three anterior flagella and a short fourth flagellum within the cytostomal cleft. Species of this genus are found in mammals, birds, reptiles, amphibian, fish and insects and are considered to be non-pathogenic.

Chilomastix species

| Species | Hosts | Site |
|--|------------------------------|---------------|
| <i>Chilomastix mesnili</i> (syn. <i>Chilomastix suis</i> , <i>Chilomastix hominis</i> , <i>Macrostoma mesnili</i>) | Human, apes, monkeys, pig | Caecum, colon |
| <i>Chilomastix gallinarum</i> | Chicken, turkey | Caeca |
| <i>Chilomastix equi</i> | Horse | Intestine |
| <i>Chilomastix caprae</i> | Goat | Rumen |
| <i>Chilomastix cuniculi</i> | Rabbit | Caecum |
| <i>Chilomastix intestinalis</i> | Guinea pig | Caecum |
| <i>Chilomastix wenrichi</i> | Guinea pig | Caecum |
| <i>Chilomastix bettencourti</i> | Rat, mouse, hamster | Caecum |

Chilomastix mesnili

Synonyms: *Chilomastix suis*, *Chilomastix hominis*, *Macrostoma mesnili*

Description: Trophozoites are pear-shaped, 6–24 by 3–10 μm , with a spiral groove crossing the middle half of the body and three anterior flagella. A slit-like cytostome, enclosing a fourth flagellum, is located in the anterior portion of the body. The lemon-shaped cysts are 6–10 μm in diameter and contain a single nucleus and cytostome.

Chilomastix gallinarum

Description: The body is pear-shaped, 11–20 by 5–12 μm , with a nucleus at the anterior end of the body. There are three anterior flagella and a short fourth flagellum that undulates within a cytostomal cleft that is shaped like a figure 8, which is located on the ventral body spiralling to the left and extending half to two-thirds of the body length (Fig. 2.19). Cysts are lemon-shaped (7–9 \times 4–6 μm) with a single nucleus.

Chilomastix equi

Description: Trophozoites are pyriform, 16–32 by 6–16 μm with a posterior spike.

Chilomastix caprae

Description: Trophozoites are pear-shaped, 8–10 by 4–6 μm .

Chilomastix cuniculi

Description: Trophozoites are pyriform, 10–15 μm long.

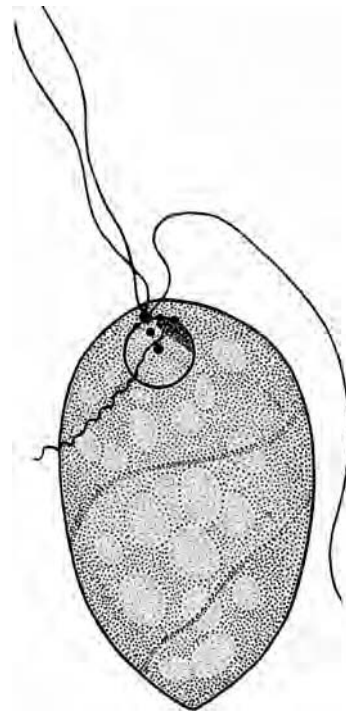

Fig. 2.19 *Chilomastix gallinarum*.

Chilomastix intestinalis

Description: Trophozoites are pyriform and 9–28 µm long by 7–11 µm wide. Cysts are 9–11 by 7–10 µm.

Chilomastix wenrichi

Description: Trophozoites are pyriform and 7.5–12 µm long.

Chilomastix bettencourti

Description: Trophozoites are pyriform and 6–24 by 3–10 µm.

ORDER DIPLOMONADIDA

FAMILY HEXAMITIDAE

The family Hexamitidae contains one main genus of veterinary interest, *Spiroucleus*, and a few minor genera considered to be non-pathogenic in animals. *Spiroucleus* (*Hexamita*) is a cause of enteritis and diarrhoea in birds (particularly in poultry, gamebirds and pigeons) and rodents. Other members of the family include *Caviomonas* which are found in the caecum of guinea pigs.

Spiroucleus

Trophozoites are bilaterally symmetrical, possessing two nuclei, two sets of three anterior flagella and two flagella which pass through the body to emerge posteriorly. These parasites used to be referred to as *Hexamita*, but members of the latter genus are usually free-living.

Spiroucleus species

| Species | Hosts | Site |
|---|---|----------------------------|
| <i>Spiroucleus columbae</i> (syn. <i>Hexamita columbae</i> , <i>Octomitus columbae</i>) | Pigeon | Small intestine |
| <i>Spiroucleus meleagridis</i> (syn. <i>Hexamita meleagridis</i>) | Turkey, gamebirds (pheasant, quail, partridge) | Small intestine, caeca |
| <i>Spiroucleus muris</i> (syn. <i>Hexamita muris</i> , <i>Octomitus muris</i> , <i>Syndyomita muris</i>) | Mouse, rat, hamster | Small intestine, caecum |
| <i>Spiroucleus pitheci</i> | Monkeys | Large intestine |

Spiroucleus columbae

Synonyms: *Hexamita columbae*, *Octomitus columbae*

Description: Trophozoites are small, measuring 5–9 by 2.5–7 µm.

Spiroucleus meleagridis

Synonyms: *Hexamita meleagridis*

Description: Trophozoites are bilaterally symmetrical, 6–12 by 2–5 µm, and possess two nuclei, two sets of three anterior flagella, and two flagella that pass through the body to emerge posteriorly (Fig. 2.20).

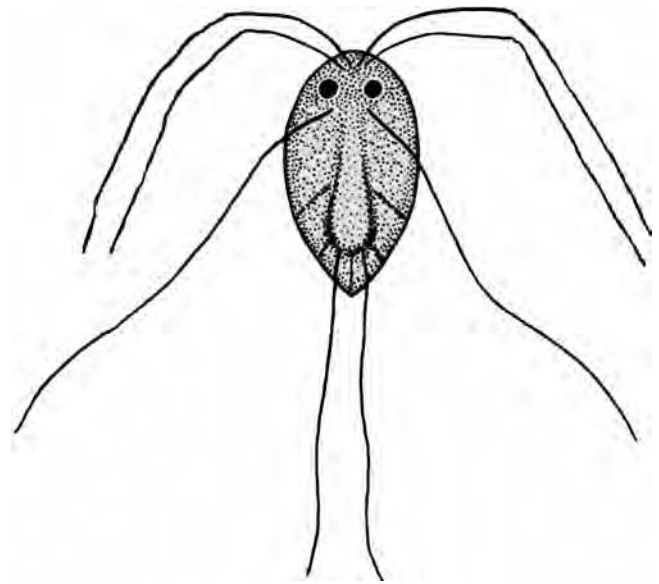

Fig. 2.20 *Spiroucleus meleagridis*.

Spiroucleus muris

Synonyms: *Hexamita muris*, *Octomitus muris*, *Syndyomita muris*

Description: The body is pyriform, 7–9 by 2–3 µm, with two nuclei near the anterior end, and six anterior and two posterior flagella. There is no cytostome.

Caviomonas

Trophozoites have a single flagellum and no cytostome.

Caviomonas species

| Species | Hosts | Site |
|---------------------------|---------------------|--------|
| <i>Caviomonas mobilis</i> | Guinea pig, hamster | Caecum |

Caviomonas mobilis

Description: Trophozoites have an ovoid to carrot-shaped body, 2–7 µm long by 2–3 µm wide, with a pointed posterior end. A single flagellum arises from the nucleus at the anterior end and extends posteriorly along the periphery of the body surface.

FAMILY ENTEROMONADIDAE

Enteromonas

Trophozoites are spherical or pyriform and possess an anterior nucleus, a strand-like funis, three short anterior flagella and a long fourth flagellum extending posteriorly beyond the body.

Enteromonas species

| Species | Hosts | Site |
|---|--|--------|
| <i>Enteromonas caviae</i> | Guinea pig | Caecum |
| <i>Enteromonas hominis</i> (syn. <i>Octomitus hominis</i> , <i>Tricercomonas intestinalis</i> , <i>Enteromonas bengalensis</i>) | Rat, hamster, human, primates (chimpanzee, macaques) | Caecum |

Enteromonas caviae

Description: Trophozoites are 3–5 µm long and 2–4 µm wide.

Enteromonas hominis

Synonyms: *Octomitus hominis*, *Tricercomonas intestinalis*, *Enteromonas bengalensis*

Description: Trophozoites are 4–10 µm long and 3–6 µm wide and contain numerous food vacuoles.

PHYLUM METAMONADA**ORDER GIARDIIDA**

According to the new systematic based on genetic, structural and biochemical data, *Giardia*, which was in the family Hexamatidae, is now placed in the phylum Metamonada, class Trepomonadea, subclass Diplozoa, order Giardiida and family Giardiidae.

FAMILY GIARDIIDAE

Giardia is a common cause of chronic diarrhoea in humans and infection also occurs in wild and domestic animals. The organism is bilaterally symmetrical and possesses eight flagella, six of which emerge as free flagella at intervals around the body. It is unique in possessing a large adhesive disc on the flat ventral surface of the body, which facilitates attachment to the epithelial cells of the intestinal mucosa.

Giardia

Trophozoites of *Giardia* have a pyriform to ellipsoidal, bilaterally symmetrical body, 12–15 µm long by 5–9 µm wide. The dorsal side is convex and there is a large sucking disc on the ventral side. There are two anterior nuclei, two slender axostyles, eight flagella in four pairs and a pair of darkly staining median bodies (Fig. 2.21).

Fig. 2.21 Trophozoite of *Giardia duodenalis*.

At least 10 species have been distinguished on the basis of light microscopic characteristics (shape of trophozoite and median body) and more recently using molecular methods, which group the species into assemblages, a system which is still evolving.

Life cycle: The life cycle is simple and direct, the trophozoite stage dividing by binary fission to produce further trophozoites. Intermittently, trophozoites encyst forming resistant cyst stages that pass out of the host in the faeces.

Giardia species

| Species | Assemblages | Hosts | Site |
|--|-------------|---|-----------------|
| <i>Giardia duodenalis</i> (syn. <i>Giardia intestinalis</i>) | A | Human, primates, dog, cat, livestock, rodents, wild mammals | Small intestine |
| <i>Giardia enterica</i> | B | Human, primates, dog, cat, some wild mammals | Small intestine |
| <i>Giardia canis</i> | C, D | Dog, other canids | Small intestine |
| <i>Giardia bovis</i> | E | Cattle, other ungulates | Small intestine |
| <i>Giardia cati</i> | F | Cat | Small intestine |
| <i>Giardia simondi</i> | G | Rat | Small intestine |
| <i>Giardia spp</i> | H | Pinnipeds | |
| <i>Giardia muris</i> | | Rodents | Small intestine |
| <i>Giardia microti</i> | | Rodents | Small intestine |
| <i>Giardia psittaci</i> | | Birds | Small intestine |
| <i>Giardia ardeae</i> | | Birds | Small intestine |

PHYLUM PREAXOSTYLA**CLASS ANAERONONADEA****ORDER OXYMONADIDA****FAMILY POLYMASTIGIDAE****Monocercomonoides**

Species of this genus have an anterior nucleus, two pairs of anterior flagella, a pelta and a filamentous axostyle. There are one to four costa-like structures (funises) extending backwards beneath the body surface. Members of this genus occur in mammals, amphibian, reptiles and insects and are considered non-pathogenic.

Monocercomonoides species

| Species | Hosts | Site |
|---|------------|--------|
| <i>Monocercomonoides caviae</i> | Guinea pig | Caecum |
| <i>Monocercomonoides wenrichi</i> | Guinea pig | Caecum |
| <i>Monocercomonoides quadrifunilis</i> | Guinea pig | Caecum |
| <i>Monocercomonoides exilis</i> | Guinea pig | Caecum |
| <i>Monocercomonoides caprae</i> (syn. <i>Monocercomonas caprae</i> , <i>Monocercomonoides sayeedi</i>) | Goat | Rumen |

Monocercomonoides caviae

Description: Trophozoites are ovoid, 4–8 µm long by 3–7 µm wide and have three funises.

Monocercomonoides wenrichi

Description: Trophozoites are 3–12 µm long by 3–8 µm wide and have a thick, single, sinuous funis.

Monocercomonoides quadrifunilis

Description: Trophozoites are 3–13 µm long by 3–11 µm wide and have four funises.

Monocercomonoides exilis

Description: Trophozoites are 4–9 µm long by 3–6 µm wide and have a single short funis.

Monocercomonoides caprae

Synonyms: *Monocercomonas caprae*, *Monocercomonoides sayeedi*

Description: Trophozoites are ovoid, 6–12 µm long by 4–8 µm wide.

PHYLUM

Protozoa within the phylum Apicomplexa (Sporozoa) are characterised by their intracellular lifestyle and possession of an apical complex at some stage of their development. The trophozoites have no cilia or flagella. Reproduction involves both asexual (merogony or schizogony) and sexual (gametogony) phases. Following gametogony, a zygote is formed which divides to produce spores (sporogony).

Within the class Conoidasida is one order of veterinary significance, the Eucoccidiorida, which are intestinal sporozoa. In the class Aconoidasida, there are two genera of veterinary interest, the Haemospororida and Piroplasmorida, which are blood sporozoa.

ORDER EUCCOCCIDIORIDA**SUBORDER EIMERIORINA**

The Eimeriorina contains parasites which occur mainly in vertebrates. Those of major veterinary importance fall into three families, the Eimeriidae, Cryptosporidiidae and Sarcocystiidae. Other families of lesser significance include the Lankesterellidae, Klossiellidae and Hepatozoidae.

GENERALISED LIFE CYCLE

The life cycle is divided into three phases: sporulation, infection and merogony (schizogony), and finally gametogony and oocyst

formation, as represented by the life cycle of the genus *Eimeria* (Fig. 2.22).

Sporulation

Unsporulated oocysts, consisting of a nucleated mass of protoplasm enclosed by a resistant wall, are passed to the exterior in the faeces. Under suitable conditions of oxygenation, high humidity and optimal temperatures of around 27°C, the nucleus divides twice and the protoplasmic mass forms four conical bodies radiating from a central mass. Each of these nucleated cones becomes rounded to form a **sporoblast**, while in some species the remaining protoplasm forms the oocyst residual body. Each sporoblast secretes a wall of refractile material and becomes known as a **sporocyst**, while the protoplasm within divides into two banana-shaped **sporozoites**. In some species the remaining protoplasm within the sporocyst forms a sporocyst residual body and the sporocyst may have a knob at one end, the **Stieda body**. The time taken for these changes varies according to temperature, but under optimal conditions usually requires 2–4 days. The oocyst, now consisting of an outer wall enclosing **sporocysts** each containing **sporozoites**, is referred to as a **sporulated oocyst** and is the infective stage.

Infection and merogony (asexual reproduction)

The host becomes infected by ingesting the sporulated oocyst. The sporocysts are then liberated either mechanically or by carbon dioxide, and the sporozoites, activated by trypsin and bile, leave the sporocyst. In most species, each sporozoite penetrates an epithelial cell, rounds up, and is then known as a **trophozoite**. After a few days each trophozoite has divided by multiple fission to form a **meront** (schizont), a structure consisting of a large number of elongated nucleated organisms known as **merozoites**. When division is complete and the meront is mature, the host cell and the meront rupture and the merozoites escape to invade neighbouring cells. Merogony may be repeated, the number of meront generations depending on the species.

Gametogony and oocyst formation (sexual reproduction)

Merogony terminates when the merozoites give rise to male and female gametocytes. The factors responsible for this switch to gametogony are not fully known. The **macrogametocytes** are female and remain unicellular, but increase in size to fill the parasitised cell. They may be distinguished from trophozoites or developing meronts by the fact that they have a single large nucleus. The male **microgametocytes** each undergo repeated division to form a large number of flagellated uninucleate organisms, the **microgametes**. It is only during this brief phase that coccidia have organs of locomotion. The microgametes are freed by rupture of the host cell, one penetrates a macrogamete, and fusion of the microgamete and macrogamete nuclei then takes place. A cyst wall forms around the resulting **zygote**, now known as an oocyst, and no further development usually takes place until this **unsporulated oocyst** is liberated from the body in the faeces.

Fig. 2.22 Life cycle of *Eimeria*.

FAMILY EIMERIIDAE

This family contains 16 genera and some 1340 named species, of which the most important are *Eimeria* and *Isospora* (*Cystisopora*) and infections with these genera are often referred to as ‘coccidiosis’. The genera are differentiated on the basis of the number of sporocysts in each oocyst and the number of sporozoites in each sporocyst (Table 2.2). Members of this family are intracellular parasites, and most undergo merogony in the intestinal cells of their hosts. The life cycle is usually homoxenous

(occurring within one host) and the majority of species are highly host-specific.

Eimeria is the largest genus in the family containing well over 1000 named species, with a number of important species affecting domestic mammals and birds. Oocysts contain four sporocysts, each with two sporozoites. Oocysts are unsporulated when passed in the faeces and require a period of development before becoming infective. Species of *Eimeria* are capable of causing significant morbidity and mortality and are discussed in detail under their respective hosts.

Isospora/Cystisopora comprises about 200 species although host specificity varies with some species. Oocysts contain two sporocysts each with four sporozoites. Species of *Cystisopora* can cause disease in pigs, dogs, cats, camels and monkeys; and *Isospora* in cage birds.

Cyclospora has been reported in monkeys, reptiles and insectivores and has been reported as a cause of gastrointestinal food-borne disease in humans. Oocysts consist of two sporocysts each with two sporozoites.

Caryospora are found primarily in birds and snakes and have a two-host life cycle in which the hosts manifest a predator-prey relationship. Oocysts consist of a single sporocyst with eight sporozoites.

The genus *Atoxoplasma* occurs in birds, with about 17 named species. Transmission is by ingestion of sporulated oocysts.

Other genera in this family include *Tyzzeria* and *Wenyonella* in birds, and *Hoarella*, *Octosporella*, *Pythonella* and *Dorisiella* in reptiles.

Table 2.2 Generic identification of coccidian parasites.

| Genus | Sporocysts per oocyst | Sporozoites per sporocyst | Total sporozoites per oocyst |
|-----------------------------|-----------------------|---------------------------|------------------------------|
| <i>Eimeria</i> | 4 | 2 | 8 |
| <i>Isospora/Cystisopora</i> | 2 | 4 | 8 |
| <i>Caryospora</i> | 1 | 8 | 8 |
| <i>Cyclospora</i> | 2 | 2 | 4 |
| <i>Hoarella</i> | 16 | 2 | 32 |
| <i>Octosporella</i> | 8 | 2 | 16 |
| <i>Pythonella</i> | 16 | 4 | 64 |
| <i>Wenyonella</i> | 4 | 4 | 16 |
| <i>Dorisiella</i> | 2 | 8 | 16 |
| <i>Tyzzeria</i> | 0 | 8 | 8 |

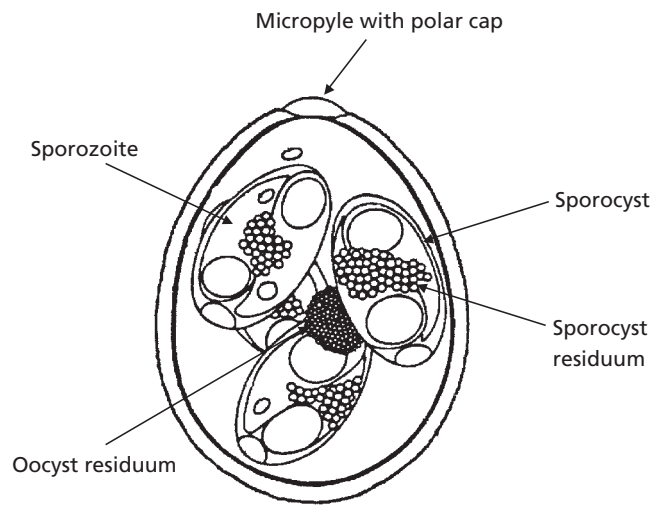

Fig. 2.23 Sporulated oocyst of *Eimeria* with four sporocysts each containing two sporozoites.

Eimeria

In this genus, the oocysts contain four sporocysts each with four sporozoites (Fig. 2.23). Both structural and biological characteristics are used to differentiate species of *Eimeria*. Since the endogenous stages of many coccidia are unknown, identification is generally based on oocyst size, morphology and knowledge of the host animal.

***Eimeria* species**

| Species | Hosts | Site |
|---|------------------------------------|------------------------------|
| <i>Eimeria acervulina</i> | Chicken | Duodenum |
| <i>Eimeria adenoides</i> | Turkey | Lower small intestine, caeca |
| <i>Eimeria ahsata</i> | Sheep | Small intestine |
| <i>Eimeria alabamensis</i> | Cattle, buffalo | Small and large intestine |
| <i>Eimeria alijevi</i> | Goat | Small and large intestine |
| <i>Eimeria alpaca</i> | Alpaca | Unknown |
| <i>Eimeria anatis</i> | Duck | Small intestine |
| <i>Eimeria anseris</i> | Goose | Small and large intestine |
| <i>Eimeria ankarensis</i> | Buffalo | Unknown |
| <i>Eimeria arctica</i> | Reindeer | Unknown |
| <i>Eimeria arloingi</i> | Goat | Small intestine |
| <i>Eimeria asymmetrica</i> | Deer (red deer) | Unknown |
| <i>Eimeria aspheronica</i> | Goat | Unknown |
| <i>Eimeria auburnensis</i> | Cattle, buffalo | Small intestine |
| <i>Eimeria austriaca</i> | Deer (red deer) | Unknown |
| <i>Eimeria bactriani</i> (syn. <i>E. noller</i>) | Camel | Small intestine |
| <i>Eimeria bakuensis</i> | Sheep | Small intestine |
| <i>Eimeria bateri</i> | Quail (Japanese, <i>Cortunix</i>) | Unknown |
| <i>Eimeria bareillyi</i> | Buffalo | Small intestine |
| <i>Eimeria bovis</i> | Cattle, buffalo | Small and large intestine |
| <i>Eimeria brasiliensis</i> | Cattle, buffalo | Unknown |

| Species | Hosts | Site |
|------------------------------|--------------------------------|--------------------------------------|
| <i>Eimeria brunetti</i> | Chicken | Lower small intestine, caeca, rectum |
| <i>Eimeria bukidnonensis</i> | Cattle, buffalo | Unknown |
| <i>Eimeria cameli</i> | Camel | Small and large intestine |
| <i>Eimeria canadensis</i> | Cattle, buffalo | Unknown |
| <i>Eimeria capralis</i> | Goat | Unknown |
| <i>Eimeria capreoli</i> | Deer (roe deer) | Unknown |
| <i>Eimeria caprina</i> | Goat | Small and large intestine |
| <i>Eimeria caprovina</i> | Goat | Unknown |
| <i>Eimeria catubrina</i> | Deer (roe deer) | Unknown |
| <i>Eimeria caucasica</i> | Partridge (rock) | Unknown |
| <i>Eimeria caviae</i> | Guinea pig | Large intestine |
| <i>Eimeria cervi</i> | Deer (red deer) | Unknown |
| <i>Eimeria charlestoni</i> | Goat | Unknown |
| <i>Eimeria christensen</i> | Goat | Small intestine |
| <i>Eimeria coecicola</i> | Rabbit | Small intestine |
| <i>Eimeria colchici</i> | Pheasant | Caeca |
| <i>Eimeria colini</i> | Quail (<i>Colinus</i>) | Unknown |
| <i>Eimeria columbae</i> | Pigeon | Unknown |
| <i>Eimeria coturnicus</i> | Quail (<i>Cortunix</i>) | Unknown |
| <i>Eimeria crandallis</i> | Sheep | Small and large intestine |
| <i>Eimeria cylindrica</i> | Cattle | Unknown |
| <i>Eimeria debliecki</i> | Pig | Small intestine |
| <i>Eimeria dispersa</i> | Turkey | Duodenum |
| <i>Eimeria dromedarii</i> | Camel | Small intestine |
| <i>Eimeria duodenalis</i> | Pheasant | Small intestine |
| <i>Eimeria elaphi</i> | Deer (red deer) | Unknown |
| <i>Eimeria ellipsoidalis</i> | Cattle, buffalo | Small intestine |
| <i>Eimeria exigua</i> | Rabbit | Small intestine |
| <i>Eimeria falciformis</i> | Mouse | Small and large intestine |
| <i>Eimeria faurei</i> | Sheep | Small and large intestine |
| <i>Eimeria ferruginea</i> | Primates (prosimians) | Unknown |
| <i>Eimeria flavescens</i> | Rabbit | Small and large intestine |
| <i>Eimeria galago</i> | Primates (prosimians) | Unknown |
| <i>Eimeria gokaki</i> | Buffalo | Unknown |
| <i>Eimeria gallapovonis</i> | Turkey | Ileum, caeca, rectum |
| <i>Eimeria gilruthi</i> | Sheep, goat | Abomasum |
| <i>Eimeria granulosa</i> | Sheep | Unknown |
| <i>Eimeria grenieri</i> | Guinea fowl | Small intestine |
| <i>Eimeria hasei</i> | Rat | Unknown |
| <i>Eimeria hindlei</i> | Mouse | Unknown |
| <i>Eimeria hirci</i> | Goat | Unknown |
| <i>Eimeria innocua</i> | Turkey | Small intestine |
| <i>Eimeria intestinalis</i> | Rabbit | Small intestine |
| <i>Eimeria intricata</i> | Sheep | Small and large intestine |
| <i>Eimeria irresidua</i> | Rabbit | Small intestine |
| <i>Eimeria ivitaensis</i> | Alpaca | Unknown |
| <i>Eimeria jolchijevi</i> | Goat | Unknown |
| <i>Eimeria keilini</i> | Mouse | Unknown |
| <i>Eimeria koifoidi</i> | Partridge (grey, chukar, rock) | Small intestine |

| <i>Eimeria punctata</i> | Sheep, occasionally goat (?) | Unknown |
| <i>Eimeria punonensis</i> | Alpaca | Unknown |
| <i>Eimeria rajasthanii</i> | Camel | Unknown |
| <i>Eimeria ratti</i> | Rat | Unknown |
| <i>Eimeria robusta</i> | Deer (red deer) | Unknown |
| <i>Eimeria rotunda</i> | Deer (roe deer) | Unknown |
| <i>Eimeria scabra</i> | Pig | Small and large intestine |
| <i>Eimeria scheuffneri</i> | Mouse | Unknown |
| <i>Eimeria separata</i> | Rat | Large intestine |
| <i>Eimeria solipedum</i> | Horse, donkey | Small intestine |
| <i>Eimeria sordida</i> | Deer (red deer) | Unknown |
| <i>Eimeria spinosa</i> | Pig | Small intestine |
| <i>Eimeria stiedai</i> | Rabbit | Liver, bile ducts |
| <i>Eimeria subrotunda</i> | Turkey | Small intestine |
| <i>Eimeria subspherica</i> | Cattle | Unknown |
| <i>Eimeria suis</i> | Pig | Unknown |
| <i>Eimeria superba</i> | Deer (roe deer) | Unknown |
| <i>Eimeria taldykurganica</i> | Quail (Japanese, <i>Cortunix</i>) | Unknown |
| <i>Eimeria tarandi</i> | Reindeer | Unknown |
| <i>Eimeria tenella</i> | Chicken | Small intestine |
| <i>Eimeria thianethi</i> | Buffalo | Unknown |
| <i>Eimeria truncata</i> | Goose | Kidney |
| <i>Eimeria tsunodai</i> | Quail (Japanese) | Caeca |
| <i>Eimeria tupaiae</i> | Primates (prosimians) | Unknown |
| <i>Eimeria uniungulata</i> | Horse, donkey | Small intestine |
| <i>Eimeria uzura</i> | Quail (Japanese) | Unknown |
| <i>Eimeria vej dovnyi</i> | Rabbit | Small intestine |
| <i>Eimeria weybridgetensis</i> | Sheep | Small intestine |
| <i>Eimeria wapiti</i> | Deer (wapiti) | Unknown |
| <i>Eimeria wyomingensis</i> | Cattle, buffalo | Unknown |
| <i>Eimeria zuernii</i> | Cattle, buffalo | Small and large intestine |

Because of the large number of species and host specificity of *Eimeria* species, descriptions of the oocysts by host are detailed in Tables 2.3, 2.4, 2.5, 2.6, 2.7, 2.8, 2.9, 2.10, 2.11, 2.12, 2.13, 2.14, 2.15, 2.16, 2.17, 2.18, 2.19, 2.20, 2.21 and 2.22. More detailed descriptions including life cycle stages are provided within the respective host chapters.

Isospora/Cystisospora

The genera *Isospora* and *Cystisospora* contain many species that parasitise a wide range of hosts. Species of *Isospora* in mammals have been reclassified as *Cystisospora* based on the absence of Stieda bodies in their sporocysts. The life cycles of *Isospora/Cystisospora* species differ from those of *Eimeria* in three respects. Firstly, the sporulated oocyst contains two sporocysts each with four sporozoites

Table 2.3 *Eimeria* species (cattle).

| Species | Oocyst description | Mean size (μm) |
|------------------------------|--|-----------------------------|
| <i>Eimeria bovis</i> | Ovoid or subspherical, colourless and have a smooth wall with inconspicuous micropyle, no polar granule or oocyst residuum | 28 × 20 |
| <i>Eimeria zuernii</i> | Subspherical, colourless, with no micropyle or oocyst residuum | 18 × 16 |
| <i>Eimeria alabamensis</i> | Usually ovoid with a smooth colourless wall with no micropyle, polar body or residuum | 19 × 13 |
| <i>Eimeria auburnensis</i> | Elongated, ovoid, yellowish-brown, with smooth or heavily granulated wall with a micropyle and polar granule, but no oocyst residuum | 38 × 23 |
| <i>Eimeria brasiliensis</i> | Ellipsoidal, yellowish-brown, with a micropyle covered by a distinct polar cap. Polar granules may also be present, but there is no oocyst residuum | 37 × 27 |
| <i>Eimeria bukidnonensis</i> | Pear-shaped or oval, tapering at one pole, yellowish-brown, with a thick, radially striated wall and micropyle. A polar granule may be present but there is no oocyst residuum | 49 × 35 |
| <i>Eimeria canadensis</i> | Ovoid or ellipsoidal, colourless or pale yellow, with an inconspicuous micropyle, one or more polar granules and an oocyst residuum | 33 × 23 |
| <i>Eimeria cylindrica</i> | Elongated, cylindrical, with a colourless smooth wall, no micropyle, and no oocyst residuum | 23 × 12 |
| <i>Eimeria ellipsoidalis</i> | Ellipsoidal to slightly ovoid, colourless, with no discernible micropyle, polar granule or oocyst residuum | 23 × 16 |
| <i>Eimeria pellita</i> | Egg-shaped, very thick brown wall with evenly distributed protruberances, with a micropyle and polar granule consisting of several rod-like bodies but no oocyst residuum | 40 × 28 |
| <i>Eimeria subspherica</i> | Round or subspherical, colourless, with no micropyle, polar granule or oocyst residuum | 11 × 10 |
| <i>Eimeria wyomingensis</i> | Ovoid, yellowish brown, with a thick wall, a wide micropyle but no polar granule or oocyst residuum | 40 × 28 |

Table 2.4 *Eimeria* species (sheep).

| Species | Oocyst description | Mean size (μm) |
|------------------------------|---|-----------------------------|
| <i>Eimeria crandallis</i> | Broadly ellipsoidal or subspherical, with or without polar cap, without oocyst residuum, sporocysts very broad, with sporocyst residuum | 22 × 19 |
| <i>Eimeria ovinoidalis</i> | Ellipsoidal, indistinct micropyle, colourless or pale yellow, without oocyst residuum, with sporocyst residuum | 23 × 18 |
| <i>Eimeria ahsata</i> | Ovoid with distinct polar cap, yellowish-brown, no oocyst residuum | 33 × 23 |
| <i>Eimeria bakuensis</i> | Ellipsoidal, with polar cap, pale yellowish-brown, without oocyst residuum, with sporocyst residuum | 31 × 20 |
| <i>Eimeria faurei</i> | Ovoid, pale yellowish-brown, without oocyst residuum or sporocyst residuum | 32 × 23 |
| <i>Eimeria granulosa</i> | Urn-shaped with large micropolar cap at broad end, yellowish-brown, without oocyst residuum | 29 × 21 |
| <i>Eimeria intricata</i> | Ellipsoidal, thick and striated wall, brown no oocyst residuum | 48 × 34 |
| <i>Eimeria marsica</i> | Ellipsoidal, with inconspicuous micropyle, colourless or pale yellow, without oocyst or sporocyst residuum | 19 × 13 |
| <i>Eimeria pallida</i> | Ellipsoidal, thin-walled, colourless to pale yellow, without oocyst residuum, but with sporocyst residuum | 14 × 10 |
| <i>Eimeria parva</i> | Spherical to subspherical, colourless, no oocyst residuum, sporocyst residuum composed of few granules | 17 × 14 |
| <i>Eimeria weybridgensis</i> | Broadly ellipsoidal or subspherical, micropyle with or without polar cap, without oocyst or sporocyst residuum | 24 × 17 |
| <i>Eimeria punctata</i> | Oocysts are ellipsoidal to ovoid, micropyle with or without polar cap, with oocyst residuum; sporocyst elongate ovoid with residuum | 24 × 18 |

Table 2.5 *Eimeria* species (goats).

| Species | Oocyst description | Mean size (μm) |
|----------------------------------|--|-----------------------------|
| <i>Eimeria caprina</i> | Ellipsoidal, dark brown to brownish-yellow, with micropyle, without oocyst residuum but with sporocyst residuum | 32 × 23 |
| <i>Eimeria ninakohlyakimovae</i> | Ellipsoidal, thin-walled, colourless, micropyle absent or indistinct, without oocyst residuum but with sporocyst residuum | 21 × 15 |
| <i>Eimeria christenseni</i> | Ovoid, thick wall, colourless to pale yellow, with micropyle and polar cap, without oocyst residuum but with sporocyst residuum | 38 × 25 |
| <i>Eimeria hirci</i> | Roundish oval, light yellow, with micropyle and polar cap, no oocyst residuum, sporocysts broadly oval with small residuum | 21 × 16 |
| <i>Eimeria alijevi</i> | Ovoid or ellipsoidal, with inconspicuous micropyle, colourless or pale yellow, without oocyst residuum but with sporocyst residuum | 17 × 15 |
| <i>Eimeria arloingi</i> | Ellipsoidal, thick wall with micropyle and polar cap, without oocyst residuum but with sporocyst residuum | 27 × 18 |
| <i>Eimeria aspheronica</i> | Ovoid, greenish to yellow-brown, with micropyle, without oocyst residuum but with sporocyst residuum | 31 × 32 |
| <i>Eimeria caprovina</i> | Ellipsoidal to subspherical, colourless, with micropyle, without oocyst residuum but with sporocyst residuum | 30 × 24 |
| <i>Eimeria jolchijevi</i> | Ellipsoidal or oval, pale yellow, with micropyle and polar cap, without oocyst residuum but with sporocyst residuum | 31 × 22 |
| <i>Eimeria capralis</i> | Ellipsoidal with a distinct micropylar cap, with Stieda body and sporocyst residuum | 29 × 20 |
| <i>Eimeria masseyensis</i> | Ellipsoidal to ovoid, with Stieda body and distinct micropylar cap | 22 × 17 |
| <i>Eimeria charlestoni</i> | Ellipsoidal with no micropylar cap. Distinctive elongate sporocysts containing prominent refractile bodies | 23 × 17 |

Table 2.6 *Eimeria* species (horses).

| Species | Oocyst description | Mean size (µm) |
|----------------------------|--|----------------|
| <i>Eimeria leuckarti</i> | Oocysts are ovoid or pyriform, flattened at the small end and very large, with a thick dark shell and distinct micropyle | 80 × 60 |
| <i>Eimeria solipedum</i> | Oocysts are spherical, orange to yellowish-brown, without an oocyst residuum or micropyle | 22 × 10 |
| <i>Eimeria uniungulata</i> | Oocysts are oval or ellipsoid, light orange, without an oocyst residuum or micropyle | 20 × 15 |

Table 2.7 *Eimeria* species (pigs).

| Species | Oocyst description | Mean size (µm) |
|-----------------------------|---|----------------|
| <i>Eimeria perminuta</i> | Ovoid to subspherical, yellow in colour, and wall with a rough surface. A polar granule is present but no micropyle or oocyst residuum | 13 × 12 |
| <i>Eimeria suis</i> | Ellipsoidal, wall smooth and colourless with a polar granule but no micropyle or oocyst residuum | 18 × 14 |
| <i>Eimeria spinosa</i> | Ovoid with a thick, rough, brown wall with long spines. There is a polar granule but no micropyle or oocyst residuum | 21 × 16 |
| <i>Eimeria neodeblickei</i> | Ellipsoidal, wall smooth and colourless with no micropyle or oocyst residuum but there is a polar granule | 21 × 16 |
| <i>Eimeria deblickei</i> | Ellipsoidal or ovoid, wall smooth and colourless with no micropyle or oocyst residuum but with a polar granule | 19 × 14 |
| <i>Eimeria polita</i> | Ellipsoidal or broad ovoid with a slightly rough yellowish-brown wall with no micropyle, oocyst residuum, although a polar granule may be present | 26 × 18 |
| <i>Eimeria porci</i> | Ovoid, colourless to yellowish-brown, with an indistinct micropyle, a polar granule but no oocyst residuum | 22 × 16 |
| <i>Eimeria scabra</i> | Ovoid or ellipsoidal, with a thick, rough, striated wall, yellow brown in colour with a micropyle and polar granule, but no oocyst residuum | 32 × 23 |

Table 2.8 *Eimeria* species (camel).

| Species | Oocyst description | Mean size (µm) |
|----------------------------|--|----------------|
| <i>Eimeria bactriani</i> | The oocysts are spherical to ellipsoidal, pale yellow-brown, smooth, with a micropyle but without micropylar cap and oocyst residuum. Sporocysts are spherical or elongate with a residuum | 28 × 24 |
| <i>Eimeria cameli</i> | The oocysts are large, pyriform, with a rough brown wall, with a micropyle, with or without a micropylar cap, and without an oocyst residuum. Sporocysts are elongate or ellipsoidal, pointed at both ends with no Stieda body, but with a residuum. Sporozoites are comma-shaped, lie lengthwise head to tail in the sporocyst, and have a clear globule at the large end | 90 × 75 |
| <i>Eimeria dromederii</i> | The oocysts are ovoid with a brown wall, with a micropylar cap, but without a polar granule or oocyst residuum. Sporocysts are ovoid or spherical, without a Stieda body, or residuum. Sporozoites are comma-shaped, with one to two clear globules | 28 × 22 |
| <i>Eimeria pellerdyi</i> | The oocysts are ovoid or ellipsoidal, smooth, colourless without a micropyle, polar granule, or oocyst residuum. Sporocysts are ovoid, with a small Stieda body and a residuum. Sporozoites are club-shaped, with a clear globule at the large end | 23 × 13 |
| <i>Eimeria rajasthanii</i> | The oocysts are ellipsoidal, light yellowish-green, with a micropylar cap, but without polar granule, or oocyst residuum. Sporocysts are ovoid, with a Stieda body and a residuum. Sporozoites are elongate with two or more clear globules | 36 × 26 |

Table 2.9 *Eimeria* species (camelids).

| Species | Oocyst description | Mean size (µm) |
|------------------------------|--|----------------|
| <i>Eimeria lamae</i> | The oocysts are ellipsoidal to ovoid, smooth, bluish to greenish yellow, with a micropyle and micropylar cap, with or without a polar granule, but without an oocyst residuum. Sporocysts are elongate ovoid with a Stieda body and a residuum. Sporozoites are elongate, with one to three clear globules | 35 × 25 |
| <i>Eimeria alpaca</i> | The oocysts are ellipsoidal, rarely ovoid, pale green-blue, smooth, with a micropyle and micropylar cap, with or without polar granules and without an oocyst residuum. Sporocysts are ovoid with a faint Stieda body and a residuum. Sporozoites are elongate and lie lengthwise head to tail in the sporocyst with one to three clear granules | 24 × 19 |
| <i>Eimeria punonensis</i> | Oocysts are ellipsoidal, smooth, with a micropyle, micropylar cap and polar granules. Sporocysts are elongate with a faint Stieda body and a sporocyst residuum | 20 × 16 |
| <i>Eimeria macusaniensis</i> | The oocysts are ovoid, sometimes pyriform, brown with a thick wall, and with a micropyle and micropylar cap, but without a polar granule, or oocyst residuum. Sporocysts are elongate ovoid, with a faint Stieda body and a residuum. Sporozoites are elongate, with a clear globule at the large end and a small one at the small end | 94 × 70 |
| <i>Eimeria ivitaensis</i> | The oocysts are dark brown in colour and ellipsoidal in shape with a micropyle. The sporozoites are elongate with a residuum with a clear globule at the large end and a small globule at the smaller end | 89 × 52 |
| <i>Eimeria peruviana</i> | Oocysts are ovoid and lack a micropyle | 32 × 19 |

Table 2.10 *Eimeria* species (rabbit).

| Species | Oocyst description | Mean size (µm) |
|-----------------------------|--|----------------|
| <i>Eimeria coecicola</i> | Ellipsoidal, light yellow to light brown in colour, with a smooth wall, a distinct micropyle with a slight collar-like protrusion, an oocyst residuum but no polar granule | 34 × 20 |
| <i>Eimeria exigua</i> | Spherical or subspherical, colourless, with no micropyle, polar granule or oocyst residuum | 15 × 14 |
| <i>Eimeria flavescens</i> | Ovoid, yellowish, with a prominent micropyle at the broad end. There is no polar granule or oocyst residuum | 30 × 21 |
| <i>Eimeria intestinalis</i> | Pyriform, yellowish-brown, with a micropyle at the narrow end and large oocyst residuum but no polar granule | 27 × 19 |
| <i>Eimeria irresidua</i> | Ovoid, barrel-shaped, smooth, yellowish, with a wide micropyle; a residuum may be present but there are no polar granules | 39 × 23 |
| <i>Eimeria magna</i> | Ovoid, dark-yellow, truncated at micropylar end with marked collar-like thickening around micropyle, with very large oocyst residuum but no polar granules | 36 × 24 |
| <i>Eimeria media</i> | Ovoid or ellipsoidal, smooth, light pink with a micropyle with a pyramidal-shaped protruberance, a medium to large oocyst residuum and no polar granule | 31 × 17 |
| <i>Eimeria perforans</i> | Ellipsoidal to sub-rectangular, smooth, colourless with a uniformly thin wall. There is an inconspicuous micropyle and an oocyst residuum but no polar granule | 22 × 14 |
| <i>Eimeria piriformis</i> | Pyriform, often asymmetrical, yellowish-brown, with a prominent micropyle but no polar granule or oocyst residuum | 30 × 18 |
| <i>Eimeria stiedai</i> | Slightly ellipsoidal, colourless or pinkish orange, with an inapparent micropyle and no oocyst residuum | 37 × 20 |
| <i>Eimeria vej dovskyi</i> | Elongate or ovoid, micropyle present without collar-like protrusion, and with medium size oocyst residuum | 32 × 19 |

Table 2.11 *Eimeria* species (guinea pig).

| Species | Oocyst description | Mean size (µm) |
|-----------------------|--|----------------|
| <i>Eimeria caviae</i> | Oocysts ellipsoidal or ovoid, smooth, brown, without a micropyle, or polar granule but with a residuum | 19 × 17 |

Table 2.12 *Eimeria* species (mouse).

| Species | Oocyst description | Mean size (µm) |
|----------------------------|---|----------------|
| <i>Eimeria falciformis</i> | Oocysts broadly ellipsoidal, smooth, colourless, without a micropyle, or oocyst residuum | 20 × 19 |
| <i>Eimeria musculi</i> | Oocysts spherical, smooth, greenish, without a micropyle, or oocyst residuum | 23 × 23 |
| <i>Eimeria scheuffneri</i> | Oocysts ellipsoidal, smooth, colourless or yellowish, without a micropyle, or oocyst residuum | 21 × 15 |
| <i>Eimeria krijgsmani</i> | Oocysts cylindrical, smooth, colourless without a micropyle, or oocyst residuum | 22 × 16 |
| <i>Eimeria keilini</i> | Oocysts ellipsoidal, smooth, yellowish, without a micropyle, or oocyst residuum | 28 × 20 |
| <i>Eimeria hindlei</i> | Oocysts ovoid, smooth, greenish, without a micropyle, or oocyst residuum | 25 × 20 |

Table 2.13 *Eimeria* species (rat).

| Species | Oocyst description | Mean size (µm) |
|---------------------------|---|----------------|
| <i>Eimeria nieschulzi</i> | Oocysts ellipsoidal or ovoid, smooth, colourless or yellowish, without a micropyle, or oocyst residuum but with a polar granule | 21 × 17 |
| <i>Eimeria hasei</i> | Oocysts ellipsoidal or ovoid, without a micropyle, or oocyst residuum but with a polar granule | 18 × 14 |
| <i>Eimeria nochtii</i> | Oocysts are ovoid, without a micropyle, oocyst residuum or polar granule | 18 × 17 |
| <i>Eimeria ratti</i> | Oocysts are cylindrical to ovoid, without a micropyle, oocyst residuum but with a polar granule | 22 × 16 |

Table 2.14 *Eimeria* species (chicken).

| Species | Oocyst description | Mean size (µm) |
|---------------------------|--|----------------|
| <i>Eimeria acervulina</i> | Ovoid, smooth without a micropyle or residuum but with a polar granule | 18 × 14 |
| <i>Eimeria brunetti</i> | Ovoid, smooth without a micropyle or residuum but with a polar granule | 26 × 22 |
| <i>Eimeria maxima</i> | Ovoid, yellowish and smooth without a micropyle or residuum but with a polar granule | 30 × 20 |
| <i>Eimeria mitis</i> | Subspherical, smooth without a micropyle or residuum but with a polar granule | 16 × 15 |
| <i>Eimeria necatrix</i> | Ovoid, smooth, colourless without a micropyle or residuum but with a polar granule | 20 × 17 |
| <i>Eimeria praecox</i> | Ovoid, smooth, colourless without a micropyle or residuum but with a polar granule | 21 × 17 |
| <i>Eimeria tenella</i> | Ovoid, smooth, colourless without a micropyle or residuum but with a polar granule | 25 × 19 |

Table 2.15 *Eimeria* species (turkey).

| Species | Oocyst description | Mean size (µm) |
|------------------------------|--|----------------|
| <i>Eimeria adenoides</i> | Ellipsoidal or ovoid, smooth, colourless with a micropyle, one to three polar granules but with no oocyst residuum | 26 × 17 |
| <i>Eimeria dispersa</i> | Ovoid, smooth with no micropyle, polar granule or oocyst residuum | 26 × 21 |
| <i>Eimeria meleagridis</i> | Ellipsoidal, smooth with no micropyle and no oocyst residuum but with one to two polar granules | 23 × 16 |
| <i>Eimeria meleagrimitis</i> | Subspherical, smooth, colourless with no micropyle or oocyst residuum, but with one to three polar granules | 19 × 16 |
| <i>Eimeria gallapovonis</i> | Ellipsoidal, smooth, colourless without a micropyle or oocyst residuum, but with one polar granule | 27 × 17 |
| <i>Eimeria innocua</i> | Subspherical, smooth, without a micropyle or polar granules | 22 × 21 |
| <i>Eimeria subrotunda</i> | Subspherical, smooth, without a micropyle or polar granules | 22 × 21 |

Table 2.16 *Eimeria* species (duck).

| Species | Oocyst description | Mean size (µm) |
|-------------------------|---|----------------|
| <i>Eimeria anatis</i> | Oocysts are ovoid, smooth, colourless, with thickened ring around the micropyle, and without a polar granule or residuum | 17 × 14 |
| <i>Eimeria truncata</i> | Oocysts are ovoid, smooth, with a narrow truncate small end, with a micropyle and micropylar cap, sometimes with a residuum | 20 × 17 |

Table 2.17 *Eimeria* species (goose).

| Species | Oocyst description | Mean size (µm) |
|------------------------|--|----------------|
| <i>Eimeria anseris</i> | Oocysts are small, pear-shaped with a truncated cone, smooth, colourless, with a micropyle, and without a polar granule but with a residuum just beneath the micropyle | 21 × 17 |
| <i>Eimeria nocens</i> | Oocysts are ellipsoidal or ovoid, thick-walled, brown, with a distinct micropyle, which is covered by the outer layer of the oocyst wall | 29 × 20 |

Table 2.18 *Eimeria* species (pheasant).

| Species | Oocyst description | Mean size (µm) |
|----------------------------|--|----------------|
| <i>Eimeria colchici</i> | Oocysts elongate, ellipsoidal with one side less rounded than the other, colourless, with an inconspicuous micropyle, a polar granule but no oocyst residuum | 27 × 17 |
| <i>Eimeria duodenalis</i> | Oocysts are subspherical to broadly ellipsoidal, smooth, colourless to pale yellowish-brown, with no micropyle and no oocyst residuum | 21 × 19 |
| <i>Eimeria megalostoma</i> | Oocysts are ovoid, yellowish-brown, with a thick oocyst wall and prominent micropyle | 24 × 19 |
| <i>Eimeria pacifica</i> | Oocysts are ovoid, with a mammillated oocyst wall | 22 × 17 |
| <i>Eimeria phasiani</i> | Oocysts are ellipsoidal, smooth, yellowish, with no micropyle and no oocyst residuum, but with one to three polar granules | 25 × 17 |

Table 2.19 *Eimeria* species (partridge).

| Species | Oocyst description | Mean size (µm) |
|----------------------------|--|----------------|
| <i>Eimeria caucasica</i> | Oocysts elongate, rarely ovoid | 33 × 19 |
| <i>Eimeria procera</i> | Oocysts elongate-elliptic | 30 × 17 |
| <i>Eimeria koifoidi</i> | Oocysts ovoid | 20 × 18 |
| <i>Eimeria legionensis</i> | Oocysts elliptic, almost symmetrical, sometimes slightly flattened | 21 × 15 |

Table 2.20 *Eimeria* species (quail).

| Species | Oocyst description | Mean size (µm) |
|-------------------------------|---|----------------|
| <i>Eimeria bateri</i> | Oocysts ellipsoidal, ovoid or infrequently round. Single refractive polar granule present, but micropyle and the residual body absent | 23 × 18 |
| <i>Eimeria colini</i> | Oocysts broadly ellipsoid, oocysts with sporocyst residuum, Stieda body and an inconspicuous micropyle, without oocyst residuum and polar granule | 25 × 21 |
| <i>Eimeria coturnicus</i> | Oocysts oval | 33 × 23 |
| <i>Eimeria taldykurganica</i> | Oocysts ovoid, one to two polar granules present but micropyle and residual body absent | 24 × 13 |
| <i>Eimeria tsunodai</i> | Oocysts ovoid | 19 × 18 |
| <i>Eimeria uzura</i> | Oocysts broadly elliptic or ovoid, two to five polar granules present but micropyle and residual body absent | 22 × 16 |

Table 2.21 *Eimeria* species (guinea fowl).

| Species | Oocyst description | Mean size (µm) |
|-------------------------|---|----------------|
| <i>Eimeria grenieri</i> | Oocysts are ellipsoidal, smooth, with a micropyle and polar granules but without a residuum | 21 × 15 |
| <i>Eimeria numidae</i> | Oocysts are ellipsoidal, smooth, with a button-shaped micropyle, a polar granule but without a residuum | 18 × 15 |

Table 2.22 *Eimeria* species (pigeon).

| Species | Oocyst description | Mean size (µm) |
|---|---|----------------|
| <i>Eimeria labbeana</i> (syn <i>Eimeria columbarum</i>) | Oocysts subspherical to spherical, smooth, colourless or slightly yellowish-brown, without a micropyle or a residuum but with a polar granule | 19 × 18 |

Fig. 2.24 Sporulated oocyst of *Cystispora* with two sporocysts each containing four sporozoites.

(Fig. 2.24). Secondly, extra-intestinal stages occurring in the spleen, liver and lymph nodes, as found in the pig for example, may reinvade the intestinal mucosa and cause clinical signs. Thirdly, rodents may, by the ingestion of oocysts from the dog and cat, become infected with asexual stages and act as reservoirs.

Cystispora species

| Species | Hosts | Site |
|---|----------|-----------------|
| <i>Cystispora canis</i> (syn. <i>Isoospora canis</i>) | Dog | Small intestine |
| <i>Cystispora felis</i> (syn. <i>Isoospora felis</i>) | Cat | Small intestine |
| <i>Cystispora ohioensis</i> (syn. <i>Isoospora ohioensis</i>) | Dog | Small intestine |
| <i>Cystispora burrowsi</i> (syn. <i>Isoospora burrowsi</i>) | Dog | Small intestine |
| <i>Cystispora rivolta</i> (syn. <i>Isoospora rivolta</i>) | Cat | Small intestine |
| <i>Cystispora suis</i> (syn. <i>Isoospora suis</i>) | Pig | Small intestine |
| <i>Cystispora orlovi</i> | Camel | Unknown |
| <i>Cystispora belli</i> | Human | Small intestine |
| <i>Cystispora aectopitheci</i> | Primates | Small intestine |
| <i>Cystispora callimico</i> | Primates | Small intestine |
| <i>Cystispora papionis</i> | Primates | Small intestine |

Cystispora canis

Synonym: *Isoospora canis*

Description: Oocysts are ellipsoidal to slightly ovoid, 34–42 by 23–36 µm (mean 38 × 30 µm) with a smooth pale wall without a micropyle, polar granule or residuum, but with a tiny blob adherent to the oocyst wall at the broad end. The two sporocysts are ellipsoidal (18–28 × 15–19 µm) with a smooth colourless wall and a prominent residuum and each contains four sausage-shaped sporozoites with clear sub-central globules.

Cystispora felis

Synonym: *Isoospora felis*

Description: Oocysts are ovoid, measuring 32–53 by 26–43 µm (mean 43 × 32 µm) with a smooth, yellowish to pale brown wall without a micropyle, polar granule or residuum. The two sporocysts are ellipsoidal (20–27 × 17–22 µm) with a smooth colourless wall and a prominent residuum and each contains four sausage-shaped sporozoites with clear sub-central globules.

Cystispora ohioensis

Synonym: *Isoospora ohioensis*

Description: Oocysts are ellipsoidal to oval, measuring 20–27 by 14–24 µm (mean 23 × 19 µm) with a smooth, colourless to pale yellow wall without a micropyle, polar granule or residuum. The two sporocysts are ellipsoidal, 12–19 by 9–13 µm (mean 14.5 × 10 µm), with a residuum and four sporozoites with one or more clear globules.

Cystispora orlovi

Synonym: *Isoospora orlovi*

Description: The oocysts are ellipsoidal, oval, cylindrical or figure 8-shaped, smooth, 27–35 by 15–20 µm, without a polar granule, micropyle or residuum. Sporocysts are ellipsoidal, ovoid (15–20 × 13–17 µm) or spherical (13–15 µm diameter) without a Stieda body, but with a residuum.

Cystispora rivolta

Synonym: *Isospora rivolta*

Description: Oocysts are ellipsoidal to ovoid, measuring 21–29 by 18–26 μm (mean 25 \times 21 μm) with a smooth, colourless to pale brown wall without a micropyle, polar granule or residuum. The two sporocysts are ellipsoidal (14–16 \times 10–13 μm) with a residuum and four sporozoites each with clear sub-central globules.

Cystispora suis

Synonym: *Isospora suis*

Description: Oocysts are spherical to subspherical, wall colourless and thin, measuring 17–25 by 16–22 μm (mean 20.6 \times 18.1 μm) and without a micropyle or residuum. The two sporocysts are ellipsoidal (13–14 \times 8–11 μm) without a Stieda body, but with a sporocyst residuum. The four sporozoites in each sporocyst are sausage-shaped with one pointed end.

Tyzzeria

Parasites of birds; the oocysts contain eight sporozoites and no sporocysts.

Tyzzeria species

| Species | Hosts | Site |
|----------------------------|-------|-----------------|
| <i>Tyzzeria pernicioso</i> | Duck | Small intestine |
| <i>Tyzzeria anseris</i> | Goose | Small intestine |

Tyzzeria pernicioso

Description: Oocysts are ellipsoidal, colourless, 10–13 by 9–11 μm (mean 12 \times 10 μm), without a micropyle and with a residuum and contain eight free sporozoites.

Tyzzeria anseris

Description: Oocysts are ellipsoidal, colourless, 10–16 by 9–14 μm , without a micropyle or residuum, with eight free sporozoites.

Wenyonella

Parasites of birds; the oocysts contain four sporocysts each with four sporozoites.

Wenyonella species

| Species | Hosts | Site |
|----------------------------|---------|-----------------|
| <i>Wenyonella gallinae</i> | Chicken | Caeca, rectum |
| <i>Wenyonella columbae</i> | Pigeon | Small intestine |

Wenyonella gallinae

Description: Oocysts are ovoid, rough, punctate and measure 29–34 by 20–23 μm (mean 31 \times 21 μm). There are four

sporocysts, which are flask-shaped (19 \times 8 μm), and each contains four sporozoites.

Life cycle: Details of the life cycle have not been described. The pre-patent period is 7–8 days and patent period 3 days. The sporulation time is 4–6 days.

Wenyonella columbae

Description: Oocysts are spherical or slightly ovoid, 21–27 by 21–26 μm , without a micropyle, polar granule or oocyst residuum.

Caryospora

The species in this genus infect birds and reptiles, with the majority of described species infecting snakes. Sporulated oocysts have one sporocyst containing eight sporozoites.

FAMILY CRYPTOSPORIDIIDAE

This family contains a single genus, *Cryptosporidium*, occurring in mammals, birds, reptiles and fish. Members of this family are small parasites infecting the brush border of epithelial cells mainly in the gastrointestinal tract.

Life cycle: The life cycle is monoxenous, but some species are capable of infecting a range of vertebrate hosts. Oocysts, each with four sporozoites, are liberated in the faeces (Fig. 2.25). Development is intracellular but extra-cytoplasmic and oocysts lack sporocysts. Gametogony follows after one to two generations of meronts, leading to the production of oocysts. Sporulation takes place within the host so that oocysts are immediately infective. Evidence also indicates that in some species two types of oocysts are produced. The first, the majority, are thick-walled and are passed in the faeces. The remaining oocysts are thin-walled and release their sporozoites in the intestine, causing autoinfection.

Fig. 2.25 Oocysts of *Cryptosporidium parvum* (Ziehl–Neelsen stain \times 1000).

Cryptosporidium

Cryptosporidium is a phenotypically and genotypically heterogeneous assemblage of largely morphologically identical genotypes and species. Species differentiation is determined largely by molecular genotyping and subtyping.

Cryptosporidium species

| Species | Hosts | Site | Oocyst size (µm) |
|------------------------------------|--|-----------------------------|------------------|
| <i>Cryptosporidium parvum</i> | Cattle, sheep, goat, horse, pig, deer, human | Small intestine | 5.0 × 4.5 |
| <i>Cryptosporidium hominis</i> | Human, sheep, dugongs | Small intestine | 5.5 × 4.5 |
| <i>Cryptosporidium bovis</i> | Cattle, sheep | Small intestine | 5.0 × 4.5 |
| <i>Cryptosporidium andersoni</i> | Cattle, camel | Abomasum | 7.4 × 5.5 |
| <i>Cryptosporidium ryanae</i> | Cattle, deer | Small intestine | 3.2 × 3.7 |
| <i>Cryptosporidium muris</i> | Rodents, human, rock hyrax | Stomach | 6.1 × 8.4 |
| <i>Cryptosporidium wrairi</i> | Guinea pig | Small intestine | 5.40 × 4.6 |
| <i>Cryptosporidium canis</i> | Dog, human | Small intestine | 4.7 × 5.0 |
| <i>Cryptosporidium fayeri</i> | Marsupials | Small intestine | 4.9 × 4.3 |
| <i>Cryptosporidium felis</i> | Cat | Small intestine | 4.5 × 5.0 |
| <i>Cryptosporidium suis</i> | Pig | Small and large intestine | 5.2 × 4.1 |
| <i>Cryptosporidium xiaoi</i> | Sheep, goat | Small intestine | 4.0 × 3.4 |
| <i>Cryptosporidium ubiquitum</i> | Deer, ruminants, rodents, carnivores | Small intestine | 5.0 × 4.7 |
| <i>Cryptosporidium baileyi</i> | Chicken, parrot, duck, ostrich | Bursa, conjunctiva, trachea | 4.6 × 6.2 |
| <i>Cryptosporidium meleagridis</i> | Turkey, chicken, duck, and other birds, rarely dogs, human | Small intestine | 4.7 × 4.9 |
| <i>Cryptosporidium galli</i> | Finches, parrot, canary and other bird species | Proventriculus | 8.3 × 6.3 |
| <i>Cryptosporidium serpentis</i> | Snakes | Stomach | 6.2 × 5.3 |
| <i>Cryptosporidium saurophilum</i> | Lizards | Stomach and small intestine | 4.7 × 5 |
| <i>Cryptosporidium molnari</i> | Fish | Stomach and intestines | 4.7 × 4.5 |

Cryptosporidium parvum

Description: Oocysts are ovoidal or spheroidal, 5.0 by 4.5 µm in size (range 4.6–5.4 × 3.8–4.7 µm); length/width ratio, 1.19.

Cryptosporidium andersoni

Description: Oocysts are ellipsoid, 7.4 by 5.5 µm (range 6.0–8.1 × 5.0–6.0 µm); length/width ratio, 1.35.

Cryptosporidium baileyi

Description: Oocysts are ellipsoid, 6.2 by 4.6 µm (range 5.6–6.3 × 4.5–4.8 µm); length/width ratio, 1.3.

Cryptosporidium meleagridis

Description: Oocysts are spherical, 4.9 by 5.4 µm (range 4.5–6.0 × 5.0–6.0 µm); length/width ratio, 1.1.

Cryptosporidium muris

Description: Oocysts are ovoid, 6.1 by 8.4 µm (range 5.6–6.4 × 8.0–9.0 µm); length/width ratio, 1.38.

Cryptosporidium ryanae

Description: Oocysts measure 2.94–4.41 by 2.94–3.68 µm (mean 3.16 × 3.73 µm); length/width shape index, 1.18.

Cryptosporidium wrairi

Description: Mature oocysts are ovoid, 4.8–5.6 by 4.0–5.0 µm (mean 5.40 × 4.6 µm); length/width ratio, 1.17.

Cryptosporidium fayeri

Description: Mature oocysts are ovoid and measure 4.5–5.1 by 3.8–5.0 µm (mean 4.9 × 4.3 µm); length/width ratio, 1.02–1.18 (mean 1.14).

Cryptosporidium xiaoi

Description: Oocysts measure 3.94 by 3.44 µm (range 2.94–4.41 × 2.94–4.41 µm); length/width shape index, 1.15.

Cryptosporidium ubiquitum

Description: Oocysts measure 5.04 by 4.66 µm (range 4.71–5.32 × 4.33–4.98 µm); length/width shape index, 1.08.

Cryptosporidium serpentis

Description: Oocysts measure 6.2 by 5.3 µm (range 5.6–6.6 × 4.8–5.6 µm); length/width shape index, 1.16.

FAMILY SARCOCYSTIIDAE

Six genera – *Besnoitia*, *Hammondia*, *Sarcocystis*, *Neospora*, *Frenkelia* and *Toxoplasma* – are of veterinary interest. Their life cycles are similar to those of *Eimeria* and *Isospora* except that the asexual and sexual stages occur in intermediate and final hosts, respectively.

Oocysts have two sporocysts each with four sporozoites. With the exception of the genus *Toxoplasma*, they are normally non-pathogenic to their final hosts and their significance is due to the cystic tissue stages in the intermediate hosts, which include ruminants, pigs, horses and humans. The tissue phase in the intermediate host is obligatory, except in *Toxoplasma* where it is facultative.

Besnoitia

Species of *Besnoitia* have been found in cattle, horses, deer, rodents, primates and reptiles. Cats are the definitive hosts. The parasites develop in connective tissue, particularly of the skin, causing skin thickening and hair loss.

Life cycle: Members of the genus are heteroxenous, reproducing sexually, and producing unsporulated oocysts in felids and multiplying by merogony in a variety of prey animals.

Besnoitia species

| Species | Hosts | Intermediate hosts | Site |
|--|---|---|-------------------|
| <i>Besnoitia besnoiti</i> (syn. <i>Sarcocystis besnoiti</i>) | Cat, wild cats (lion, cheetah, leopard) | Cattle, goat, wild ruminants (wildebeest, impala, kudu) | Skin, conjunctiva |
| <i>Besnoitia bennetti</i> | Unknown | Horse, donkey | Skin, conjunctiva |
| <i>Besnoitia tarandi</i> | Unknown | Reindeer, caribou | Skin, conjunctiva |

Besnoitia besnoiti

Synonym: *Sarcocystis besnoiti*

Description: Oocysts in the definitive hosts are ovoid, 14–16 by 12–14 μm , and after sporulation contain two sporocysts each with four sporozoites. The pseudocysts in the intermediate hosts are non-septate and about 100–600 μm in diameter, with a thick wall containing thousands of merozoites but no merozoites (Fig. 2.26).

Besnoitia bennetti

Description: Oocysts have not been described. The pseudocysts in the intermediate hosts are non-septate and about 100–1000 μm in diameter.

Fig. 2.26 Tissue cyst *Besnoitia besnoiti*.

Hammondia

The genus is closely related to *Toxoplasma* and has a heteroxenous life cycle with a carnivore definitive host and an intermediate (prey species) host. Reproduction (gametogony) occurs in the small intestine of the final host. Cysts containing bradyzoites occur in the skeletal muscle of the prey host.

Hammondia species

| Species | Hosts | Intermediate hosts | Site |
|---|----------------------|--|-----------------|
| <i>Hammondia hammondi</i> (syn. <i>Isospora hammondi</i> , <i>Toxoplasma hammondi</i>) | Cat and other felids | Rodents | Skeletal muscle |
| <i>Hammondia heydorni</i> | Dog and other canids | Cattle, sheep, goat, rodents, guinea pig | Skeletal muscle |

Hammondia hammondi

Synonyms: *Isospora hammondi*, *Toxoplasma hammondi*

Description: Unsporulated oocysts are colourless, spherical to subspherical, 11–13 by 10–13 μm without a micropyle or residuum; and subspherical to ellipsoidal, 13–14 by 10–11 μm (mean 13 \times 11 μm) after sporulation. The sporocysts are ellipsoidal, 8–11 by 6–8 μm (mean 10 \times 6.5 μm) and have no Stieda body but have a residuum. The sporozoites are elongate and curved with a nucleus near the centre.

Life cycle: The cat is infected by ingesting the infected rodents containing meronts. After ingestion, there is multiplication in the small intestine epithelium followed by gametogony. The prepatent period in the cat is 5–16 days and the patent period can be as long as 136 days.

Hammondia heydorni

Synonyms: *Isospora heydorni*, *Toxoplasma heydorni*

Description: Unsporulated oocysts are colourless, spherical to subspherical, 11–13 by 10–13 μm without a micropyle or residuum; and subspherical to ellipsoidal, 13–14 by 10–11 μm (mean 13 \times 11 μm) after sporulation. The sporocysts are ellipsoidal, 8–11 by 6–8 μm (mean 10 \times 6.5 μm) and have a residuum. The sporozoites are elongate and curved with a nucleus near the centre.

Life cycle: Unsporulated oocysts are produced in the faeces and, following infection of the intermediate hosts, the multiplication of tachyzoites in the lamina propria of the intestinal wall is followed by the production of cysts containing bradyzoites in the skeletal muscle. The prepatent period is 6–7 days. Sporulation time is 3 days.

Sarcocystis

There are about 130 recognised species in this genus reported from the striated muscles of mammals, birds, reptiles and humans. *Sarcocystis* is one of the most prevalent parasites of livestock and infects mammals, including humans, birds and lower vertebrates. The parasites derive their name from the intramuscular cyst stage

Fig. 2.27 Sarcocysts in bovine muscle.

(sarcocyst) present in the intermediate (prey) host (Fig. 2.27). Most *Sarcocystis* species, infecting human and domestic animals, are species-specific for their intermediate hosts and family-specific for their final hosts. *Sarcocystis* infections in the intermediate host are usually asymptomatic. Gastrointestinal disease is occasionally reported in humans.

Sarcocysts are found in striated and heart muscles and may be either microscopic or visible to the naked eye and contain meronts initially, and bradyzoites when mature. Oocysts sporulate within the predator host and are passed in the faeces. Revision of the taxonomy of the genus is ongoing, and many of the currently recognised species may be synonyms of species that can infect multiple hosts.

Life cycle: The life cycle for all species is heteroxenous. Sexual stages occur in the predator and oocysts are passed in the faeces. Infection in the dog and cat is by ingestion of bradyzoite cysts in the muscles of infected intermediate hosts. The bradyzoites are liberated in the intestine and the freed zoites pass to the subepithelial lamina propria and differentiate into micro- and macro-gametocytes. Following conjugation of gametes, thin-walled oocysts are formed which, unlike those of most other enteric sporozoans, sporulate within the body. Two sporocysts are formed, each containing four sporozoites. Usually the fragile oocyst wall ruptures and free sporocysts are found in the faeces.

Sarcocystis species

| Species | Final hosts | Intermediate hosts | Site |
|---|---------------------------|--------------------------------|--------|
| <i>Sarcocystis alceslatrans</i> | Dog, coyote | Deer (moose) | Muscle |
| <i>Sarcocystis aucheniae</i> (syn. <i>Sarcocystis tilopodi</i> , <i>Sarcocystis guanicoecanis</i>) | Dog | Llama, guanaco, alpaca | Muscle |
| <i>Sarcocystis bovicanis</i> (syn. <i>Sarcocystis cruzi</i> , <i>Sarcocystis fusiformis</i>) | Dog, fox, wolf, coyote | Cattle | Muscle |
| <i>Sarcocystis bovisfelis</i> (syn. <i>Sarcocystis hirsuta</i> , <i>Sarcocystis fusiformis</i>) | Cat | Cattle | Muscle |
| <i>Sarcocystis bovihominis</i> (syn. <i>Sarcocystis hominis</i>) | Human, primates | Cattle | Muscle |
| <i>Sarcocystis cameli</i> | Dog | Camel (Bactrian, dromedary) | Muscle |
| <i>Sarcocystis capracanis</i> | Dog | Goat | Muscle |
| <i>Sarcocystis capreolicanis</i> | Dog, fox | Deer (roe deer) | Muscle |

| Species | Final hosts | Intermediate hosts | Site |
|--|--------------------------|---|-----------------------|
| <i>Sarcocystis cervicanis</i> | Dog | Deer (red deer) | Muscle |
| <i>Sarcocystis cuniculi</i> | Cat | Rabbit | Muscle |
| <i>Sarcocystis equicanis</i> (syn. <i>Sarcocystis bertrami</i>) | Dog | Horse | Muscle |

Sarcocystis bovicanis

Synonyms: *Sarcocystis cruzi*, *Sarcocystis fusiformis*

Description: Meronts found in the endothelial cells are quite small, measuring 2–8 µm in diameter. The bradyzoite cysts can be large and visible to the naked eye as whitish streaks running in the direction of the muscle fibres. They have been reported as reaching several centimetres in length, but more commonly range from 0.5 to 5.0 mm. The cyst wall is thin and smooth and has a small number of flattened protrusions 0.3–0.6 µm long, without fibrils.

Sporulated oocysts are fully sporulated and dumb-bell shaped if passed in the faeces, 19–21 by 15–18 μm , with a thin oocyst wall sunken between two sporocysts, without a micropyle, polar granule or oocyst residuum. However, it is usually the sporulated sporocyst that is found free in the faeces. Sporocysts are ellipsoidal, 14.3–17.4 by 8.7–13.3 μm (mean 16.3 \times 10.8 μm), smooth, colourless without a Stieda body but with a residuum and each has four sporozoites.

Sarcocystis bovifelis

Synonyms: *Sarcocystis hirsuta*, *Sarcocystis fusiformis*

Description: First-generation meronts measure 37 by 22 μm and contain more than 100 tachyzoites. Second-generation meronts, when mature, are 14 by 6.5 μm and contain up to 35 tachyzoites. Sarcocysts are up to 8 mm long with a striated wall, 7 μm thick, and may be visible to the naked eye.

Oocysts are smooth, colourless, 12–18 by 11–14 μm and contain two sporocysts each with four sporozoites, dumb-bell shape in appearance, and with no micropyle, polar granule or oocyst residuum. Sporocysts are ellipsoidal, 11–14 by 7–9 μm (mean 12.5 \times 7.8 μm) without a Stieda body but with a residuum.

Sarcocystis bovi hominis

Synonym: *Sarcocystis hominis*

Description: First-generation meronts are 37 by 22 μm and contain more than 100 tachyzoites. Second-generation meronts, when mature, are 14 by 6.5 μm and contain up to 35 tachyzoites. Sarcocysts are up to 8 mm long with a striated wall, 7 μm thick.

Sarcocystis ovicanis

Synonyms: *Sarcocystis tenella*, *Isospora bigemina*

Description: First-generation meronts found in the endothelial cells are 19–29 by 7.5–24 μm and contain 120–280 merozoites. Tissue cysts are microscopic in size (500 \times 60–100 μm) and are found in skeletal and cardiac muscle. The wall of the cyst appears thick (up to 2.5 μm) and radially striated with long palisade-like protrusions without fibrils visible on electron microscopy. Oocysts are sporulated when passed in the faeces and contain two sporocysts each with four sporozoites; usually the sporulated sporocyst is found free in the faeces. In *S. ovicanis*, the sporulated sporocysts measure approximately 13.1–16.1 by 8.5–10.8 μm (mean 14.8 \times 9.9 μm).

Life cycle: Sheep become infected by ingesting sporocysts passed in the faeces of the dog. Once ingested, there are three asexual generations. In the first, sporozoites, released from the sporocysts, invade the intestinal wall and enter the capillaries where they locate in endothelial cells in many organs and undergo two merogony cycles. A third asexual cycle occurs in the circulating lymphocytes, the resulting merozoites penetrating muscle cells. There they encyst and then divide by a process of budding or endodyogeny, giving rise to broad banana-shaped bradyzoites contained within a cyst; this is the mature sarcocyst and is the infective stage for the dog final host.

Sarcocystis ovifelis

Synonyms: *Sarcocystis tenella*, *Sarcocystis gigantea*, *Sarcocystis medusiformis*, *Isospora bigemina*

Description: Meronts found in the endothelial cells are quite small, measuring 2–8 μm in diameter. Bradyzoite cysts have been reported as reaching several centimetres in length, but more commonly they range up to 1.5 cm by 0.2–5 mm. The cyst wall has numerous cauliflower-like protrusions 1–4.5 μm long, each containing numerous fibrils. The parasitised host cell is enclosed in connective tissue forming a secondary cyst wall. Sporulated sporocysts are ellipsoidal and measure 10.8–13.9 by 7.7–9.3 μm (mean 12.4 \times 8.1 μm).

Life cycle: Infection is by ingestion of the sporocysts and this is followed by a single asexual generation in capillaries and arterioles of the lung, kidney and brain, from which the resulting merozoites penetrate muscle cells. There they encyst and then divide by a process of budding or endodyogeny, giving rise to broad banana-shaped bradyzoites contained within the sarcocyst. Sarcocysts are found primarily in the muscles of the oesophagus, larynx, tongue and, to a lesser extent, diaphragm and skeletal muscles. Cats are the final host.

Sarcocystis capracanis

Description: Tissue cysts are microscopic in size (130–800 \times 50–70 μm) and are found in skeletal and cardiac muscle. The wall of the cyst appears thick (up to 2.6 μm) and radially striated with long finger-like protrusions. The oocysts have not been described. The sporulated sporocysts are ellipsoidal and measure approximately 12–15 by 8–10 μm .

Life cycle: As described for sheep species. There are three merogony cycles.

Sarcocystis hircicanis

Description: Tissue cysts are up to 2.5 mm in size and are found in skeletal and cardiac muscle. The wall of the cyst is thin, smooth and striated with long hair-like protrusions. The oocysts have not been described. The sporulated sporocysts are ellipsoidal and measure approximately 15–17.3 by 10.5–11.3 μm .

Life cycle: As for *S. capracanis*. The number of merogony stages is unknown.

Sarcocystis hircifelis

Synonym: *Sarcocystis moulei*

Description: The sarcocysts are elongate, compartmented and up to 12 mm in length and have a thick striated wall. Sporocysts measure 12.4 by 9.1 μm .

Life cycle: As described for *S. hircicanis* except that the cat is the final host. The number of merogony stages is unknown.

Sarcocystis equicanis

Synonym: *Sarcocystis bertrami*

Description: Tissue cysts are segmented, up to 10 mm long with a smooth wall less than 1 μm thick with no radial striations. A small

number of 0.4–2.0 µm protrusions are evident on electron microscopy. Sporulated sporocysts measure 15–16.3 by 8.8–11.3 µm (mean 15.2–10 µm).

Sarcocystis fayeri

Description: Tissue cysts are up to 900 µm long by 70 µm wide. The cyst wall is 1–2 µm thick and radially striated. Sporulated sporocysts measure 11–13 by 7–8.5 µm (mean 12.0 × 7.9 µm).

Sarcocystis neurona

Description: Meronts present in the cytoplasm of neural cells, leucocytes and giant cells in the grey and white matter of the brain and spinal cord measure 5–35 by 5–20 mm and contain 4–40 merozoites when mature.

Life cycle: Details of the life cycle are not completely known. The North American opossum is thought to be one definitive host with transmission to the horse via sporocysts in faeces. The life cycle may also involve opossums scavenging on bird carcasses containing an identical organism, *Sarcocystis falcatula*, a parasite of several North American bird species. In this respect, horses may be acting as an abnormal, aberrant host.

Sarcocystis suicanis

Synonyms: *Sarcocystis porcicanis*, *Sarcocystis miescheriana*

Description: Tissue cysts are compartmented up to 0.5–1.5 mm long by 15–100 µm. The cyst wall has numerous palisade-like processes with randomly arranged filaments seen on electron microscopy. Sporulated sporocysts found free in the faeces measure approximately 12.7 by 10.1 µm.

Life cycle: Infection is by ingestion of the sporocysts and this is followed by three asexual generations. In the first, sporozoites, released from the sporocysts, invade the venules of the liver where they locate in endothelial cells. The second-generation meronts are found in the endothelial cells of capillaries of all organs and the resulting merozoites penetrate muscle cells. There they encyst and then divide by a process of budding or endodyogeny, giving rise to broad banana-shaped bradyzoites contained within a cyst; this is the mature sarcocyst and is the infective stage for the carnivorous final host. Cysts are found in skeletal and cardiac muscle.

Sarcocystis porcifelis

Synonym: *Sarcocystis suisfelis*

Description: The sporulated sporocysts are ellipsoidal and measure 13.2–13.5 by 7.2–8 µm, without a Stieda body, but with a residuum.

Sarcocystis suihominis

Synonym: *Sarcocystis porcihominis*

Description: Mature sarcocysts are thin-walled, compartmented, up to 1.5 mm long and have protrusions up to 13 µm long, folded closely on the surface.

Life cycle: Infection is by ingestion of the sporocysts and this is followed by at least three asexual generations. In the first, sporozoites, released from the sporocysts, invade the intestinal wall and the endothelial cells of blood vessels in the liver, where they undergo two merogony cycles. Sarcocysts can be found in the striated muscles, heart and brain. At first they contain only metrocytes but these divide rapidly to form bradyzoites contained within the thin-walled cyst; this is the mature sarcocyst and is the infective stage for the final host. The prepatent period is about 12–14 days and the patent period lasts at least 18 days.

Sarcocystis hovarthi

Synonym: *Sarcocystis gallinarum*

Description: Tissue cysts are 1–10 mm long with striated walls and are found in skeletal muscles of the breast, thigh, neck and oesophagus. The oocysts have not been described. The sporulated sporocysts are ellipsoidal and measure approximately 10–13 by 7–9 µm.

Frenkelia

The closely related genus, *Frenkelia*, differs from *Sarcocystis* in that its last-generation meronts occur in the brain rather than in the muscles. The protozoa in this genus infect the gastrointestinal tract of birds of prey (definitive hosts) and the tissues of small rodents (intermediate hosts).

Neospora

The single species in this genus, *Neospora caninum*, is an important pathogen in cattle and dogs. *Neospora* is a cause of paralysis in dogs and abortion in cattle. Recent evidence indicates members of the dog family are the final hosts.

Neospora species

| Species | Final hosts | Intermediate hosts | Site |
|-------------------------|-------------------|--------------------|-------------------------------|
| <i>Neospora caninum</i> | Dog, other canids | Cattle | Brain, heart, liver, placenta |

Neospora caninum

Description: Unsporulated oocysts in dogs are reported to measure 11.7 by 11.3 µm (10.6–12.4 × 10.6–12.0 µm). Tachyzoites measure 6 by 2 µm and are usually located in the cytoplasm of cells. Tissue cysts are oval, 107 µm long, and have a thick wall (up to 4 µm) and are found only in neural tissue.

Life cycle: The complete life cycle of *Neospora caninum* has only recently been elucidated. Oocysts are passed in the faeces of the definitive host 8–23 days after infection. When ingested by the intermediate hosts, such as cattle, they become permanently infected and form tissue cysts. Pregnancy activates these cysts and may cause spontaneous abortion. If the aborted fetus and placenta are eaten by the final carnivore host, they become infected and the life

cycle is complete. Transplacental infection has been shown to occur in cattle, sheep, dogs and cats. Dogs and foxes can also act as intermediate hosts.

Toxoplasma

The genus *Toxoplasma* contains a single species. Unsporulated oocysts are passed in the faeces of cats and other felids. *Toxoplasma* shows a complete lack of species specificity in the intermediate host and is capable of infecting any warm-blooded animal and is an important zoonosis.

Life cycle: The final host is the cat, in which gametogony takes place. A range of mammals (and birds) act as intermediate hosts, in which the cycle is extra-intestinal and results in the formation of tachyzoites and bradyzoites, which are the only forms found in non-feline hosts. Infection usually occurs through the ingestion of sporulated oocysts. The liberated sporozoites rapidly penetrate the intestinal wall and spread by the haematogenous route. This invasive and proliferative stage is called the tachyzoite and, on entering a cell, it multiplies asexually in a vacuole by a process of budding or endodyogeny, in which two individuals are formed within the mother cell, the pellicle of the latter being used by the daughter cells. When 8–16 tachyzoites have accumulated, the cell ruptures and new cells are infected. This is the acute phase of toxoplasmosis. In most instances, the host survives and antibody is produced which limits the invasiveness of the tachyzoites and results in the formation of cysts containing thousands of organisms which, because endodyogeny and growth are slow, are termed bradyzoites. The cyst containing the bradyzoites is the latent form, multiplication being held in check by the acquired immunity of the host. If this immunity wanes, the cyst may rupture, releasing the bradyzoites, which become active and resume the invasive characteristics of the tachyzoites.

Toxoplasma species

| Species | Final hosts | Intermediate hosts | Site |
|--------------------------|-------------------|--|--|
| <i>Toxoplasma gondii</i> | Cat, other felids | Any mammal, including humans, or birds | Muscle, lung, liver, reproductive system, central nervous system |

Toxoplasma gondii

Description: Oocysts are round to slightly oval and measure 11–15 μm (mean 13 μm) by 8–12 μm (mean 11 μm). Sporulated oocysts contain two ellipsoidal sporocysts (8.5 \times 6 μm) each containing four sporozoites. Tachyzoites are found developing in vacuoles in many cell types, for example fibroblasts, hepatocytes, reticular cells and myocardial cells. In any one cell there may be 8–16 organisms, each measuring 6.0–8.0 μm . Tissue cysts, measuring up to 100 μm in diameter, are found mainly in the muscle, liver, lung and brain and may contain several thousand lancet-shaped bradyzoites.

FAMILY LANKESTERELLIDAE

Lankesterella occur in amphibians; *Schellakia* are found in reptiles. Transmission is by leeches, mites and insects.

SUBORDER ADELEORINA

FAMILY KLOSSIELLIDAE

Klossiella is the only genus in this family. Its members are essentially non-pathogenic, with most species occurring in the kidneys. The oocysts reside in the kidney tubules, where they contain as many as 40 sporocysts, each with 8–15 sporozoites. The sporocysts pass out in the urine and infect new hosts when they are ingested.

Klossiella

Members of the genus are homoxenous, with meronts and merozoites present in the Bowman's capsules and gamonts in the tubules of the kidney.

Life cycle: The life cycle is not clearly understood. Within epithelial cells of kidney tubules, trophozoites form meronts and merozoites, which in turn form gamonts. Fertilised gametes are believed to develop into sporonts, which bud to form sporoblasts. Each of these sporoblasts undergoes successive divisions to form sporocysts that contain sporozoites. Mature sporocysts are surrounded by a thick wall and pass from the body in the urine. When ingested by another host, the sporozoites are released from the sporocyst and move to the kidney, where they enter epithelial cells and initiate the cycle.

Klossiella species

| Species | Hosts | Site |
|---------------------------|----------------------|--------|
| <i>Klossiella equi</i> | Horse, donkey, zebra | Kidney |
| <i>Klossiella cobayae</i> | Guinea pig | Kidney |
| <i>Klossiella muris</i> | Mouse | Kidney |
| <i>Klossiella boae</i> | Snakes | Kidney |

Klossiella equi

Description: Meronts in endothelial cells of the Bowman's capsule in the kidneys are 8–12 μm in diameter with 20–30 nuclei. Second-generation meronts found in epithelial cells of the proximal convoluted tubules are 15–23 μm in diameter and contain 15–20 merozoites. Gametogony and sporogony occur in the epithelial cells of the thick limb of Henle's loop. Mature sporocysts are surrounded by a thick wall and each contains 10–15 sporozoites.

FAMILY HAEMOGREGARINIDAE

Parasites of the genus *Haemogregarina* have been described from the red blood cells of chelonia and are generally considered to be non-pathogenic. The definitive hosts are leeches.

FAMILY HEPATOZOIDAE

The genus *Hepatozoon* has been reported from mammals, reptiles and birds and is of importance in dogs. Definitive hosts include ticks, mites, sandflies, tsetse flies, mosquitoes, fleas, lice, reduviid bugs and leeches.

Hepatozoon

Parasites of this genus share a basic life cycle that includes sexual development and sporogony in a haematophagous invertebrate definitive host, and merogony followed by gametogony in a vertebrate intermediate host. Transmission takes place by ingestion of the definitive host, an invertebrate containing *Hepatozoon* oocysts, by the intermediate host.

Hepatozoon species

| Species | Hosts | Intermediate hosts | Site |
|------------------------------|---|--------------------|-----------------------------|
| <i>Hepatozoon canis</i> | Ticks (<i>Rhipicephalus</i>) | Dog | Blood, liver, kidney |
| <i>Hepatozoon americanum</i> | Ticks (<i>Amblyomma</i>) | Dog | Blood, muscle |
| <i>Hepatozoon</i> spp. | Unknown | Cat | Myocardium, skeletal muscle |
| <i>Hepatozoon cuniculi</i> | Unknown | Rabbit | Spleen |
| <i>Hepatozoon muris</i> | Spiny rat mite (<i>Echinolaelaps</i>) | Rat | Blood, liver |

Hepatozoon canis

Description: Gamonts, found in circulating neutrophils, are ellipsoidal in shape, about 11 by 4 μm , and are enveloped in a thick membrane. Meronts are usually round to oval, about 30 μm in diameter, and include elongated micromerozoites with defined nuclei, which in cross-section have a 'wheel-spoke' appearance.

Life cycle: The life cycle involves two hosts. The tick is a final host in which syngamy occurs, and the dog is an intermediate host in which asexual reproduction occurs. Nymphal ticks engorge with gamont-infected leucocytes in an infected dog. Following ingestion the gamonts are freed from the leucocytes, associate in pairs and transform into male and female gametes leading to the formation of zygotes and oocysts. Each mature oocyst contains numerous sporocysts, each containing 10–26 sporozoites. After the tick moults, oocysts are found in the haemocoel and each tick may carry thousands of infective sporozoites. Since the sporozoites remain in the body cavity, the dog is apparently infected by ingesting the tick. Once ingested the sporozoites are released from the oocysts, penetrate the intestinal wall and are transported to target tissues and organs in the blood and lymph. They primarily infect the spleen, lymph nodes and bone marrow where merogony occurs in macrophages and endothelial cells. Two forms of meronts are found in infected tissues, one type containing two to four macromerozoites, and a second type containing 20 elongated micromerozoites. When the meront matures and ruptures, merozoites are released and penetrate circulating neutrophils, in which they develop into gamonts that circulate in peripheral blood. The cycle is completed when the tick ingests infected blood. The period of development in the dog from infection to the appearance of gamonts is about 28 days.

Hepatozoon americanum

Description: Gamonts present within neutrophils are ellipsoidal in shape, 8.8 by 3.9 μm , with a central compact nucleus and enveloped in a thick membrane. The cytoplasm stains pale blue and the nucleus dark reddish with Giemsa stain. Muscle cysts are round to

oval, 250–500 μm in diameter, with the outer portion composed of concentric layers of fine, pale-staining laminar membranes that give the cyst an 'onion skin' appearance.

Life cycle: Similar to that of *H. canis*. The parasite infects skeletal and cardiac muscle, where it develops between myocytes within host cells of undetermined origin. Mucopolysaccharide layers encyst the infected cells in the muscle where the parasite undergoes merogony. At maturation, the cyst ruptures releasing merozoites into adjacent tissue. Neutrophils and macrophages are recruited to the area and many become infected, leading to pyogranuloma formation with increased vascularisation, allowing infected leucocytes containing gamonts to enter the circulation and repeat the asexual reproductive phase at other sites. The cycle is completed when the tick ingests infected blood. The period of development in the dog from infection to the appearance of gamonts is about 32 days.

Hepatozoon cuniculi

Description: Merocysts may reach 4–6 mm in diameter.

Life cycle: The life cycle is unknown. Meronts are found in the spleen and gamonts within leucocytes.

Hepatozoon muris

Synonyms: *Hepatozoon perniciosum*, *Leucocytozoon muris*, *Leucocytozoon ratti*

Description: Meronts in the liver are 10–30 μm in diameter. Gamonts in the lymphocytes appear in stained blood smears as elongated oval bodies, 8–12 by 3–6 μm .

Life cycle: Rats become infected by ingesting the invertebrate host, the spiny rat mite *Echinolaelaps echidninus*. Sporozoites are released in the intestine, enter the hepatic portal system and are transported to the liver. Merogony takes place in the liver parenchymal cells. Merozoites enter the lymphocytes in the blood and become gamonts. Fertilisation and sporogony occur in the arthropod vector following ingestion.

ORDER HAEMOSPORORIDA

A single family, the Plasmodiidae, contains a number of genera of medical and veterinary interest. All species are heteroxenous with merogony occurring in a vertebrate host and sporogony in an invertebrate host. There are no sporocysts, with the sporozoites lying free within the oocysts.

FAMILY PLASMODIIDAE

Within the family Plasmodiidae are the species of *Plasmodium* which cause malaria in humans, one of the most prevalent diseases of humans in the world. Sporozoites are inoculated into humans by female anopheline mosquitoes. *Plasmodium falciparum* causes malignant tertian or falciparum malaria; *P. vivax* causes benign malaria; *P. malariae* causes quartan or malariae malaria; and *P. ovale* causes a type of tertian malaria. Malaria is also one of the most common haemoprotozoal parasitic diseases of primates in

Table 2.23 Species of *Plasmodium* from non-human primates.

| Prosimians | Old World Monkeys | New World Monkeys | Apes |
|---|---|-------------------------------|---|
| Quotidian | <i>Plasmodium knowlesi</i> | | |
| Tertian <i>Plasmodium lemuris</i> | <i>Plasmodium cynomolgi</i> <i>Plasmodium coatneyi</i> <i>Plasmodium fragile</i> <i>Plasmodium siminovale</i> <i>Plasmodium fieldi</i> <i>Plasmodium gonderi</i> <i>Plasmodium eylesi</i> <i>Plasmodium jefferyi</i> <i>Plasmodium youngi</i> | <i>Plasmodium simium</i> | <i>Plasmodium pitheci</i> <i>Plasmodium reichenowi</i> <i>Plasmodium schwetzi</i> <i>Plasmodium silvaticum</i> |
| Quartan <i>Plasmodium girardi</i> | <i>Plasmodium inui</i> <i>Plasmodium hylobati</i> <i>Plasmodium shortii</i> | <i>Plasmodium brazilianum</i> | <i>Plasmodium malariae</i> (syn. <i>Plasmodium rodhaini</i>) |

tropical and semi-tropical regions. Malaria parasites that infect the apes are different to those affecting monkeys and are homologous to the human malaria parasites and morphologically indistinguishable (Table 2.23).

Three separate genera in this family, *Plasmodium*, *Haemoproteus* and *Leucocytozoon*, are the causes of avian 'malaria' in domestic and wild birds, a disease most common in the tropics and transmitted by biting dipteran flies. The vectors differ, in that avian species of *Plasmodium* are transmitted by mosquitoes, *Haemoproteus* by midges or hippoboscids flies, and *Leucocytozoon* by *Simulium* spp.

Plasmodium

Avian malaria is a common mosquito-transmitted disease of wild birds that infects domestic fowl and cage birds when suitable vectors and wild reservoir hosts are present. There are over 30 species of *Plasmodium* affecting birds and which differ widely in host range, geographical distribution, vectors and pathogenicity. Avian species of malaria fall into two groups, with either round or elongate gamonts present within the erythrocytes, and can be grouped into five subgenera (Table 2.24) according to morphological characteristics that include size and shape of the gamonts and meronts. Species that infect domestic birds occur in four of the five subgenera.

Table 2.24 Avian subgenera of *Plasmodium*.

| Description | Subgenus |
|--|----------------------|
| Parasites without pigment | |
| Gametocytes and meronts large and when mature displace host cell nucleus; present only in circulating leucocytes | <i>Plasmodioides</i> |
| Parasites with pigments | |
| Rounded gametocytes displacing host cell nucleus towards pole | <i>Haemamoeba</i> |
| Gametocytes elongate; no displacement of host cell nucleus; meronts in circulating erythrocyte precursors only | <i>Huffia</i> |
| Gametocytes elongate; no displacement of host cell nucleus; meronts in mature erythrocytes only; larger than host cell nucleus containing large amounts of cytoplasm | <i>Giovannolaia</i> |
| Meronts in mature erythrocytes only; smaller than host cell nucleus with little cytoplasm | <i>Novyella</i> |

Plasmodium spp. are distinguished from the genera *Haemoproteus* and *Leucocytozoon* by the presence of merogony in circulating erythrocytes. Meronts for the majority of avian *Plasmodium* species are found within endothelial cells of the lymphoid-macrophage system. With one exception, all species of *Plasmodium* are transmitted by culicine mosquitoes. Pre-erythrocytic meronts develop in the liver and produce merozoites, which enter into the erythrocytes producing gamonts. Intraerythrocytic merogony may continue indefinitely leading to persistent infection with frequent relapses.

Avian *Plasmodium* species

| Species | Subgenus | Hosts |
|---------------------------------|---------------------|-----------------------------------|
| <i>Plasmodium gallinaceum</i> | <i>Haemamoeba</i> | Chicken, guinea fowl |
| <i>Plasmodium relictum</i> | <i>Haemamoeba</i> | Pigeon, dove, duck, wild birds |
| <i>Plasmodium hermani</i> | <i>Huffia</i> | Turkey, wild birds |
| <i>Plasmodium durae</i> | <i>Giovannolaia</i> | Turkey, peafowl |
| <i>Plasmodium juxtanucleare</i> | <i>Novyella</i> | Chicken, other gallinaceous birds |
| <i>Plasmodium struthionis</i> | ? | Ostrich |

Plasmodium gallinaceum

Subgenus: *Haemamoeba*

Description: The trophozoite is a small rounded form containing a large vacuole, which displaces the cytoplasm of the parasite to the periphery of the erythrocyte (Fig. 2.28). The nucleus is situated at one of the poles, giving the young form a 'signet ring' appearance when stained by Giemsa. Both gametocytes and meronts can be round, oval or irregular in shape. The nucleus of host cells is rarely expelled during infection, but may be displaced by the parasite. Each meront produces 8–36 merozoites and on average there are 16–20 merozoites in erythrocytic meronts.

Life cycle: Following the introduction of the sporozoites from infected mosquitoes, numerous pre-erythrocytic meronts (cryptozoites) are found in the macrophages and fibroblasts of the skin near the point of entry. Merozoites from this first generation of pre-erythrocytic meronts form a second generation of pre-erythrocytic meronts, the metacryptozoites, which reach maturity at about 72 hours. Merozoites from the metacryptozoites enter erythrocytes

Fig. 2.28 *Plasmodium gallinaceum* macrogamont within an erythrocyte located below the cell nucleus.

and cells of the lymphoid–macrophage system in the skin, spleen, lungs and capillary endothelial cells of the major organs. In this species, the exoerythrocytic developmental stages may be added to by forms which are derived from the erythrocytic cycle. These are known as phanerozoites, being derived from the merozoites of the meronts in the erythrocytic cycle.

The erythrocytic cycle is initiated 7–10 days after infection by merozoites from metacryptozoites and at other times by merozoites from exoerythrocytic meronts located, according to species, in the endothelial or haemopoietic cells. Once within the erythrocyte the merozoite rounds up to form a trophozoite. The early trophozoites undergo merogony to produce merozoites, which are released from the meronts synchronously. After a number of asexual generations have occurred, some merozoites undergo sexual development with the formation of microgametocytes and macrogametocytes, the latter being generally more numerous and staining more intensely blue with Giemsa than do the microgametocytes. Further development of the gametocyte stages can take place only when a suitable mosquito host ingests the blood. Development in the mosquito is rapid. Following ingestion, the nucleus of the microgametocyte divides and, through a process of exflagellation, 6–8 μm long, thin, flagella-like microgametes are extruded from the parent cell, become detached and swim away to find, and fertilise, the macrogamete. The resulting zygote (ookinete) is motile and penetrates the midgut mucosa and comes to lie on the outer surface of the stomach, forming an early oocyst about 50–60 μm in diameter. The nucleus of the oocyst divides repeatedly to produce a very large number of sporozoites. Maturation of the oocyst takes a variable period of time depending on the species of parasite, temperature and the species of mosquito, but in general it is 10–20 days. When mature, the oocyst ruptures,

liberating the sporozoites into the body cavity of the mosquito, which then migrate all over the body of the mosquito but eventually reach the salivary glands and are now infective to a new host, infection occurring when the mosquito takes a blood meal. A mosquito remains infected for its lifespan, transmitting malarial parasites every time it takes a blood meal.

Plasmodium relictum

Subgenus: *Haemamoeba*

Description: Gamonts are round or irregular, larger forms displacing or expelling the host cell nucleus. Pigment granules are relatively fine. Meronts produce 8–32 merozoites.

Plasmodium hermani

Subgenus: *Huffia*

Description: Meronts are oval or round with 6–14 merozoites and are only present in immature erythrocytes. Gamonts are elongate and present in mature erythrocytes.

Plasmodium juxtannucleare

Subgenus: *Novyella*

Description: Meronts are small, round, ovoid or irregular and usually in contact with the erythrocyte host cell nucleus and produce two to seven (mean: four) merozoites. Gamonts are round, ovoid, irregular or elongate pyriform, leading to the host erythrocyte often being distorted.

Life cycle: Details of the pre-erythrocytic development following inoculation by a mosquito vector are not known. Extra-erythrocytic meronts have been reported in lymphoid–macrophage cells of the spleen, liver, kidney, heart, lung, bone marrow, testes, pancreas and brain, being most common in the spleen. Erythrocytic cycles peak at 6–8 days, with merozoites undergoing sexual development with the formation of microgametocytes and macrogametocytes; the latter are generally more numerous and stain more intensely blue with Giemsa than do the microgametocytes. Further development of the gametocyte stages can take place only when a suitable mosquito host ingests the blood. Development in the mosquito is similar to that in other species.

Plasmodium durae

Subgenus: *Giovannolaia*

Description: Trophozoites are amoeboid in appearance. Mature meronts rarely displace the host cell nucleus and contain 6–14 (mean 8) merozoites. Gamonts are elongate, at the end or side of the host cell, and often displace the host cell nucleus, although the host cell is not usually enlarged. Pigment granules are usually large, round and black.

Life cycle: The detailed life cycle has not been described. Exoerythrocytic meronts have been found in capillary endothelial cells of lung, liver, spleen and brain tissue, but are especially numerous in the brain.

In turkeys, parasitaemias peak between 15 and 25 days post infection. Within the erythrocytes, the merozoites round up to form trophozoites. The early trophozoites undergo merogony to produce merozoites, which are released from the meronts synchronously. After a number of asexual generations, some merozoites undergo sexual development with the formation of microgametocytes and macrogametocytes. Further development of the gametocyte stages can take place only when a suitable mosquito host ingests the blood. Development in the mosquito is similar to that in other species.

Hepatocystis

Hepatocystis parasitise arboreal tropical mammals such as squirrels, fruit bats and monkeys and are transmitted by midges (*Culicoides* spp.). *Hepatocystis* spp. are distributed throughout the Indian subcontinent and Africa south of the Sahara.

Life cycle: The life cycle resembles that of *Plasmodium*, with the major exception that schizogony takes place in the liver producing grossly visible cysts (merocysts). Macrogamonts and microgamonts develop within erythrocytes and, following ingestion by the vector host, the microgametes are formed and fertilisation and sporogony take place.

Hepatocystis species

| Species | Hosts | Vectors |
|---|---------|------------------------------|
| <i>Hepatocystis kochi</i> (syn. <i>Hepatocystis simiae</i>) | Monkeys | Midges (<i>Culicoides</i>) |
| <i>Hepatocystis semnopithecii</i> | Monkeys | Midges (<i>Culicoides</i>) |
| <i>Hepatocystis taiwanensis</i> | Monkeys | Midges (<i>Culicoides</i>) |
| <i>Hepatocystis bouillezi</i> | Monkeys | Midges (<i>Culicoides</i>) |
| <i>Hepatocystis cercopithecii</i> | Monkeys | Midges (<i>Culicoides</i>) |
| <i>Hepatocystis foleyii</i> | Monkeys | Midges (<i>Culicoides</i>) |

Haemoproteus

Gamonts present within erythrocytes are usually elongate and curved (halter-shaped) around the host cell nucleus (Fig. 2.29). Merogony takes place in the endothelial cells of the blood vessels, especially in the lungs. Members of this genus are parasites of birds, reptiles and some amphibians, and are very common in domestic pigeons, ducks and turkeys. Known vectors are louse flies (hippoboscids) and midges (*Culicoides*).

Haemoproteus species

| Species | Hosts | Vectors |
|---|-----------------------------------|-------------------------------|
| <i>Haemoproteus meleagridis</i> | Turkey | Midges or hippoboscids flies? |
| <i>Haemoproteus nettionis</i> (syn. <i>Haemoproteus anatis</i> , <i>Haemoproteus anseris</i> , <i>Haemoproteus hermani</i>) | Duck, wild ducks, goose, swans | Midges or hippoboscids flies? |
| <i>Haemoproteus columbae</i> | Pigeon, dove | Hippoboscids flies |
| <i>Haemoproteus sacharovi</i> | Pigeon, dove | Hippoboscids flies? |

Haemoproteus meleagridis

Description: Macrogametes and microgametes present in erythrocytes are elongate and curve around the host cell nucleus,

Fig. 2.29 *Haemoproteus columbae* elongate gamont surrounding the erythrocyte nucleus.

occupying about half to three-quarters of the host cell. The nucleus of macrogametocytes is generally more compact, the cytoplasm denser, and melanin granules evenly distributed compared with the polar clustering in microgametocytes.

Life cycle: Details of the life cycle are incomplete. Sporozoites in the salivary gland of the insect vector enter the circulation of the host when the insect bites. Meronts occur in the vascular epithelium of the lung, liver, kidney and spleen. Merozoites develop within the meront in clusters and when mature are released into the circulation as tiny round bodies which transform into macrogametes and microgamonts within erythrocytes.

Haemoproteus nettionis

Synonyms: *Haemoproteus anatis*, *Haemoproteus anseris*, *Haemoproteus hermani*

Description: Macrogametes and microgametes are elongate and curve around the erythrocyte cell nucleus, partially encircling the host cell nucleus and often displacing it. They contain a few to 30 or more pigment granules, which are usually coarse and round and often grouped at the ends of the cell. The host cell is not enlarged.

Life cycle: Details as for *H. meleagridis*.

Haemoproteus columbae

Description: Macrogametes and microgametes present in erythrocytes range from tiny ring forms to elongate crescent-shapes that curve around the host cell nucleus in the form of a halter.

Macrogametes stain dark blue with Giemsa stains, the nucleus is red to dark purple and compact, and pigment granules are dispersed throughout the cytoplasm.

Life cycle: Sporozoites in the salivary gland of the fly enter the circulation of the host when the insect bites and penetrate endothelial cells of blood vessels where they develop into meronts forming 15 or more cytomeres, each producing large numbers of merozoites. When merozoites are mature they are released into the circulation as tiny round bodies which transform into macrogametes and microgamonts within erythrocytes. Further development takes place in the insect host after blood feeding. After fertilisation, a zygote forms in the insect midgut where sporogony takes place, forming sporozoites. These are liberated in the body cavity and pass to the salivary glands.

Haemoproteus sacharovi

Description: Macrogametes and microgametes completely fill the erythrocyte when mature, distorting and pushing the nucleus to one side. Pigment granules are sparse compared with other species.

Leucocytozoon

Leucocytozoon are parasites of birds. Macrogametes and microgametes reside in the leucocytes, or with some species occasionally in the erythrocytes. Merogony takes place in the parenchyma of the liver, heart, kidney and other organs, with meronts forming large bodies (megalomeronts) divided into cytomeres. Merogony does not occur in erythrocytes or leucocytes. Known vectors are blackflies (*Simulium*) or midges (*Culicoides*).

Leucocytozoon species

| Species | Hosts | Vectors |
|--|----------------------|--------------------------------|
| <i>Leucocytozoon caulleryi</i> | Chicken, guinea fowl | Midges (<i>Culicoides</i>) |
| <i>Leucocytozoon sabrezezi</i> | Chicken, guinea fowl | Midges (<i>Culicoides</i>) |
| <i>Leucocytozoon smithi</i> (syn. <i>Leucocytozoon schueffneri</i> , <i>Leucocytozoon macleani</i>) | Turkey | Blackflies (<i>Simulium</i>) |
| <i>Leucocytozoon simondi</i> | Duck, goose | Blackflies (<i>Simulium</i>) |
| <i>Leucocytozoon marchouxii</i> (syn. <i>Leucocytozoon turtur</i>) | Pigeon, dove | Blackflies (<i>Simulium</i>) |
| <i>Leucocytozoon struthionis</i> | Ostrich | Blackflies (<i>Simulium</i>) |

Leucocytozoon caulleryi

Description: Gamonts present in erythrocytes when mature are round, 15.5 by 15 μm , and distort the host cell causing the host cell nucleus to form a narrow dark band extending about one-third around the parasite. Megalomeronts present within tissues are 26–300 μm in diameter.

Life cycle: Sporozoites are introduced into a new host by the feeding insects. Parasites undergo merogony in the endothelial cells of the liver, heart, kidney, spleen, thymus, pancreas and other organs of the avian host. The meronts are spherical or lobed and divide at first into cytomeres, which eventually fuse forming megalomeronts,

which produce a great number of merozoites. Gamonts appear in the blood about 14 days post infection and are found in erythrocytes or sometimes erythroblasts, and the infected host cells become distorted and assume a spindle shape. When mature the parasites break out of the host cell and lie free in the plasma. When ingested during blood feeding by the vector insect, *Culicoides* spp., a zygote is formed which elongates into an ookinete about 21 μm long, which passes through the midgut wall to form subspherical oocysts on the midgut outer wall. Sporozoites are formed and pass to the salivary glands and are introduced to the new host when the midges bite them.

Leucocytozoon sabrezezi

Description: Gamonts when mature are elongate, 22–24 by 4–7 μm , and distort the erythrocyte, which becomes spindle shaped (67 \times 6 μm) with long cytoplasmic horns extending beyond the parasites. The host cell nucleus forms a narrow, darkly staining band along one side of the parasite.

Life cycle: As for *L. caulleryi*.

Leucocytozoon smithi

Synonyms: *Leucocytozoon schueffneri*, *Leucocytozoon macleani*

Description: The mature gamonts are rounded at first but later become elongate, averaging 20–22 μm in length. Their host cells are elongate, averaging 45 by 14 μm , with pale cytoplasmic horns extending out beyond the enclosed parasite. The host cell nucleus is elongate, forming a thin dark band along one side of the parasite (Fig. 2.30), often splitting to form a band on each side of the parasite. Meronts in the hepatocytes of the liver are 10–20 by 7–14 μm (mean 13.5 \times 10.5 μm).

Life cycle: Birds become infected when bitten by a blackfly vector. The sporozoites enter the bloodstream, invade various tissue cells, round up, and become meronts. Hepatic meronts occur in the liver cells, the earliest stage containing round and

Fig. 2.30 *Leucocytozoon smithi* gamont within an elongated lymphocyte.

crescent-shaped basophilic cytomeres, which develop into masses of deeply staining merozoites that completely fill the host cell cytoplasm. Megalomeronts have not been seen but eventually merozoites enter blood cells and form gamonts. In the blackfly's midgut, microgametes are formed and develop into oocysts to produce sporozoites, which break out of the oocysts and pass to the salivary glands, where they accumulate. The prepatent period is 9 days.

Leucocytozoon simondi

Description: Mature macrogametes and microgamonts are elongate, sometimes rounded, 14–22 µm long, and present within erythrocytes or leucocytes, which become elongate, up to 45–55 µm long, with their nucleus forming a long, thin, dark band along one side. Infected host cells have pale cytoplasmic horns extending out beyond the parasite and the nucleus. Hepatic meronts are 11–18 µm in diameter; megalomeronts found in various tissues of the body are 6–164 µm in diameter when mature.

Life cycle: Birds become infected when bitten by a blackfly vector. The sporozoites enter the bloodstream, invade various tissue cells, round up, and become meronts. Two types of meront occur in the duck. Hepatic meronts occur in the liver cells, forming a number of cytomeres, which in turn form small merozoites by multiple fission. Megalomeronts are found in the brain, lungs, liver, heart, kidney, gizzard, intestine and lymphoid tissues 4–6 days after exposure. They are more common than the hepatic meronts. Each megalomeront produces many thousands of bipolar merozoites. The merozoites enter blood cells and form gamonts. Merogony continues in the internal organs for an indefinite but long time, although at a much reduced rate. During this relapse phase adult birds are not seriously affected but they are the source of infection for the new crop of ducklings. In the blackfly's midgut, four to eight microgametes are formed by exflagellation from the microgamonts. These fertilise the macrogametes to form a motile zygote or ookinete about 33 by 5 µm. Ookinetes are present in the blackfly midgut 2–6 hours after ingestion of infected blood. They develop into oocysts both in the midgut wall and in the midgut itself and produce several slender sporozoites 5–10 µm long, with one end rounded and the other pointed. They break out of the oocysts and pass to the salivary glands, where they accumulate. Viable sporozoites can be found for at least 18 days after an infective feeding.

Leucocytozoon marchouxi

Description: Macrogametes are rounded or elliptical, stain dark blue with Giemsa and have a compact, reddish nucleus. This species forms rounded megalomeronts in nearly all internal organs.

Life cycle: Sporozoites are introduced into a new host by the feeding insects. Parasites undergo merogony in the endothelial cells of internal organs forming megaloschizonts. These lead to the production of gametocytes in the blood which, after ingestion by the vector insect, form zygote and oocysts. These undergo sporogony leading to the formation of sporozoites, which pass to the salivary glands and are introduced to the new host when the insect vectors feed.

Leucocytozoon struthionis

Description: Gamonts are round and present within erythrocytes.

FAMILY HEPATOZOIDAE

Hepatozostis kochi

Description: The intraerythrocytic parasites have an unusual nucleus that, when stained with Giemsa, displays a large, oval, pink nucleoplasm that occupies one-third or more of the parasite. Within the nucleus are numerous red chromatin granules.

ORDER PIROPLASMORIDA

Often referred to as 'piroplasms,' these parasites are found mainly in the erythrocytes or leucocytes of vertebrates. No oocysts are formed and reproduction in the vertebrate host is asexual, with sexual reproduction occurring in the invertebrate host. The piroplasms are heteroxenous with known vectors ixodid or argasid ticks.

FAMILY BABESIIDAE

Babesia

The genus *Babesia* are intraerythrocytic parasites of domestic animals and are transmitted by ticks in which the protozoan passes transovarially, via the egg, from one tick generation to the next. The disease, babesiosis, is particularly severe in naive animals introduced into endemic areas and is a considerable constraint on livestock development in many parts of the world.

Life cycle: Infective sporozoites present in the tick are injected into the host within saliva when the tick feeds. Multiplication in the vertebrate host occurs in the erythrocytes by binary fission, endodyogeny, endopolygeny (budding) or merogony to form merozoites. The erythrocytes rupture during repeated phases of merogony releasing merozoites that invade other erythrocytes. In chronic infections parasites become sequestered within capillary networks of the spleen, liver and other organs, from where they are released periodically into the circulation. On ingestion by the tick these forms become vermiform and enter the body cavity, then the ovary and penetrate the eggs where they round up and divide to form small round organisms. When the larval tick moults into the nymph stage, the parasites enter the salivary gland and undergo a series of binary fissions, entering the cells of the salivary gland. They multiply further until the host cells are filled with thousands of minute parasites. These become vermiform, break out of the host cell, lie in the lumen of the gland, and are injected into the mammalian host when the tick feeds.

Babesia species

| Species | Hosts | Vectors |
|--|-----------------------|--|
| <i>Babesia bigemina</i> | Cattle, buffalo | <i>Rhipicephalus (Boophilus) annulatus</i> , <i>R. (B.) microplus</i> and <i>R. (B.) decoloratus</i> |
| <i>Babesia bovis</i> (syn. <i>Babesia argentina</i>) | Cattle, buffalo, deer | <i>Rhipicephalus (Boophilus) annulatus</i> , <i>R. (B.) microplus</i> |

| Species | Hosts | Vectors |

Babesia bigemina

Description: *Babesia bigemina* is a large pleomorphic *Babesia* but characteristically is seen and identified by the pear-shaped bodies joined at an acute angle within the mature erythrocyte. Round forms measure 2 µm and the pear-shaped elongated ones are 4–5 µm. The erythrocytic stages lack a conoid, micropores and typical mitochondria, but have an anterior and posterior polar ring and typically two rhoptries.

Babesia bovis

Synonym: *Babesia argentina*

Description: *Babesia bovis* is small pleomorphic *Babesia*, typically identified as a single body, as small round bodies or as paired pear-shaped bodies joined at an obtuse angle within the centre of the

mature erythrocyte. The round forms measure 1–1.5 µm and the pear-shaped bodies 1.5 by 2.4 µm in size. Vacuolated signet ring forms are especially common.

Babesia divergens

Description: The organisms within red cells are almost always found singly or in pairs, often arranged at a characteristic angle with their narrow ends opposed. Typically, they are pyriform, but may be round, elongated or cigar-shaped. *Babesia divergens* is a 'small *Babesia*' and in blood films typically appears as paired, widely divergent organisms, 1.5 by 0.4 µm, lying near the edge of the red cell. Other forms may be present measuring 2 by 1 µm, while some are circular up to 2 µm in diameter and a few may be vacuolated (Fig. 2.31).

Babesia major

Description: This is a 'large *Babesia*', with pyriform bodies 2.6 by 1.5 µm, being characteristically paired at an acute angle less than 90° and found in the centre of the erythrocyte, although round forms about 1.8 µm diameter may also form.

Babesia motasi

Description: *Babesia motasi* is a large species, 2.5–4 by 2 µm, and is usually pyriform. The merozoites occur singly or in pairs, and the angle between members of a pair is usually acute.

Babesia ovis

Description: *Babesia ovis* is a small species, 1–2.5 µm long, mostly rounded and located in the margin of the host erythrocytes, with paired pyriform trophozoites usually lying at an obtuse angle.

Fig. 2.31 Diverse forms of *Babesia divergens* in bovine red cells.

Babesia caballi

Description: Trophozoites within erythrocytes are pear-shaped measuring 2–5 μm in length, commonly occurring in pairs joined at the posterior ends, with the angle between the organisms acute. Round or oval forms 1.5–3 μm in diameter may also occur.

Babesia perroncitoi

Description: A ‘small *Babesia*’ occurring most commonly as annular forms measuring 0.7–2 μm , although oval to pyriform forms, 1–3 by 1–2 μm in size, may also occur. Merozoites usually occur singly in erythrocytes, but sometimes two or more may be present.

Babesia trautmanni

Description: A ‘large *Babesia*’ occurring as oval, pyriform and, less commonly, round forms. Merozoites measure 2.5–4 by 1.5–2 μm , and usually occur in pairs within erythrocytes, but sometimes four or more may be present.

Babesia canis

Subspecies: *Babesia canis canis*, *Babesia canis rossi*, *Babesia canis vogeli*

Description: Large piroplasms, pyriform in shape, 4–5 μm in length, pointed at one end and rounded at the other (Fig. 2.32). Amoeboid forms have been described that are 2–4 μm in diameter and usually contain a vacuole.

Babesia gibsoni

Description: A small piroplasm, annular or oval in shape, and no more than one-eighth the diameter of the host erythrocyte.

Fig. 2.32 Intraerythrocytic stages of *Babesia canis*.

Babesia felis

Synonyms: *Nuttalia felis*, *Babesia cati*

Description: Small piroplasms, with the majority of merozoites present in erythrocytes, round, irregularly round and 1.5–2 μm in diameter; some are elongate 2–3 μm long and may form cruciform meronts.

Babesia pitheci

Description: The piroplasms are pyriform in shape and measure 2–6 μm long. Round, oval and lanceolate shapes have also been reported.

FAMILY THEILERIIDAE

The diseases caused by several species of *Theileria* are a serious constraint on livestock development in Africa, Asia and the Middle East. The parasites, which are transmitted by ticks, undergo repeated schizogony in the lymphocytes, ultimately releasing small merozoites, which invade the red cells to become piroplasms. *Theileria* are widely distributed in cattle and sheep in Africa, Asia, Europe and Australia, have a variety of tick vectors and are associated with infections that range from clinically inapparent to rapidly fatal.

Various species of *Cytauxzoon* occur as *Theileria*-like piroplasms in the red cells of wild animals. The genus differs from *Theileria* in that schizogony occurs in the reticuloendothelial cells rather than lymphocytes. *Cytauxzoon* is the cause of a fatal disease of domestic cats, characterised by fever, anaemia and icterus, in southern USA. The reservoir hosts are wild cats.

Theileria

Life cycle: The life cycle of *Theileria* spp. involves erythrocytic merozoites, which are ingested by the tick intermediate host and which develop into macrogamonts and microgamonts to produce zygotes. These develop and enter the haemolymph to become kinetes and then the salivary glands to become fission bodies. In adult ticks, the primary fission bodies divide into secondary (primary sporoblasts) and tertiary (secondary sporoblasts) fission bodies and produce sporozoites that are released into the saliva. Animals are infected when the ticks suck blood. Species in this genus undergo exoerythrocytic merogony in the lymphocytes, histiocytes, erythroblasts and other cells of the internal organs. Leucocytes filled with meronts (schizonts) are called Koch bodies. Both macromeronts and micromeronts occur, producing micromerozoites that invade erythrocytes, where usually another round of division occurs, producing a generation of merozoites, which in turn infect new erythrocytes. Multiplication in erythrocytes results in four (rarely two) merozoites forming characteristic tetrads (the Maltese cross). Some species (*T. parva*) do not multiply in the red blood cells, and asexual division is confined only to lymphocytes. Gametogony occurs in the tick vector's intestine and sporogony in the salivary glands.

Theileria species

| Species | Hosts | Vector |
|--|---|---|
| <i>Theileria annae</i> (syn. <i>Babesia annae</i>) | Dog | <i>Ixodes hexagonus</i> ? <i>I. ricinus</i> ? |
| <i>Theileria annulata</i> | Cattle, buffalo | <i>Hyalomma detritum</i> , <i>H. anatolicum excavatum</i> , <i>H. truncatum</i> , <i>H. dromedarii</i> , <i>H. turanicum</i> , <i>H. marginatum</i> |
| <i>Theileria cervi</i> (syn. <i>Theileria tarandi</i>) | Deer (fallow, red, sika, white-tailed, reindeer) | Unknown |
| <i>Theileria camelensis</i> | Camel | <i>Hyalomma dromedarii</i> |
| <i>Theileria equi</i> (syn. <i>Babesia equi</i> , <i>Nuttalia equi</i>) | Horse, donkey | <i>Dermacentor reticulatus</i> , <i>D. albipictus</i> , <i>D. variabilis</i> , <i>D. nitens</i> , <i>Hyalomma</i> <i>marginatum</i> , <i>H. scupense</i> (syn. <i>H. detritum</i>), <i>H.</i> <i>anatolicum</i> , <i>H. dromedarii</i> , <i>Rhipicephalus bursa</i> , <i>R.</i> <i>evertsi</i> , <i>R. sanguineus</i> |
| <i>Theileria hirci</i> (syn. <i>Theileria</i> <i>lestoaquardi</i>) | Sheep, goat | <i>Rhipicephalus bursa</i> , <i>Hyalomma anatolicum</i> |
| <i>Theileria orientalis</i> complex <i>Theileria mutans</i> <i>Theileria buffeli</i> <i>Theileria sergenti</i> | Cattle, buffalo | <i>Amblyomma variegatum</i> , <i>A. cohaerens</i> , <i>A. hebraeum</i> , <i>Haemaphysalis bispinosa</i> |
| <i>Theileria ovis</i> | Sheep, goat | <i>Rhipicephalus bursa</i> , <i>R. evertsi</i> |
| <i>Theileria recondita</i> | Sheep, goat, deer | <i>Haemaphysalis punctata</i> |
| <i>Theileria separata</i> | Sheep, goat | <i>Rhipicephalus evertsi</i> |
| <i>Theileria parva</i> (subsp. <i>Theileria</i> <i>parva lawrencei</i> , <i>Theileria parva parva</i>) | Cattle, buffalo | <i>Rhipicephalus appendiculatus</i> |
| <i>Theileria taurotragi</i> (syn. <i>Cytauxzoon</i> <i>taurotragi</i>) | Cattle, antelope, particularly the eland | <i>Rhipicephalus appendiculatus</i> , <i>R. pulchellus</i> |
| <i>Theileria velifera</i> (syn. <i>Haematoxenus</i> <i>veliferus</i>) | Cattle, zebu | <i>Amblyomma variegatum</i> , <i>A.</i> <i>lepidum</i> , <i>A. hebraeum</i> |

Theileria annae

Synonyms: *Babesia annae*, *Babesia microti*-like

Description: Merozoites are small, usually singular, 1 by 2.5 μm .

Life cycle: The life cycle has not been described but *T. annae* is thought to be transmitted by the hedgehog tick, *Ixodes hexagonus*.

Theileria parva

Subspecies: *Theileria parva lawrencei*, *Theileria parva parva*

Description: Trophozoite forms in the erythrocyte are predominantly rod-shaped (1.5–2.0 \times 0.1–1.0 μm), but may also be round, oval and comma-shaped (Fig. 2.33). Koch bodies are found in the lymphocytes and endothelial cells of the spleen or lymph nodes where they are very numerous and average 8 μm but can range up to 12 μm or more. Two types have been described: macroschizonts containing chromatin granules 0.4–2.0 μm in diameter; these divide further to become microschantons that contain chromatin

Fig. 2.33 Intraerythrocytic stages of *Theileria parva*.

granules 0.3–0.8 μm in diameter and produce merozoites 0.7–1 μm in diameter.

Life cycle: Erythrocytic merozoites are ingested by the tick intermediate host, *Rhipicephalus appendiculatus* (the brown ear tick), and develop into macrogamonts and microgamonts to produce zygotes. These develop and enter the haemolymph to become kinetes. These enter the salivary glands to become fission bodies. In adult ticks, the primary fission bodies divide into secondary (primary sporoblasts) and tertiary (secondary sporoblasts) fission bodies and produce sporozoites that are released into the saliva.

Cattle are infected when the ticks suck blood. The sporozoites are inoculated into cattle and quickly enter lymphocytes in an associated lymph gland, usually the parotid. The parasitised lymphocyte transforms to a lymphoblast, which divides rapidly as the macroschizont develops. This division is apparently stimulated by the parasite, which itself divides synchronously with the lymphoblast to produce two infected cells. The rate of proliferation is such that a 10-fold increase in infected cells may occur every 3 days. About 12 days after infection, a proportion of the macroschizonts develop into microschantons and within a day or so these produce the micromerozoites that enter erythrocytes, which after a few binary fissions produce the varied forms present in the red cells.

For completion of the life cycle, the piroplasm requires to be ingested by the larvae or nymphal stages of the three-host vector, *R. appendiculatus*. In these, the sexual phase described above occurs in the tick gut followed by the formation of sporoblasts in the salivary glands. No further development occurs until the next stage of the tick starts to feed when the sporoblasts produce infective sporozoites from about day 4 onwards. Since female ticks feed continuously for about 10 days and males intermittently over a longer period, this allows ample time for infection of the host. Transmission is transstadial, i.e. by the next stage of the tick, and transovarian transmission does not occur. The incubation period following tick transmission is 8–24 days.

Theileria annulata

Description: Trophozoite forms in the erythrocyte are predominantly round (0.5–2.7 μm) to oval (2 \times 0.6 μm), but may also be

rod-shaped or comma-shaped ($1.2 \times 0.5 \mu\text{m}$). Division by binary fission may form two or four daughter cells, the latter in the shape of a cross. Koch bodies are in the lymphocytes of the spleen or lymph nodes or even free in these organs. They average $8 \mu\text{m}$ but can be up to $27 \mu\text{m}$. Two types have been described: macromeronts containing chromatin granules $0.4\text{--}1.9 \mu\text{m}$ in diameter; these divide further to become micromeronts that contain chromatin granules $0.3\text{--}0.8 \mu\text{m}$ in diameter and produce merozoites $0.7\text{--}1 \mu\text{m}$ in diameter.

Life cycle: Erythrocytic merozoites, ingested by the tick intermediate host, develop into macrogamonts and microgamonts to produce zygotes. These develop and enter the haemolymph to become kinetes, which then enter the salivary glands to become fission bodies. In adult ticks, the primary fission bodies divide into secondary (primary sporoblasts) and tertiary (secondary sporoblasts) fission bodies and produce sporozoites that are released into the saliva. Cattle are infected when the ticks suck blood. The sporozoites enter lymphocytes and become meronts, initially macromeronts and then micromeronts. Micromerozoites enter erythrocytes, and after a few binary fissions produce the varied forms that are taken up by other ticks. The incubation period following tick transmission is 9–25 days (mean 15 days).

Theileria equi

Description: The merozoites in the erythrocytes are relatively small, $2\text{--}3 \mu\text{m}$, rounded, amoeboid or most often pyriform, and are readily recognised in blood smears from acute cases, since apart from size, the piroplasms characteristically form a 'Maltese cross' of four organisms (Fig. 2.34).

Theileria camelensis

Description: Trophozoite forms in the erythrocyte are predominantly round.

Theileria hirci

Synonym: *Theileria lestoquardi*

Fig. 2.34 Intraerythrocytic stages of *Theileria equi*. The characteristic 'Maltese cross' of four organisms can be seen within an erythrocyte (bottom centre).

Description: Trophozoites are found in lymphocytes and erythrocytes as round forms ($0.6\text{--}2.0 \mu\text{m}$ in diameter), oval, or rod-shaped ($1.6 \mu\text{m}$ long). Binary or quadruple fission takes place in the erythrocytes. Meronts (Koch bodies), averaging $8 \mu\text{m}$ in diameter but ranging up to $10\text{--}20 \mu\text{m}$ and containing $1\text{--}80$ granules, are common in the lymphocytes of the spleen and lymph nodes.

Theileria orientalis complex

Synonyms: *Theileria mutans*, *Theileria buffeli*, *Theileria sergenti*

Description: Trophozoite forms in erythrocytes are round ($1\text{--}2 \mu\text{m}$ diameter), oval ($1.5 \times 0.6 \mu\text{m}$), pyriform or comma-shaped. Binary fission produces two or four daughter cells. There are relatively few Koch bodies ($8\text{--}20 \mu\text{m}$) in the lymphocytes of the spleen and lymph nodes and these contain $1\text{--}80$ chromatin granules ($1\text{--}2 \mu\text{m}$ in diameter).

Life cycle: As for *T. annulata*.

Theileria ovis

Description: Erythrocytic stages are similar in appearance to *T. hirci* and are found in lymphocytes and erythrocytes as round forms ($0.6\text{--}2.0 \mu\text{m}$ in diameter), oval, or rod-shaped ($1.6 \mu\text{m}$ long) but are sparser with less than 2% of erythrocytes infected.

Theileria recondita

Description: Merozoites in the erythrocytes are relatively small, with either rod forms ($2 \mu\text{m}$) or ring forms ($1.22 \mu\text{m}$ diameter) predominating.

Theileria taurotragi

Synonym: *Cytauxzoon taurotragi*

Description: Erythrocytic forms are similar in appearance to *T. parva*. Trophozoite forms in the erythrocyte are predominantly round to oval, but may also be rod-shaped or comma-shaped ($1.2 \times 0.5 \mu\text{m}$).

Life cycle: As for *T. annulata*.

Theileria velifera

Synonym: *Haematoxenus veliferus*

Description: Trophozoite forms within erythrocytes are pleomorphic but most often small rods $1\text{--}2 \mu\text{m}$ long. The great majority have a rectangular 'veil' $1\text{--}3.5 \mu\text{m}$ extending out from the side.

Life cycle: As for *T. annulata*.

Cytauxzoon

Cytauxzoon species

| Species | Hosts | Vector |
|---|-------|--------------------------------|
| <i>Cytauxzoon felis</i> (syn. <i>Theileria felis</i>) | Cat | <i>Dermaacentor variabilis</i> |

Cytauxzoon felis

Synonym: *Theileria felis*

Description: The single signet-ring shaped forms present within erythrocytes are 1–1.2 µm in diameter. Bipolar oval forms, tetrads and dark-staining 'dots' may also be seen.

Life cycle: The life cycle is poorly understood. Infective sporozoites are injected into the cat from the salivary glands of an infective tick. Meronts develop primarily within tissue histiocytes in many organs and develop to release merozoites, which invade monocytes and erythrocytes.

PHYLUM CILIOPHORA

The ciliates of domestic animals all belong to the phylum Ciliophora. Individual organisms have a **micronucleus** containing a normal set of chromosomes which are active in reproduction, and a polyploid **macronucleus**, involved in vegetative functions. Ciliates have either simple cilia or compound **cilia** in at least one stage of their life cycle. Infraciliature are found in the cortex beneath the pellicle composed of ciliary basal granules (**kinetosomes**) and associated fibrils (**kinetodesmata**). Reproduction is by transverse binary fission and sexual reproduction by conjugation, in which there is a transfer of micronuclear material between individuals. Many species of ciliates occur as harmless commensals in the rumen and reticulum of ruminants, and the large intestine of equids. The only ciliate of importance in veterinary medicine occurs in the family Balantidiidae.

FAMILY BALANTIDIIDAE

The only genus of importance is *Balantidium*, which has an ovoid, ellipsoidal body with elongate macronucleus and a single micronucleus with a cytostome at the base of an anterior vestibulum (see Fig. 2.2). *Balantidium* has worldwide distribution and is found in pigs, monkeys and humans.

Life cycle: Reproduction is by binary fission. Conjugation, a temporary attachment of two individuals during which nuclear material is exchanged, also occurs, after which both cells separate. Eventually cysts are formed which are passed in the faeces; these have a thick yellowish wall, through which the parasite may be seen, and are viable for 2 weeks at room temperature. Infection of a new host is by ingestion of the cysts.

Balantidium

Balantidium species

| Species | Hosts | Site |
|-------------------------|---|-----------------|
| <i>Balantidium coli</i> | Pig, human, camel, monkeys, dog (rarely), rat | Large intestine |

Balantidium coli

Description: An actively motile organism, up to 300 µm, whose pellicle possesses rows of longitudinally arranged cilia. At the anterior

end there is a funnel-shaped depression, the peristome, which leads to the cytostome or mouth; from this, food particles are passed to vacuoles in the cytoplasm and digested. Internally there are two nuclei, a macronucleus and adjacent micronucleus, and two contractile vacuoles, which regulate osmotic pressure. Cysts are spherical to ovoid, 40–60 µm in diameter.

FAMILY PYCNOTRICHIDAE

This family contains the genus *Buxtonella*, which has an ovoid, uniformly ciliated body with a prominent curved groove and a cyathostome near the anterior end. *Buxtonella* has worldwide distribution and is found in the caecum of cattle.

Life cycle: The life cycle has not been described.

Buxtonella

Buxtonella species

| Species | Hosts | Site |
|---------------------------|---|-----------------|
| <i>Buxtonella sulcata</i> | Cattle, buffalo, goat, sheep, deer, camel, rarely human | Large intestine |

Buxtonella sulcata

Description: The body is ovoid, 100 by 72 µm, and uniformly ciliated with a prominent curved groove bordered by two ridges running from end to end with a cyathostome at the anterior end, and an oval or bean-shaped macronucleus 28 by 14 µm in size.

FAMILY NYCTOTHERIDAE

The genus *Nyctotherus* comprises coprophilic ciliated protozoa with a peristome at the anterior end, ending in a cytostome in the middle of the body. *Nyctotherus* is found in the faeces of various species of chelonians and vegetarian lizards such as iguanas.

MISCELLANEOUS 'PROTOZOAL' ORGANISMS

The organisms described in this section have traditionally been included in veterinary parasitology textbooks. For many of these organisms the taxonomy still remains complicated and confusing. Their inclusion in this text is for completeness and to aid differentiation from morphologically similar protozoal organisms.

KINGDOM FUNGI

PHYLUM MICROSPORIDIA

All Microsporida are obligate intracellular parasites with unicellular spores, the spore possessing an extrusion apparatus and a coiled polar tube, typically filamentous, extending backwards to form a polar cap. Most are parasites of insects.

ORDER MICROSPORIDA**FAMILY ENTEROCYTOZONIDAE**

The Enterocytozoonidae have ellipsoidal or oval spores consisting of an external wall, sporoplasm, a coiled polar tube and a polar capsule.

Encephalitozoon

The genus *Encephalitozoon* is of minor significance in veterinary medicine, causing disease in dogs, rabbits, other mammals and humans. Three strains of *Encephalitozoon* have been identified: strain I ('rabbit strain'), strain II ('rodent strain') and strain III ('dog strain'). Each of the three strains has been reported in humans and infections in animals may therefore pose a potential zoonotic risk.

Life cycle: The infective spore stages are highly resistant and can survive for many years. When spores are ingested, the polar tube is everted and when fully extended the sporoplasm passes through the tube and is inoculated into the cytoplasm of the host cell. There then follows a phase of multiplication by binary or multiple fission (merogony). This is followed by sporogony to form sporoblasts, which then mature into spores.

***Encephalitozoon* species**

| Species | Hosts | Site |
|---|---|---------------------------------|
| <i>Encephalitozoon cuniculi</i> (syn. <i>Nosema cuniculi</i>) | Rabbit, dog, red fox, blue fox, silver fox, cat, mouse, rat, human, monkeys | Brain, kidneys, heart, lungs |

Encephalitozoon cuniculi

Synonym: *Nosema cuniculi*

Description: Trophozoites are 2–2.5 by 0.8–1.2 µm in tissue sections or 4 by 2.5 µm in smears. Spores are about 2 µm long and contain a spirally coiled polar filament with four to five coils.

Enterocytozoon

Enterocytozoon is an intestinal microsporidian frequently found in humans but has also been reported in dogs, cats, cattle, pigs and other domestic animals. Its significance in animal hosts is unknown.

***Enterocytozoon* species**

| Species | Hosts | Site |
|--------------------------------|---|-----------------|
| <i>Enterocytozoon bieneusi</i> | Dog, cat, cattle, pig, rabbit, chicken, turkey | Small intestine |

Enterocytozoon bieneusi

Description: Trophozoites range from 1 to 1.5 µm in size. Spores have a double row of polar tubule coils.

PHYLUM ASCOMYCOTA**FAMILY PNEUMOCYSTIDACEAE*****Pneumocystis***

Pneumocystis carinii is widely distributed in a wide range of healthy, domestic and wild animals. Currently, it is considered to be an opportunistic mycoses of the family Pneumocystidaceae (phylum Ascomycota, class Pneumocystidomycetes) causing infections in humans, non-human primates and monkeys, particularly in the immunocompromised. Its significance in other hosts is not known.

Life cycle: The life cycle of *Pneumocystis* still remains poorly understood. Information is mostly derived from histochemical and ultrastructural analysis of the lung tissue of rodents and infected humans. Current knowledge suggests that the trophic (trophozoite) forms are produced during asexual development. These forms are usually pleomorphic and found in clusters. They appear capable of replicating asexually by binary fission and also replicate sexually by conjugation, producing a diploid zygote, which undergoes meiosis and subsequent mitosis, resulting in the formation of a precyst initially and then an early cyst and eventually a mature cyst. During differentiation of the organism from precyst to mature cyst, eight intracystic spores, or 'daughter cells', are produced. These intracystic spores are subsequently released as the mature cyst ruptures and develop into trophic forms.

KINGDOM CHROMALVEOLATA**PHYLUM HETEROKONTOPHYTA****FAMILY BLASTOCYTTIDAE*****Blastocystis***

Blastocystis was for many years described as a yeast but then considered to be a protozoan in the subphylum Blastocysta, but more latterly is considered to belong to a group of organisms known as heterokonts (Stramenopiles) in the phylum Heterokontophyta (kingdom Chromalveolata). The organism is found in the intestinal tract of humans and in many animals including monkeys, pigs, birds, rodents, snakes and invertebrates. There appears to be poor host specificity such that species names are now considered redundant and are instead referred to as subtypes (ST1–ST10).

***Blastocystis* species**

| Species | Hosts | Site |
|---|--|------------------------------|
| <i>Blastocystis</i> spp. (syn. <i>Blastocystis hominis</i>) | Human | Small and large intestine |
| <i>Blastocystis</i> spp. (syn. <i>Blastocystis galli</i>) | Chicken, gallinaceous birds (pheasant, partridge) | Large intestine, caeca |

***Blastocystis* spp.**

Description: Vacuolar forms are brightly refractile, of widely variable diameter (4–15 µm) with a thin band of central cytoplasm

surrounding a central vacuole (Fig. 2.35). The cyst form is generally smaller in size and has a thick multilayered cyst wall and lacks a central vacuole.

KINGDOM BACTERIA

PHYLUM PROTEOBACTERIA

ORDER RICKETTSIALES

Rickettsial organisms are parasitic Gram-negative microorganisms, associated with arthropods, which may act as vectors or primary hosts. While the *Rickettsia* are now considered to be in the kingdom Bacteria, for historical reasons they are included in parasitological texts and for this reason mention is made to some genera (Table 2.25).

Fig. 2.35 Vacuolar and cyst forms of *Blastocystis* spp. in faeces of red legged partridge.

Table 2.25 Rickettsial organisms of veterinary importance.

| Genus/species | Vector | Hosts | Geographic distribution |
|--|--|---|---|
| Aegyptianella | Ticks | | |
| <i>Aegyptianella pullorum</i> | <i>Argas persicus</i> | Chicken, duck, goose | Southeast Europe, Africa, Asia |
| <i>Aegyptianella moshkovskii</i> | <i>Argas persicus</i> | Chicken, turkey, pheasant, wild birds | Africa, India, Southeast Asia, Egypt, Russia |
| Anaplasma | Ticks and biting flies | | |
| <i>Anaplasma centrale</i> | <i>Dermacentor</i> spp., <i>Tabanus</i> , <i>Chrysops</i> spp., <i>Stomoxys</i> , <i>Psorophora</i> spp. | Cattle | Africa, Asia, Australia, southern Europe, North Central and South America |
| <i>Anaplasma marginale</i> | | Cattle | |
| <i>Anaplasma ovis</i> | | Sheep and goats | |
| <i>Anaplasma phagocytophilum</i> (tick-borne fever) | <i>Ixodes ricinus</i> | Sheep, cattle, dog, horse, deer, rodents, human | Probably worldwide. Europe, USA, South America, Australia |
| <i>Anaplasma ruminantium</i> (syn. <i>Cowdria ruminantium</i>) (heartwater) | Ticks <i>Amblyomma</i> spp. | Cattle, sheep, goats and other ruminants | Africa, Asia, Africa, Caribbean |
| Ehrlichia | Ticks | | |
| <i>Ehrlichia bovis</i> | <i>Hyalomma</i> spp., <i>Amblyomma</i> spp., <i>Rhipicephalus</i> spp. | Cattle, buffalo | Africa, Asia and South America |
| <i>Ehrlichia canis</i> | <i>Rhipicephalus sanguineus</i> | Dog | Asia, Europe, Africa, Australia and America |
| <i>Ehrlichia chaffensis</i> | <i>Rhipicephalus sanguineus</i> | Dog, deer, human | USA |
| <i>Ehrlichia ewingii</i> | <i>Rhipicephalus sanguineus</i> | Dog | USA |
| <i>Ehrlichia equi</i> | Ticks/flies? | Horses | India, Sri Lanka |
| <i>Ehrlichia ovina</i> | <i>Rhipicephalus</i> spp. | Sheep | North America |
| <i>Ehrlichia risticii</i> (Potomac horse fever; equine monocytic ehrlichiosis) | Unknown. ?Trematode metacercariae/snails/aquatic insects | Horse | USA |
| Neorickettsia | | | |
| <i>Neorickettsia helminthoeca</i> (salmon poisoning disease) | Trematode (<i>Nanophyetus salmincola</i>) | Dog, fish-eating mammals, human | North America |
| Rickettsia | Lice/fleas/ticks/mites | | |
| <i>Rickettsia akari</i> | <i>Liponyssoides sanguineus</i> | Mice, human | North America, Russia, Southeast Asia |
| <i>Rickettsia australis</i> (Queensland tick typhus) | <i>Ixodes holocyclus</i> | Human | Australia |
| <i>Rickettsia conorii</i> (boutonneuse fever) | <i>Amblyomma</i> , <i>Hyalomma</i> , <i>Rhipicephalus</i> spp. | Dog, rat, human | Africa, Middle East, southern Europe |
| <i>Rickettsia prowazekii</i> (epidemic typhus) | <i>Pediculus</i> spp. | Human, flying squirrel | Worldwide |
| <i>Rickettsia rickettsii</i> (Rocky Mountain spotted fever) | <i>Amblyomma</i> spp., <i>Dermacentor</i> spp., <i>Ixodes</i> spp., <i>Rhipicephalus</i> spp. | Dog, fox, raccoon, human | North and South America |
| <i>Rickettsia tsutsugamushi</i> | Mites (<i>Leptotrombidium</i>) | Rat, small mammals, birds | Asia, Australia |
| <i>Rickettsia felis</i> | Fleas | Cat, dog, human | North and South America, Europe |
| <i>Rickettsia typhi</i> (murine typhus) | Fleas (<i>Xenopsylla cheopis</i>) | Rat, human | Worldwide |

FAMILY RICKETTSIACEAE

This is the most important family, which in vertebrates are parasites of tissue cells other than erythrocytes and are transmitted by arthropods. The Rickettsiae are capable of infecting suitable vertebrate hosts including humans, who may be the primary host but are more often incidental hosts.

Species of *Rickettsia* are important human pathogens but some species can affect dogs and cats and many have a wildlife reservoir. With the exception of louse-borne typhus and trench fever, all these human infections are zoonoses with no person-to-person or person-to-animal transmission occurring. Three groups can be distinguished within the genus: typhus group, spotted fever group and scrub typhus group.

Rickettsia conorii

Description: Small, pleomorphic, Gram-negative, coccoid, obligatory intracellular organisms infecting endothelial cells of smaller blood vessels.

Life cycle: Ticks become infected with *R. conorii* by feeding on infected small rodents that are the main reservoir of disease. Immature ticks become infected and infection is transmitted trans-stadially and transovarially to later tick stages, which feed on larger mammals.

Rickettsia felis

Description: Small, pleomorphic, Gram-negative, coccoid, obligatory intracellular organisms infecting endothelial cells of smaller blood vessels.

Life cycle: Fleas become infected with *R. felis* by feeding on infected animals. Infection in the flea is transmitted trans-stadially and transovarially to later stages, and transmission occurs when the adult flea feeds.

Rickettsia rickettsii

Description: Small, pleomorphic, Gram-negative, coccoid, obligatory intracellular organisms infecting endothelial cells of smaller blood vessels.

Life cycle: Ticks become infected with *R. rickettsii* by feeding on infected small rodents that are the main reservoir of disease. Immature ticks become infected and infection is transmitted trans-stadially and transovarially to later tick stages, which feed on larger mammals.

Species of *Rochalimaea* are the cause of trench fever in humans and the disease is transmitted by lice.

FAMILY ANAPLASMATACEAE

The Anaplasmataceae are very small, rickettsia-like particles occurring in or on the erythrocytes of vertebrates and are transmitted by arthropods. Four genera, *Anaplasma*, *Ehrlichia* and *Aegyptianella*, are important pathogens of domestic animals.

Anaplasma

Species of *Anaplasma* are very small (0.3–1.0 µm diameter) parasites of the erythrocytes of ruminants and are transmitted biologically by ticks and mechanically by sucking flies, especially tabanids. *Anaplasma phagocytophilum* comb. nov. (formerly known as three separate ehrlichiae, *E. phagocytophila*, *E. equi* and *Anaplasma platys* [formerly known as *Ehrlichia platys*]) causes canine, equine and human granulocytic ehrlichiosis.

Life cycle: *Anaplasma* are obligate intracellular organisms infecting granulocytes, predominantly neutrophils, appearing within the cytoplasm as membrane-bound vacuoles, and can be transmitted by ticks, and also mechanically by biting flies or contaminated surgical instruments. Once in the blood, the organism enters the red cell by invaginating the cell membrane so that a vacuole is formed; thereafter it divides to form an inclusion body containing up to eight 'initial bodies' packed together (morulae). The inclusion bodies are most numerous during the acute phase of the infection, but some persist for years afterwards. The organisms spend part of their normal life cycle within the tick and are transmitted trans-stadially. As the tick vector feeds on a wide range of vertebrate animals, transmission of the infectious agent may take place to multiple host species.

Anaplasma phagocytophilum

Description: Blood smears stained with Giemsa or Wright's stain reveal one or more loose aggregates (morulae or inclusion bodies, 1.5–5 µm in diameter) of blue–grey to dark blue coccoid, coccobacillary or pleomorphic organisms within the cytoplasm of neutrophils.

Anaplasma marginale

Description: In Giemsa-stained blood films the organisms of *A. marginale* are seen as small, round, dark-red 'inclusion bodies', approximately 0.3–1.0 µm, within the red cell (see Fig. 8.39). Often there is only one organism in a red cell and characteristically this lies at the outer margin; however these two features are not constant.

Anaplasma centrale

Description: As for *A. marginale*, except that the organisms are commonly found in the centre of the erythrocyte.

Ehrlichia

Ehrlichia spp. are found in leucocytes in the circulating blood and are transmitted by ixodid ticks. Several species of *Ehrlichia* are found in cattle and sheep. *Ehrlichia ruminantium*, which causes heartwater in ruminants, is transmitted by at least five species of *Amblyomma* ticks.

Three species of *Ehrlichia* are important pathogens in dogs. *Ehrlichia canis* and *Ehrlichia chaffensis* cause canine monocytic ehrlichiosis or tropical canine pancytopenia; *Ehrlichia ewingii* causes canine granulocytic ehrlichiosis. *Ehrlichia risticii* is the cause of Potomac horse fever.

Ehrlichia bovis

Description: Round or irregular-shaped intracytoplasmic organisms (2–10 µm in diameter), present in mononuclear cells, particularly monocytes.

Life cycle: Infection is transmitted through the bite of an infected tick. Rickettsiae multiply within monocytes forming morulae. The incubation period is reported to be 15–18 days.

***Ehrlichia canis*
(canine monocytic ehrlichiosis,
tropical canine pancytopenia)**

Description: *Ehrlichia canis* is a small, pleomorphic, Gram-negative, coccoid, obligatory intracellular bacterium that parasitises circulating monocytes, intracytoplasmically in clusters (morulae). The earliest stages are small elementary bodies 0.2–0.4 µm in diameter, followed by slightly larger initial bodies 0.5–4 µm in diameter, and finally even larger inclusion bodies 4–6 µm in diameter. The organisms stain blue with Romanowsky stain, light red with Machiavello stain and brown–black by silver stain.

Life cycle: Infection is transmitted to the dog through the bite of an infected *Rhipicephalus sanguineus* tick. Transmission in the tick occurs trans-stadially, but not transovarially. Larvae and nymphs become infected while feeding on rickettsaemic dogs and transmit the infection to the host after moulting to nymphs and adults, respectively.

***Ehrlichia chaffensis*
(canine monocytic ehrlichiosis)**

Description: *Ehrlichia chaffensis* is a small, pleomorphic, Gram-negative, coccoid, obligatory intracellular bacterium that parasitises circulating monocytes and macrophages, intracytoplasmically in clusters (morulae).

Ehrlichia ewingii

Description: *Ehrlichia ewingii* is a small, pleomorphic, Gram-negative, coccoid, obligatory intracellular bacterium that parasitises circulating neutrophils and eosinophils, intracytoplasmically in clusters (morulae).

Life cycle: Infection is transmitted to the dog through the bite of an infected *Amblyomma americanum* tick. Transmission in the tick occurs trans-stadially, but not transovarially. Larvae and nymphs become infected while feeding on rickettsaemic dogs and transmit the infection to the host after moulting to nymphs and adults, respectively.

***Ehrlichia ruminantium* (heartwater)**

Synonym: *Cowdria ruminantium*

Description: Organisms are seen as close-packed colonies consisting of less than ten to many hundred cocci. The organism varies in size from 0.2 to greater than 1.5 µm. The diameter of individual

organisms in a given cluster is rather uniform but groups are very pleomorphic. The small granules tend to be coccoid, with larger ones looking like rings, horseshoes, rods and irregular masses.

Life cycle: *Ehrlichia ruminantium* is transmitted by at least five species of *Amblyomma* ticks. In the ruminant host it is first found in reticuloendothelial cells and then parasitises vascular endothelial cells. Division is by binary fission and it produces morula-like colonies in the cytoplasm of infected cells.

***Ehrlichia risticii*
(Potomac horse fever)**

Synonym: *Neorickettsia risticii*

Description: *Ehrlichia risticii* is a Gram-negative obligate intracellular bacterium, 0.6–1.5 µm in size, with a trophism for monocytes. The organism is not visible in monocytes in blood films from clinical cases.

Life cycle: Details of the life cycle are incomplete but infection to horses appears to involve ingestion of metacercarial stages of trematodes or inadvertent ingestion of aquatic insect stages.

Aegyptianella

Aegyptianella infect a wide range of wild and domestic birds in the warmer parts of the world and have been recorded from Africa, Asia and southern Europe.

Life cycle: The life cycle is simple, with multiplication of the organisms within erythrocytes. The main vectors are ticks of the genus *Argas*.

Aegyptianella pullorum

Description: *Anaplasma*-like bodies of various sizes are found in the cytoplasm of erythrocytes. The organisms occur as initial bodies followed by development forms and marginal bodies ('signet-ring') in the cytoplasm of erythrocytes. The early trophozoites or initial bodies occur in erythrocytes, are small (0.5–1.0 µm) and round to oval. Spherical bodies up to 4 µm containing up to 25 small granules may occur.

Aegyptianella moshkovskii

Description: The organism usually produces four to six trophozoites. The early trophozoites within the erythrocytes are small (0.2–0.6 µm). Larger mature forms are 2.1 by 1.4 µm with large oval or irregular forms (0.9–5.3 µm).

ORDER RHIZOBILAES**FAMILY BARTONELLACEAE**

Members of the Bartonellaceae are polymorphic, often rod-shaped microorganisms that are distinguished from the Anaplasmataceae by cultural and structural characteristics. The Bartonellaceae

include two genera, *Bartonella* and *Grahamella*. Several species of *Bartonella* have been described in both cats and dogs, of which one, *B. henselae*, is an important zoonosis.

ORDER LEGIONELLALES

FAMILY COXIELLACEAE

The genus *Coxiella* has a single species with worldwide distribution and is the cause of Q fever. Infection is enzootic in cattle, sheep and goats but can cause severe disease in humans. The organism is widely disseminated among wild mammals and birds and has been found in ixodid and argasid ticks, gamasid mites and in human body lice (*Pediculus*).

Neorickettsia helminthoeca is the agent of 'salmon poisoning', which frequently produces severe and fatal infections in dogs, foxes and other animals.

PHYLUM FIRMICUTES

ORDER MYCOPLASMATALES

FAMILY MYCOPLASMATACEAE

Contains two genera, *Eperythrozoon* and *Haemobartonella*, that used to be classified in the rickettsial family Anaplasmataceae but these genera have now been reclassified into the bacterial family Mycoplasmataceae (class Mollicutes) based on 16S rRNA gene sequences and phylogenetic analysis.

Haemobartonella felis (syn. *Mycoplasma haemofelis*) is a cause of anaemia and fever in cats and is transmitted by lice, fleas or ticks. Vertical transmission has also been implicated.

Eperythrozoon

Species of *Eperythrozoon* are occasionally responsible for fever, anaemia and loss of weight in ruminants and pigs.

Life cycle: Organisms are transmitted by biting insects and ticks. Replication takes place by binary fission or budding.

Eperythrozoon wenyonii

Synonym: *Mycoplasma wenyonii*

Description: Coccoid, ring- or rod-shaped structures on the surface of red cells, blue to purple when stained with Giemsa.

Eperythrozoon ovis

Synonym: *Mycoplasma ovis*

Description: Pleomorphic coccobacilli occurring either as erythrocytic organisms in depressions on the cell surface, or free in the plasma (see Fig. 9.57). Single comma-shaped or ring-form cocci predominate in light to moderate infections but form irregular complex bodies in severe parasitaemias. Cocci appear light blue with Giemsa or Romanowsky stains.

Eperythrozoon suis

Synonym: *Mycoplasma haemosuis*

Description: Pleomorphic coccobacilli occurring either in depressions on the cell surface of erythrocytes or free in the plasma. Cocci appear light blue with Giemsa or Romanowsky's stains.

Veterinary entomology

Veterinary entomology, in its literal sense, means the study of insects of veterinary importance. This term, however, is commonly used to describe the wider study of all arthropods parasitic on animals (ectoparasites), including arachnids such as ticks and mites.

The association between an arthropod ectoparasite and a vertebrate host may take on a variety of forms. Those parasites that do not need to live or feed on a living host to complete their life cycle, and do so only when suitable hosts are available, are described as **facultative**. Facultative parasites may have only intermittent contact with their hosts, are less host-specific and are usually free-living for the major part of their life cycles. In other cases the parasites may be totally dependent on the host to complete their life cycle, in which case they are described as **obligatory**. Obligatory parasites live in continuous association with their host and in many cases are highly host-specific.

Facultative ectoparasites are covered in greater detail in Chapter 17. Obligatory ectoparasites are described in detail in the chapters relating to their specific or main animal hosts.

PHYLUM ARTHROPODA

The phylum Arthropoda contains over 80% of all known animal species, with almost a million species described, and consists of invertebrates whose major characteristics are a hard chitinous exoskeleton, a segmented body and jointed limbs.

CLASSIFICATION

There are two major classes of arthropods of veterinary importance, namely the Insecta and Arachnida; the important orders in these classes are summarised in Figs 3.1 and 3.2. Families and genera are listed in Table 3.1. The two major classes can be differentiated by the following general characteristics.

Insecta: These have three pairs of legs, the head, thorax and abdomen are distinct, and they have a single pair of antennae.

Arachnida: The adults have four pairs of legs and the body is divided into the gnathosoma (mouthparts) and idiosoma (fused cephalothorax and abdomen); there are no antennae.

A third class of arthropod, the **Pentastomida**, is of lesser veterinary importance. The adults are found in the respiratory passages of vertebrates and superficially resemble annelid worms rather than arthropods.

STRUCTURE AND FUNCTION

Segmentation

Arthropods are **metameric**, i.e. they are divided into segments. However, within a number of arthropod classes, particularly the arachnids, there has been a tendency for segmentation to become greatly reduced and, in many of the mites for example, it has almost disappeared. Segments have become fused into clusters, such as the head, thorax and

to a lesser extent the abdomen. Each group of segments is specialised for functions different from those of the other parts of the body.

Exoskeleton

The **exoskeleton** is the outer covering, which provides support and protection to the living tissues of arthropods. The exoskeleton is non-cellular. Instead it is composed of a number of layers

of **cuticle**, which are secreted by a single outer cell layer of the body known as the **epidermis** (Fig. 3.3). The outer layer of cuticle, the **epicuticle**, is composed largely of proteins and, in many arthropods, is covered by a waxy layer. The next two layers are the outer **exocuticle** and the inner **endocuticle**. Both are composed of a protein and a polysaccharide called **chitin**, which has long fibrous molecules containing nitrogen. For extra strength the exocuticle may be tanned, or **sclerotised**. This is where proteins, interwoven between the chitin bundles, become tightly cross-

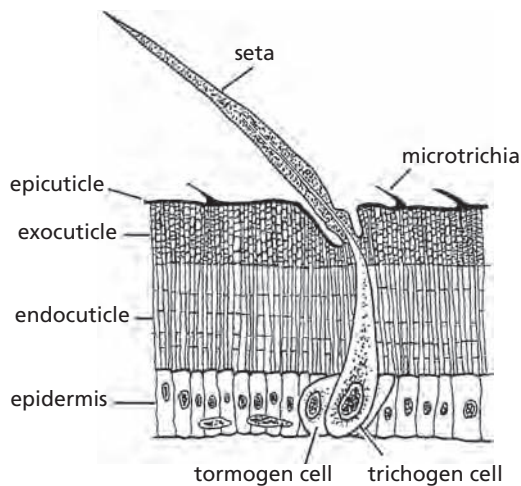

Fig. 3.3 Diagrammatic section through the arthropod integument.

linked giving it extra strength. The sclerotised cuticle is hard and dark in colour.

The cuticle is often penetrated by fine pore canals, which allow the passage of secretions from the epidermis to the surface. The cuticle has many outgrowths in the form of scales, spines, hairs and bristles.

Movement is made possible by the division of the cuticle into separate plates, called **sclerites**. Plates are connected by **intersegmental** or **articular membranes**, where the cuticle is soft and flexible (Fig. 3.4). The muscles attach on the inside of the exoskeleton to rod-like invaginations of the cuticle called **apodemes**. The cuticle of many larval arthropods is also largely soft, flexible, pale and unsclerotised.

Appendages

Primitively each arthropod segment bears a pair of leg-like appendages. However, the number of appendages has frequently been modified through loss or structural differentiation. In insects there are always three pairs of legs in the adult stage. In mites and ticks there are three pairs of legs in the larval stage and four pairs in the nymphal and adult stages. The cuticular exoskeleton of the legs is divided into tube-like segments connected to one another by soft articular membranes, creating joints at each junction.

Fig. 3.5 A spiracle, trachea and tracheoles. (Adapted from Snodgrass, 1935.)

Gas exchange

For some small arthropods the exoskeleton is thin and lacks a waxy epicuticle. For these animals oxygen and carbon dioxide simply diffuse directly across the cuticle. However, this method of gas exchange is only functional over very short distances and for very small animals. In most of the terrestrial groups of arthropod ectoparasites, the protective cuticle is punctured by a number of openings. In the insects these openings are called **spiracles**; in the mites and ticks they are called **stigmata** (Fig. 3.5).

Typically spiracles or stigmata open into cuticle-lined, air-conducting tubes called **tracheae**, which form longitudinal and transverse tracheal trunks that interconnect among the segments. The tracheae branch repeatedly as they extend to all parts of the body. The branches of the tracheae end within the cells of muscles and other tissues in extremely fine **tracheoles**, which are the principal sites of gas exchange. The ends of the tracheoles contain fluid and are usually less than 1 μm in diameter. Tracheoles are particularly numerous in tissues with high oxygen requirements.

Oxygen enters through the respiratory openings and passes down the tracheae, usually by diffusion along a concentration gradient. Carbon dioxide and (in terrestrial insects) water vapour move in the opposite direction. Reducing water loss is a major problem for most terrestrial arthropods and for them gas exchange is often a compromise between getting enough oxygen into the body while making sure that they do not desiccate. Hence in periods of inactivity the respiratory openings are often kept closed by valves which open only periodically. In large and highly mobile insects, active pumping movements of the thorax and/or abdomen may be used to help ventilate the outer parts of the tracheal system.

Circulatory system

The arthropod circulatory system is relatively simple, consisting of a series of central cavities or sinuses, called a **haemocoel** (Fig. 3.6). The haemocoel contains blood, called **haemolymph**, in which hormones are transported, nutrients are distributed from the gut and wastes removed via the excretory organs. The haemolymph is not usually involved in gas exchange and in most parasitic arthropods there is no respiratory pigment (however, some exceptions do exist, for example in *Gasterophilus* larvae which live in the extremely oxygen-deficient environment of the host's gut).

Fig. 3.6 Generalised arthropod circulatory system. (a) Longitudinal section through the body. (b) Transverse section through the abdomen. (From Gullan and Cranston, 1994, after Wigglesworth, 1972.)

In most mites the circulatory system consists only of a network of sinuses and circulation probably results from contraction of body muscles. Insects, on the other hand, have a functional equivalent of the heart, the **dorsal vessel**. This is essentially a tube running along the length of the body. The dorsal vessel is open at its anterior end, closed at its posterior end and is perforated by pairs of lateral openings called **ostia**. The ostia only permit a one-way flow of haemolymph into the dorsal vessel. The dorsal vessel pumps haemolymph forward, eventually into sinuses of the haemocoel in the head. Haemolymph then percolates back through the haemocoel, until it is again moved into the dorsal vessel through the ostia.

Nervous system

Arthropods have a complex nervous system associated with the well-developed sense organs, such as eyes and antennae, and behaviour that is often highly elaborate. The central nervous system consists of a dorsal brain in the head which is connected by a pair of nerves which run around the foregut to a series of ventral nerve cord ganglia.

Digestive system

The gut of an arthropod is essentially a simple tube that runs from mouth to anus. The precise shape of the gut varies between arthropods depending on the nature of their diet.

The gut is divided into three sections: the foregut, midgut and hindgut (Fig. 3.7). The foregut and hindgut are lined with cuticle. In fluid-feeding arthropods there are prominent muscles that attach to the walls of the pharynx to form a pump. The foregut is concerned primarily with the ingestion and storage of food, the latter usually taking place in the **crop**. Between the foregut and the midgut is a valve called the **proventriculus** or **gizzard**. The midgut is the principal site of digestion and absorption. It has a cellular lining, which secretes digestive enzymes. Absorption takes place largely in the

Fig. 3.7 Digestive tract of a generalised arthropod, showing the foregut, midgut and hindgut. The cuticular linings of the foregut and hindgut are indicated by thickened lines.

anterior of the midgut, in large outpockets called **gastric caecae**. The hindgut terminates in an expanded region, the **rectum**, which functions in the absorption of water and the formation of faeces. Nitrogenous wastes are eliminated from the haemolymph by long thin projections called the **Malpighian tubules**, which extend into the haemocoel and open into the gut at the junction of the midgut and the hindgut. In mites and ticks the gut follows a broadly similar plan, but may be simplified, often with only one pair of Malpighian tubules.

Arthropod sense organs

The sensory receptors of arthropods are usually associated with modifications of the chitinous exoskeleton. The most common type of receptor is associated with hairs, bristles and setae. Bristles may act as mechanoreceptors, with movement triggering the receptor at its base. Alternatively, the bristle may carry a range of chemoreceptors, which may be sensitive to specific cues, such as carbon dioxide or temperature. The sensory hairs and bristles are distributed most densely at particular locations such as the antennae or legs.

Most arthropods have eyes, but these can vary greatly in complexity. Simple eyes, known as **stemma** and consisting of only a few sensory cells, are found in many larval insects. More complex **ocelli**, which contain between 1 and 1000 sensory cells and an overlying corneal lens, are found in some larval and many adult insects. These simple eyes do not form images but are very sensitive at low light intensities and to changes in light intensity. The most complex type of arthropod eye, known as a compound eye, is large with thousands of long cylindrical units called **ommatidia**, each covered by a translucent cornea, called a **facet**. There is no mechanism for accommodation, the compound eye does not form an effective image and its principal function is in detecting movement. In the females of some species of insect the eyes are distinctly separated (**dichoptic**) while in the males they may be very close together (**holoptic**). Ocelli and compound eyes may both occur in the same animal. In some arthropods, such as the mites, ticks and lice, eyes may be greatly reduced or absent. In others such as some blood-sucking flies, whose sight is important in locating their hosts, the eyes are well developed.

Reproductive system

In most arthropods the sexes are separate and mating is usually required for the production of fertile eggs. The female reproductive system is composed of a pair of **ovaries**. Each ovary is divided into egg tubes, or **ovarioles**. The ovarioles lead, via the **oviduct**, to

an **ovipositor**. Most arthropods lay eggs, but some retain the eggs which hatch within the oviduct, and live larvae may be deposited at various stages of development.

The male reproductive system is usually composed of a pair of **testes**, each subdivided into a set of sperm tubes, leading to the vas deferens and the external genitalia, with a penis, or **aedeagus**. Accessory glands produce secretions that may form a packet called a **spermatophore**, which encloses the sperm and protects it during insemination.

Sperm may be delivered directly to the female during copulation or, in some species of mite, the spermatophore is deposited on the ground and the female is induced to walk over and pick up the spermatophore with her genital opening. Sperm are usually stored by the female in organs called **spermathecae**. As an ovulated egg passes down the oviduct it is fertilised by sperm released from the spermathecae.

Moulting

To grow, arthropods must shed the exoskeleton periodically; this is described as **moulting** or, more properly, **ecdysis**. Before the old exoskeleton is shed the epidermis secretes a new epicuticle. The new epicuticle is soft and wrinkled at this stage. When the old skeleton is shed the soft whitish exoskeleton of the newly moulted animal is stretched, often by the ingestion of air or water. Once expanded, sclerotisation occurs, resulting in hardening and darkening of the cuticle. The forms that occur between moults are known as **stages**, or **stadia**, and morphologically distinct life cycle-stages are known as **instars**.

CLASS INSECTA

GENERAL MORPHOLOGY AND LIFE CYCLE

Members of the class Insecta can be distinguished from the other arthropods by the presence of only three pairs of legs in the adults, and the broad division of the body into three sections: the head, thorax and abdomen.

The head carries the main sensory organs: the single pair of antennae, a pair of compound eyes and often a number of ocelli. The mouth is surrounded by mouthparts, which are very variable in form. In the ancestral form, represented by living insects such as cockroaches and grasshoppers, the mouthparts are composed of the following elements (Fig. 3.8). The **labrum** is a hinged plate attached to the front of the head by the clypeus. The paired **mandibles** (jaws) and **maxillae** (secondary jaws) have areas of their surfaces adapted for cutting, slashing or grinding. The maxillae may also carry maxillary palps, which are sensory in function and used in the monitoring of food. A **hypopharynx**, arising from the floor of the mouth, may be considered in some ways to act as a tongue. Finally, a **labium** or lower lip usually bears two sensory labial palps, but these may be extensively modified, especially in flies. Insect mouthparts show a remarkable variety of specialisation, related to their diets.

The thorax is composed of three fused segments: the **prothorax**, the **mesothorax** and the **metathorax**. On each of these segments there is a single pair of legs. Each leg is composed of six segments. The basal section of the leg articulating with the body is the **coxa**, which is followed by a short triangular **trochanter**. There then follows the **femur**, the **tibia**, one to five segments of the **tarsus**,

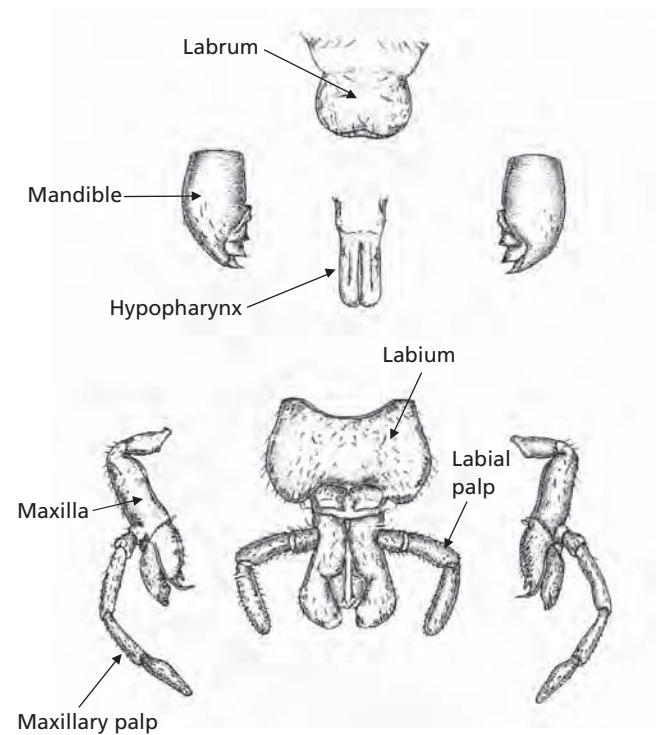

Fig. 3.8 Mouthparts of a generalised omnivorous insect.

the tarsomeres and, finally, the **pretarsus** composed of claws and ridged pads. Between the claws there may be two pad-like **pulvilli** surrounding a central bristle or pad, known as the **empodium** (Fig. 3.9). The legs of insects are generally adapted for walking or running but some are modified for specialised functions, such as jumping (fleas) or clinging to the hairs of their host's body (lice).

Most orders of insect have two pairs of wings articulating with the mesothorax and metathorax (pterygotes). Some orders of primitive insects have never developed wings (apterygotes), while others such as the fleas and lice, which once had wings, have now lost them completely. Others, such as some of the hippoboscids, have wings for only a short time as adults, after which they are shed. The wing consists of a network of sclerotised veins, which enclose regions of thin transparent cuticle called cells. The veins act as a framework to brace and stabilise the wing and may carry haemolymph and nerves. The arrangement of the veins tends to be characteristic of

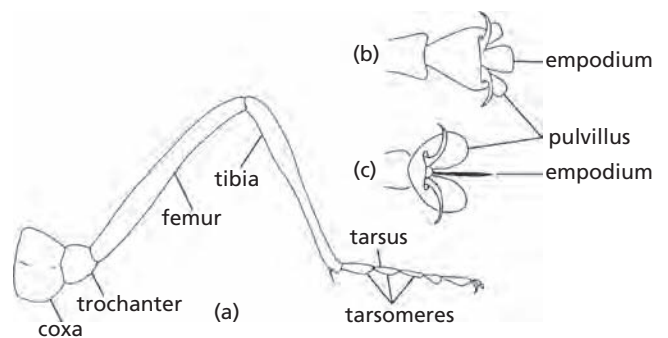

Fig. 3.9 The segments of the leg (a), and the empodium and pulvilli of adult brachyceran (b) and cyclorrhaphous (c) Diptera.

various groups of insect species and so is important in identification and taxonomy (Fig. 3.10). In several groups of insects, such as beetles, the front wings have been modified to various degrees as protective coverings for the hindwings and abdomen and are known as **elytra**. In the true flies (the Diptera) the hindwings have been reduced to form a pair of club-like **halteres**, which are used as stabilising organs to assist in flight.

The abdomen is composed primitively of 11 segments, although the tenth and eleventh segments are usually small and not externally visible and the eleventh segment has been lost in most advanced groups. The genital ducts open ventrally on segment 8 or 9 of the abdomen and these segments often bear external organs that assist in reproduction. The genitalia are composed of structures which probably originated from simple abdominal appendages. In the male, the basic external genitalia consist of one or two pairs of claspers, which grasp the female in copulation, and the penis (aedeagus). However, there is considerable variation in the precise shape of the male genitalia in various groups of insect and these differences may be important in the identification of species. In the female, there may be a specialised appendicular ovipositor, composed of appendages on the terminal segments of the abdomen, or the tip of the abdomen may be elongated at the time of oviposition to form a more simple substitutional ovipositor.

Within the class Insecta there are generally considered to be 30 orders (although the precise number may vary depending on which classification system is used), of which only three, the flies (Diptera), fleas (Siphonaptera) and lice (Phthiraptera), are of major veterinary importance.

Insect life cycles

In most insect orders, the juvenile stadia broadly resemble the adult except that the genitalia and, where appropriate, wings are not developed. The juveniles, usually called **nymphs**, make a new cuticle and shed the old one at intervals throughout development, typically four or five times, increasing in size before the emergence of the adult. This is often described as a simple life cycle with incomplete or partial metamorphosis, known as **hemimetabolous development** (Fig. 3.11).

In other, more advanced, insects the juvenile and adult stages are dissimilar. The juvenile instar, which may be referred to as a **larva**, **maggot**, **grub** or **caterpillar**, is concerned primarily with feeding and growth. In contrast, the adult, or **imago**, has become the specialised reproductive and dispersal life-cycle stage. To reach the adult form, the larva must undergo complete metamorphosis, during which the entire body is reorganised and reconstructed. The transformation between the juvenile and the adult is made pos-

Fig. 3.11 Life cycle of a generalised louse displaying hemimetabolous metamorphosis and passing through three nymphal stages prior to emergence as a reproductive adult.

Fig. 3.12 Life cycle of a fly, *Stomoxys calcitrans*, displaying holometabolous metamorphosis, with the egg giving rise to maggot-like larva, pupa and finally reproductive adult.

Fig. 3.10 The wing veins and cells of a typical insect, the calypterate dipteran *Calliphora vicina*.

sible by the incorporation of a **pupal** stage, which acts as a bridge between juvenile and adult. The pupa does not feed and is generally (but not always) immobile. However, it is metabolically very active as old larval tissues and organs are lost or remoulded and replaced by adult organs. This pattern of development is described as a **complex life cycle with holometabolous development** (Fig. 3.12).

ORDER HEMIPTERA

This order includes a large number of plant lice and bugs of considerable economic importance. Only a small number of species are of veterinary importance.

FAMILY CIMICIDAE

Cimex

Bed bugs of the genus *Cimex* are blood feeders on a wide range of animals and humans. Two species are of particular importance: *Cimex lectularius* is a cosmopolitan species of temperate and subtropical regions feeding on humans, bats, chickens and other domestic animals; *Cimex hemipterus* is tropicopolitan and subtropical, and feeds on humans and chickens.

Description: Bed bugs have oval flattened bodies. The forewings are reduced to hemelytral pads, and the hindwings are absent. The adult bed bug measures 5–7 mm when unfed, with females being slightly larger than males. They are generally red–brown in colour, although they appear darker following a blood meal (see Fig. 17.1). The head bears long four-segmented antennae, of which the last three segments are long and slender, and a pair of widely separated compound eyes placed laterally at the sides of the head; there are no ocelli. The labium has three obvious segments and is reflected backwards under the head reaching as far as the coxae of the first pair of legs. The abdomen is 11-segmented, with segments 2–9 being easily recognisable dorsally. When the bed bug engorges, the abdomen increases greatly in volume. There are seven pairs of spiracles located ventrally on abdominal segments 2–8. Nymphs are smaller than adults, lack mature genitalia, but also blood-feed.

Life cycle: There are some minor differences between the species but, for *C. lectularius*, eggs are laid on rough rather than smooth surfaces and generally inserted into cracks and crevices. They are laid individually and held in place by transparent cement. The eggs are cream in colour, approximately 1 mm in length and less than 0.5 mm in breadth. The eggs are fertilised while still in the ovary, and embryos undergo some development before being laid. At 22°C eggs take 10–12 days to hatch, and the shortest time for development is 4–5 days at 30–35°C. Hatching does not occur at 37°C or above or at temperatures below 13°C, although eggs can remain viable for short periods (less than 3 months) as the temperature approaches 0°C. In temperate climates, eggs laid in the autumn are likely to have died before the temperature rises above the threshold in spring, except in houses with heating.

There are five juvenile stages, with each stage requiring at least one blood meal (often two) to moult to the next stage. Nymphs will feed within 24 hours of emergence or of moulting to the next instar. Time for development through the instars is very similar for the first four, but the fifth is usually somewhat longer. The length of the life cycle is very dependent on ambient temperature. The entire nymphal development can take 6–8 weeks at 22°C, after which the adults can live up to around 6 months, but at 30°C development from egg to adult can be completed in 3 weeks and overall lifespan is shorter.

FAMILY REDUVIIDAE

Triatome or cone-nose bugs, sometimes called kissing or assassin bugs, of the genera *Rhodnius*, *Triatoma* and *Panstrongylus*, are blood feeders on a wide range of animals and humans. They are vectors of the protozoan parasite *Trypanosoma cruzi* which causes Chagas' disease in South America. Important species include *Triatoma infestans* and *Rhodnius prolixus*.

Description: The adult reduviid bugs range in length from 10 to 40 mm; the majority of species are around 20–30 mm in length. They are usually dark brown to black in colour, with contrasting patterns of red, orange or yellow marks around the edge of the abdomen. The body is flattened and elongated. The forewings have a hardened basal section and a distal membranous section and overlie the entirely membranous hindwings. The antennae are elbowed with four segments. They also have a piercing proboscis that is three-segmented, tapered and slender and bent back under the body when not in use. Nymphs are smaller than adults, lack mature genitalia or wings, but also blood-feed.

Life cycle: All species are nocturnal, obligate, blood-feeding bugs. Gravid females start to lay eggs about 2 weeks after mating. They then lay one or two eggs daily, each female producing about 200 eggs in total. Each egg is about 2 mm in length. Eggs hatch about 2 weeks after oviposition, although this is temperature dependent. There are five nymphal stages, all of which blood-feed. The entire egg to adult life cycle may take 2–3 months, but more usually 1–2 years.

Feeding is initiated by chemical and physical cues. Carbon dioxide causes increased activity and heat stimulates probing. When probing is initiated, the rostrum is swung forward and the mandibular stylets are used to cut through the skin and then anchor the mouthparts. The maxillary stylets probe for a blood vessel and saliva, containing an anticoagulant, passes down the salivary canal while blood is pumped up the food canal. Feeding may take between 3 and 30 minutes. After engorging, the rostrum is removed from the host and the bug defecates, after which it crawls away to find shelter.

ORDER DIPTERA

The Diptera are the true flies; this order is one of the largest orders in the class Insecta, with over 120,000 described species. They have only one pair of wings, the hind pair having been reduced to become halteres, which help the insect to maintain stable flight. All species of Diptera have a complex life cycle with complete metamorphosis. As a result, dipterous flies can be parasites as larvae or adults, but they are rarely parasites in both life-cycle stages. The adults of many members of this order are also important vectors of disease.

The order Diptera has traditionally been divided into three suborders, **Cyclorrhapha**, **Brachycera** and **Nematocera**, distinguished morphologically by wing venation (Fig. 3.13) and antennal structure (Fig. 3.14), although in recent studies the suborder Cyclorrhapha is usually replaced by an infraorder known as the Muscomorpha, within an enlarged suborder Brachycera. This is known as the 'McAlpine classification'.

SUBORDER NEMATOCERA

Flies of the suborder Nematocera are usually small, slender and delicate with long filamentous antennae composed of many articulating segments (Fig. 3.14). The wings are often long and narrow, with conspicuous longitudinal veins (Fig. 3.13). The palps are usually pendulous, though not in mosquitoes, and are usually composed of four or five segments. Only the females are parasitic and have piercing–sucking mouthparts. Eggs are laid in or near water and develop into aquatic larvae and pupae: both of these stages have recognisable heads and are mobile.

Fig. 3.13 Variations in typical wing venation found in the three suborders of Diptera.

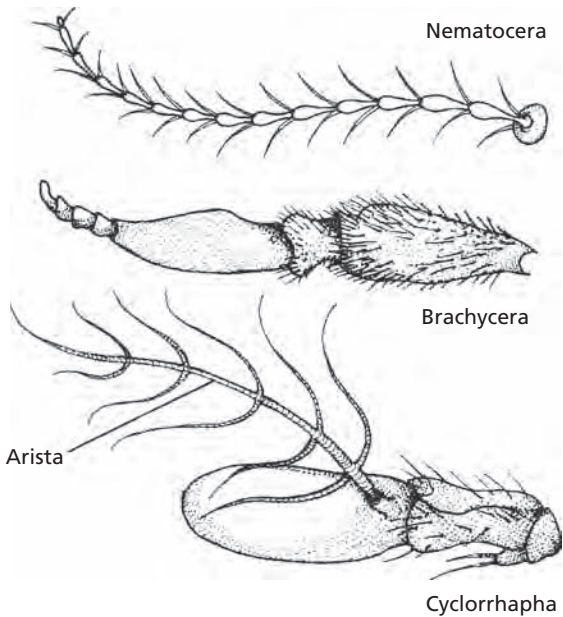

Fig. 3.14 Variations in the antennae found in the three suborders of Diptera.

The labium forms a protective sheath for the other mouthparts, known collectively as the stylets, and ends in two small sensory labella (Fig. 3.15). Inside the labium lies the labrum which is curled inwards to the edges so that it almost forms a complete tube. The gap in the labrum is closed by the very fine paired mandibles to form a food canal. Behind the mandibles lies the slender hypopharynx, bearing the salivary canal, and behind this are the paired maxillae (laciniae). Both the mandibles and maxillae are finely toothed towards their tips. At the base of the mouthparts is a single pair of sensory maxillary palps. The structure of these mouthparts

Fig. 3.15 Mouthparts of a mosquito (Diptera: Nematocera): (a) anterior view; (b) transverse section. (From Gullan and Cranston, 1994.)

is essentially similar in all families of blood-feeding Nematocera. However, they are greatly elongated in the mosquitoes.

FAMILY CERATOPOGONIDAE

This family consists of very small flies, commonly known as biting midges. The females feed on humans and animals and are known to transmit various viruses, protozoa and helminths. The only important genus from a veterinary standpoint is the genus *Culicoides*, of which over 1000 species have been described. Midges feed on birds or mammals, inflicting a painful bite and transmitting many disease pathogens. Most importantly, they act as vectors of more than 50 arboviruses.

Culicoides

Description: *Culicoides* midge adults are 1.5–5 mm in length with the thorax humped over a small head (Fig. 3.16). The wings are generally mottled in pattern, and at rest are held like a closed pair of scissors over the grey or brownish-black abdomen. The legs are relatively short, particularly the forelegs, and the small mouthparts hang vertically. The short piercing proboscis consists of a sharp labrum, two maxillae, two mandibles, a hypopharynx and a fleshy labium, which does not enter the skin during feeding by the adult female. In the male, the long antennae are feathery or plumose, whereas those of the female possess only short hairs and are known as pilose antennae. Microscopic hairs cover the wings. Ceratopogonids have a forked medial vein (M_1 , M_2) and species of the genus *Culicoides* usually have a distinct pattern of radial cells on their wings (Fig. 3.16).

Fig. 3.16 (a) Adult female *Culicoides nubeculosus* at rest. (b) Wing venation typical of species of *Culicoides*, showing the two elongate radial cells. (From Edwards *et al.*, 1939.)

Life cycle: The eggs, which are brown or black, are cylindrical or banana-shaped and 0.5 mm in length. Eggs are laid in damp marshy ground or in decaying vegetable matter near water. Hatching occurs in 2–9 days depending on the species and temperature, but temperate species may overwinter as eggs. There are four larval stages and these are characterised by having small dark heads, segmented bodies and terminal anal gills. They have a serpentine swimming action in water and feed on decaying vegetation. Larval development is complete in warm countries in 14–25 days, but in temperate areas this may be delayed for periods of up to 7 months. The less active brown pupae, 2–4 mm long, are found at the surface or edges of water and are characterised by a pair of respiratory trumpets on the cephalothorax and a pair of terminal horns that enable the pupa to move. Adult flies emerge from the pupae in 3–10 days. Only females blood-feed and inflict a painful bite. Adult *Culicoides* are not strong fliers and they are usually found close to larval habitats in small and inconspicuous swarms. Adult *Culicoides* feed especially in dull humid weather and tend to be crepuscular and nocturnal. Females are attracted to the smell and warmth of their hosts and different species may be host-specific to varying degrees.

FAMILY SIMULIIDAE

Of the 12 genera belonging to this family of small flies, *Simulium* is the most important. Commonly referred to as ‘blackflies’ or ‘buffalo gnats’, they have a wide host range, feeding on a great variety of mammals and birds and causing annoyance due to their painful

bites. In humans, however, they are most important as vectors of *Onchocerca volvulus*, the filarioid nematode that causes ‘river blindness’ in Africa and Central and South America. More than 1700 species of blackflies have been described worldwide, although only 10–20% of these are regarded as pests of humans and their animals.

Simulium

Description: As their common names indicate, these flies are usually black with a humped thorax. The adults are 1.5–5 mm in length and relatively stout-bodied, with broad colourless wings that show indistinct venation and which are held at rest like the closed blades of a pair of scissors. The wings are short, typically 1.5–6.5 mm long, broad with a large anal lobe, and have veins that are thickened at the anterior margin of the wing (Fig. 3.17). The first abdominal tergite is modified to form a prominent basal scale, fringed with fine hairs. Morphologically, adult male and female flies are similar, but can be differentiated by the fact that in the female the eyes are distinctly separated (dichoptic), whereas in males the eyes are very close together (holoptic) with characteristic enlarged ommatidia in the upper part of the eye. This may help males to locate females against the blue backdrop of the sky. Compared with other closely related

Fig. 3.17 (a) Adult female *Simulium*. (b) Wing venation typical of *Simulium*, showing the large anal lobe and crowding of the veins towards the leading edge. (From Smart, 1943.)

flies, the antennae, although segmented, are relatively short, stout and devoid of bristles. The mouthparts resemble those of the biting midges except for the presence of conspicuous segmented maxillary palps. The body is covered with short golden or silvery hairs.

Life cycle: Eggs, 0.1–0.4 mm in length, are laid in sticky masses of 150–600 on partially submerged stones or vegetation in fast-flowing water. Hatching takes only a few days in warm conditions, but may take weeks in temperate areas and in some species the eggs can overwinter. There may be up to eight larval stadia. The mature larvae are 5–13 mm long, light coloured and poorly segmented, and are distinguishable by a blackish head, which bears a prominent pair of feeding brushes (Fig. 3.18). The body is swollen posteriorly and just below the head is an appendage called the proleg, which bears hooks. Larvae normally remain attached to submerged vegetation or rocks by a cirlet of posterior hooks, but may change their position in a looping manner by alternate use of the proleg and the posterior hooks. The larvae remain in areas of fast-flowing current, since they require highly oxygenated water to survive. They use the water current to passively filter-feed on suspended debris and bacteria. In deoxygenated water, the larvae detach from their silken pads and drift downstream. Larval maturation takes from several weeks to several months, and in some species larvae can overwinter. Mature larvae pupate in a slipper-shaped brownish cocoon fixed to submerged objects. The pupa has prominent respiratory gills projecting from the cocoon. In the final stages of pupation, a film of air is secreted between the developing adult and the pupal cuticle. When the pupal case splits the emerging adult rises to the surface

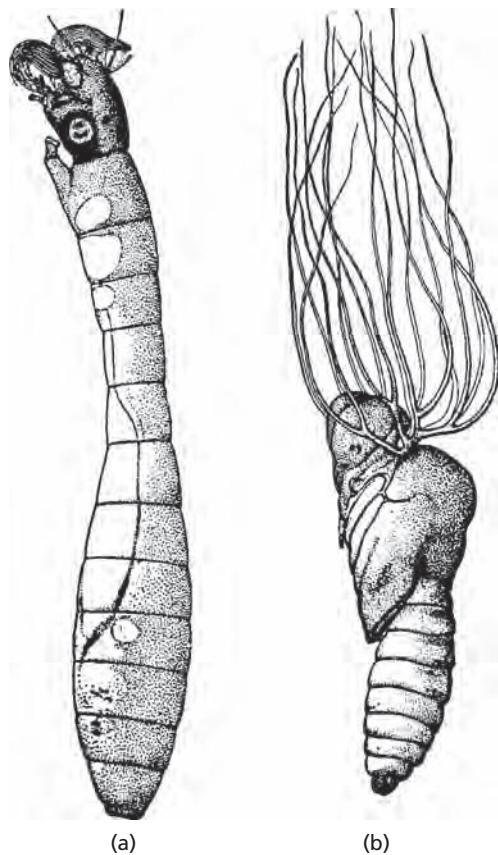

Fig. 3.18 Immature stages of Simuliidae: (a) larva; (b) pupa. (From Castellani and Chalmers, 1910.)

in a bubble of air and is able to fly away immediately. The pupal period is normally 2–6 days and a characteristic feature of many species is that there is simultaneous mass emergence of the adult flies, which take flight from the surface of the water. The duration of the life cycle from egg to adult is variable, depending on the species and water temperature. Typical longevity for adult blackflies ranges from 2–3 weeks to as long as 85 days. Adult flies feed on plant nectar, but in most species females require a blood meal to obtain the protein necessary to mature their eggs.

FAMILY PSYCHODIDAE

The flies of this family are called the ‘sandflies’, with *Phlebotomus* the main genus of veterinary importance. In the New World the genus *Lutzomyia* is of medical importance. Both genera are important as vectors of *Leishmania*. Since, in some areas of the world, the term ‘sandflies’ includes some biting midges and blackflies, a better term is ‘phlebotomine sandflies’.

Phlebotomus and *Lutzomyia*

Description, adult: These small flies are up to 5 mm long and are characterised by their hairy appearance, large black eyes and long legs (Fig. 3.19). The wings, which unlike those of other biting flies are lanceolate in outline, are also covered in hairs and are held erect over the body at rest. As in many other nematoceran flies, the mouthparts are of short to medium length, hang downwards and are adapted for piercing and sucking. The maxillary palps are relatively conspicuous and consist of five segments. In both sexes the antennae are long, 16-segmented, filamentous and covered in fine setae.

Fig. 3.19 (a) Adult female sandfly, *Phlebotomus papatasi*. (b) Wing venation typical of species of *Phlebotomus* (Psychodidae). (From Smart, 1943.)

Description, larvae: The mature larva is greyish-white with a dark head. The head carries chewing mouthparts, which are used to feed on decaying organic matter. The antennae are small. The abdominal segments bear hairs and ventral unsegmented leg-like structures (pseudopods), which are used in locomotion. A characteristic feature of phlebotomine larvae is the presence of long caudal setae, one pair in first-stage larvae and two pairs in second-, third- and fourth-stage larvae.

Life cycle: Up to 100 ovoid, 0.3–0.4 mm long, brown or black eggs may be laid at each oviposition in small cracks or holes in the ground, the floors of animal houses, or in leaf litter. Although they are not laid in water, the eggs need moist conditions for survival, as do the larvae and pupae. A minimum temperature of 15°C is required for egg development. Under optimal conditions the eggs can hatch in 1–2 weeks, but this may be prolonged in cold weather. The larvae, which resemble small caterpillars, scavenge on organic matter and can survive flooding. There are four larval stages, maturation taking 3 weeks to several months, depending on species, temperature and food availability. In more temperate regions these flies overwinter as mature larvae. The mature larvae are 4–6 mm in length, have a well-developed black head with eyespots, and a segmented greyish body, which is covered in bristles. The pupae attach themselves to the substrate in an erect position with the exuviae of the last larval instar attached at the caudal end. The adults emerge from pupation after 1–2 weeks. The whole life cycle takes 30–100 days, or even longer in cool weather.

FAMILY CULICIDAE

The Culicidae are the mosquitoes, with over 3000 species described. They are small slender flies with long legs. The main genera of importance are *Anopheles*, *Aedes* and *Culex*.

Their bites are a severe nuisance to humans and animals, commonly causing inflammatory skin reactions and mild allergic responses to their salivary secretions when they bite; while more severe allergic reactions have been reported, anaphylaxis is rare.

They can also cause serious adverse impacts on animal herds attacked by extraordinary numbers of blood-seeking mosquitoes. However, the main medical and veterinary importance relies on their role as vectors of disease-causing pathogens; they are principally important as vectors of malaria (*Plasmodium* spp.), filarial nematodes and viruses. Transmission of the canine heartworm, *Dirofilaria immitis*, may be of particular significance, mainly in the tropics and subtropics, where it infests dogs, other canids and rarely cats. Some pathogens can be transmitted mechanically by mosquitoes, the principal disease example being the myxoma virus that is spread among rabbits primarily by mosquitoes in Australia (although in Europe the principal vector of myxomatosis is the flea *Spilopsyllus cuniculi*). Primarily because of their importance as vectors of human malaria there is a vast literature on their classification, behaviour and control, but the family is of relatively limited veterinary significance.

Description: Mosquitoes vary from 2 to 10 mm in length and the adults have slender bodies, prominent eyes and long legs (Fig. 3.20c). The long narrow wings are held crossed flat over the abdomen at rest and bear scales, which project as a fringe on the posterior margin. The mouthparts consist of a conspicuous, forward-projecting, elongated proboscis adapted for piercing and sucking. Individual elements comprise a long U-shaped fleshy labium containing paired maxillae, mandibles and a hypopharynx, which carries a salivary duct that delivers anticoagulant into the host's tissues. The labrum forms the roof of the proboscis. All the elements, with the exception of the labium, enter the skin during feeding by the females, forming a tube through which blood is sucked. In the non-parasitic males the maxillae and mandibles are reduced or absent. The maxillary palps of different species are variable in length and morphology. Both sexes have long, filamentous, segmented antennae, pilose in females and plumose in males.

General life cycle: The larvae of all species are aquatic and occur in a wide variety of habitats, ranging from extensive areas such as marshes to smaller areas such as the edge of permanent pools, marshes, puddles, flooded tree-holes and even, for some species, temporary water-filled containers (Fig. 3.21). However, they are

Fig. 3.20 *Aedes atropalpus*: (a) larva; (b) pupa; (c) adult. (From Eidmann and Kuhlhorn, 1970.)

Fig. 3.21 Life cycle of the mosquito *Culex pipiens*: (a) adult ovipositing; (b) larvae at the water surface; (c) pupa suspended from the water surface; (d) adult emerging from its pupal case at the water surface. (From Gullan and Cranston, 1994.)

usually absent from large tracts of uninterrupted water, such as lakes, and from fast-flowing streams or rivers. Mosquito larvae are known as 'wrigglers' and require 3–20 days to develop through four stadia. Hatching is temperature dependent and occurs after several days or weeks, but in some temperate species eggs may overwinter. All four larval stages are aquatic. There is a distinct head with one pair of antennae, compound eyes and prominent mouth brushes, used in feeding on organic material (Fig. 3.20a). Maturation of larvae can extend from 1 week to several months, and several species overwinter as larvae in temperate areas.

With the final larval moult, the pupal stage occurs. Mosquito pupae (known as 'tumblers') usually remain at the water surface, but when disturbed can be highly mobile. All mosquito pupae are aquatic, motile and comma-shaped, with a distinct cephalothorax that bears a pair of respiratory trumpets (Fig. 3.20b). The tegument of the cephalothorax is transparent and the eyes, legs and other structures of the developing adult are readily visible. The tapering abdominal segments have short hairs, and terminally there is a pair of oval paddle-like extensions, which enable the pupa to move up and down in the water. Generally the pupal stage is short, only a few days in the tropics and several weeks or longer in temperate regions. The adult emerges through a dorsal split in the pupal tegument. Adults usually only fly up to a few hundred metres from their breeding sites, but may be dispersed long distances by winds. Although the lifespan of adult flies is generally short, some species can overwinter by hibernating.

When adult mosquitoes emerge from the pupal case they crawl to a nearby object, where they harden their cuticle and inflate their wings. Mating normally occurs within 24 hours of emergence and is completed in flight. One insemination is usually sufficient for the fertilisation of all eggs. For normal activity and flight, mosquitoes feed on nectar and plant juices, but females are anautogenous – they

need an initial blood meal to develop their ovaries and must feed again between each egg batch matured. A female mosquito will live for an average of 2–3 weeks, while the male's lifespan is shorter.

Mosquitoes are nocturnal or crepuscular feeders with a wide host range. Host selection is extremely opportunistic and is largely influenced by the relative abundance of hosts found in the habitat. Host location is achieved using a range of olfactory and visual cues, orientation to wind direction and body warmth. Oviposition begins as soon as a suitable site is located. Adult mosquitoes are strong fliers.

SUBFAMILY CULICINAE

Aedes and *Culex*

Description: The culicine adult rests with its body angled and its abdomen directed towards the surface (Fig. 3.22). The palps of female culicine mosquitoes are usually only about one-quarter the length of the proboscis.

Life cycle: After a blood meal the gravid female lays up to 300 eggs singly on the surface of water. The eggs are dark coloured, either elongate or ovoid, and cannot survive desiccation. Most species of *Aedes* lay their eggs on moist substrates rather than on the water itself, where they mature and await adequate water to stimulate hatching. In some cases the eggs may remain viable for up to 3 years. Despite some degree of temperature tolerance, freezing and temperatures in excess of 40°C will kill most eggs.

In species of the genus *Culex*, eggs are laid in groups forming 'egg-rafts'. A female *Culex* mosquito may lay a raft of eggs every third night during its lifetime, hence oviposition typically occurs around six or seven times. When the eggs mature they will hatch

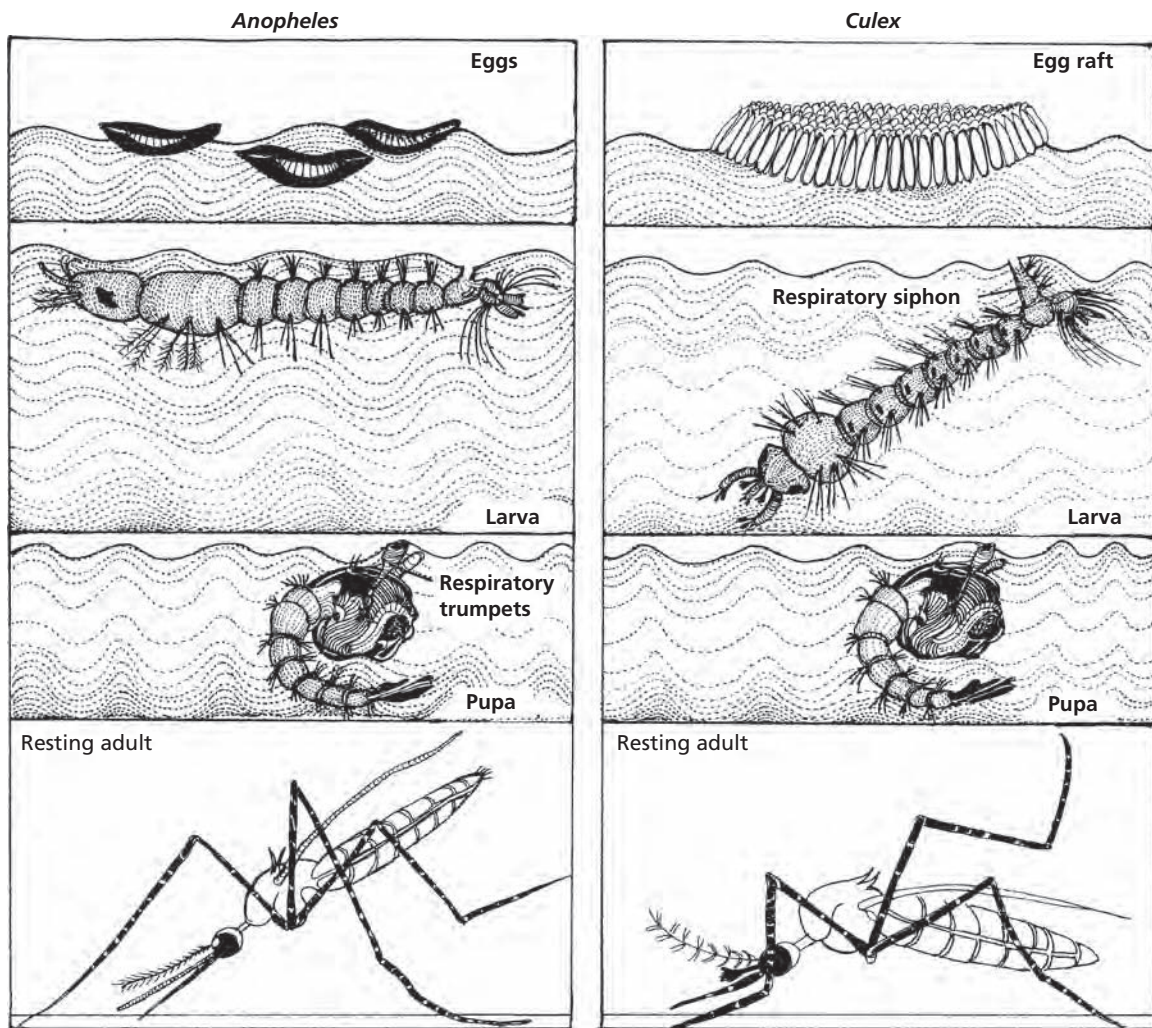

Fig. 3.22 The comparative life cycles of anopheline and culicine mosquitoes.

into larvae regardless of the availability of water. Hatching is temperature dependent and occurs after several days to weeks, but in some temperate species eggs may overwinter.

All four larval stages are aquatic and the larvae take in air through a pair of spiracles situated at the end the respiratory siphon.

SUBFAMILY ANOPHELINAE

Anopheles spp.

Description: Living anopheline adults can readily be distinguished from culicines, such as *Aedes* and *Culex*, when resting on a flat surface. On landing, anopheline mosquitoes rest with the proboscis, head, thorax and abdomen in one straight line at an angle to the surface (Fig. 3.22). The palps of female anopheline mosquitoes are as long and straight as the proboscis. The abdomen of *Anopheles* bears hairs but not scales.

Life cycle: The eggs are dark-coloured and boat-shaped and possess characteristic lateral floats that prevent them from sinking and maintain their orientation in the water. Such eggs usually hatch

within 2 or 3 days and cannot survive desiccation. Most larvae of *Anopheles* lie parallel to the water surface and take in air through a pair of spiracles on the penultimate abdominal segment.

SUBORDER BRACHYCERA

The Brachycera are a major suborder of the Diptera consisting of around 120 families. Their most distinguishing characteristic is reduced antenna segmentation. The organisation of subgroups within the Brachycera is a source of much confusion and controversy, with many of the names used historically no longer in use.

The Tabanidae is one of the largest families of Diptera, containing an estimated 8000 species divided into 30 genera, only three of which are of major veterinary importance: *Tabanus* (horse flies), *Haematopota* and *Chrysops* (deer flies). Species of the genus *Tabanus* are found worldwide; the *Haematopota* are largely Palaearctic, Afro-tropical and Oriental in distribution; species of the genus *Chrysops* are largely Holarctic and Oriental.

Other groups of flies of veterinary interest in this order are divided into the three superfamilies: **Muscoidea**, **Hippoboscoidea** and **Oestroidea**. The Muscoidea and Hippoboscoidea each contain

two families of veterinary interest, the **Muscidae** and **Fanniidae** and the **Hippoboscidae** and **Glossinidae**, respectively. The superfamily Oestroidea contains three families of veterinary interest, **Oestridae**, **Calliphoridae** and **Sarcophagidae**, species of which are primarily associated with **myiasis**, the infestation of the tissues of a living host with fly larvae.

There are two basic functional types of mouthpart seen in the adult flies of veterinary interest. Sponging mouthparts are used for feeding on liquid films. Such mouthparts are found in groups such as the house flies, blowflies and face flies. Biting mouthparts are used for puncturing the skin and drinking blood. They occur in groups such as the stable flies, horn flies and tsetse flies.

In the sponging-type mouthparts, as seen in the house fly, the proboscis is an elongate feeding tube, composed of a basal **rostrum** bearing the maxillary palps, a median flexible **haustellum**, composed of the labium and flap-like labrum, and apical **labella** (Fig. 3.23). Mandibles and maxillae are absent. The labrum and the hypopharynx lie within the flexible anterior gutter in the labium. The labella are sponging organs, the inner surface of which are lined by grooves called **pseudotracheae**. The grooves lead towards the **oral aperture**, known as the **prestomum**. When feeding, the labella are expanded by blood pressure and opened to expose their inner surface. They are then applied to the liquid film. Liquid flows into and along the grooves by capillary action and then is drawn up the food canal by muscular pumping action. At rest, the inner surfaces of the labella are in close contact and kept moist by secretions from the labial salivary glands.

The house fly proboscis is jointed and can be withdrawn into the head capsule when not in use by the retraction of the rostrum. There are a number of minute teeth surrounding the prestomum, which can be used directly to rasp at the food. These teeth may be well developed and important in the feeding of various species of Muscidae, for example *Hydrotaea irritans*. The ancestral Diptera probably had sponging mouthparts as described, without mandibles and maxillae. However, a number of species, such as stable flies and tsetse flies, have evolved a blood-sucking capability and show modifications of the basic house fly mouthparts that reflect this behaviour.

In blood-feeding Muscidae, the labella have been reduced in size and the pseudotracheae have been replaced by sharp teeth. The labium has been lengthened and surrounds the labrum and hypopharynx (Fig. 3.24). The rostrum is reduced and the rigid

Fig. 3.23 The head and mouthparts of an adult house fly in (a) anterior and (b) lateral views. The mandibles and maxillae have been lost, the labrum reduced, and the labial palps expanded to form two large fleshy labella. The labella are covered by a series of fine grooves, called pseudotracheae, along which liquid flows to the oral aperture by capillary action. The labium is flexible and the mouthparts can be retracted into the head. (Adapted from Snodgrass, 1935.)

Fig. 3.24 Mouthparts of a stable fly in lateral view (a) and cross-section (b). (c) Proboscis and palps of a tsetse fly. (From Newstead *et al.*, 1924.)

haustellum cannot be retracted. In feeding, the teeth of the labella cut into the skin. The entire labium and the labrum–hypopharynx, forming the food canal, are inserted into the wound. Saliva passes down a duct in the hypopharynx and blood is sucked up the food canal. Variations on this general pattern range from the robust mouthparts of stable flies to the delicate mouthparts of tsetse flies.

The larvae have a poorly defined head, and are mobile and worm-like, often being referred to as ‘maggots’ (Fig. 3.25). The mature larva moults to become a pupa on or in the ground, within a hard pupal case formed from the last larval integument, which is not shed and which is known as a puparium. The pupa is usually immobile.

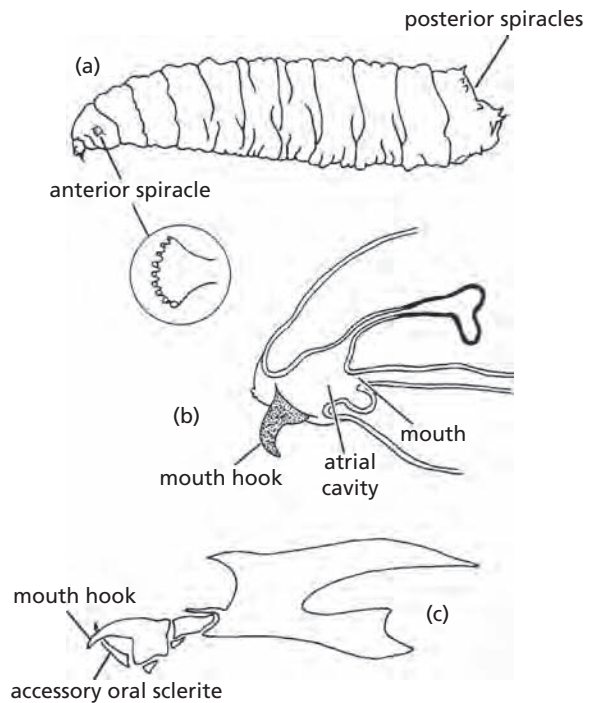

Fig. 3.25 Structure of a cyclorrhaphous fly larva. (a) Lateral view with detail of anterior spiracle (adapted from Hall and Smith, 1993). (b) Transverse section through the head and mouthparts. (c) Cephalopharyngeal skeleton.

Fig. 3.26 Antennae of (a) *Tabanus*, (b) *Haematopota* and (c) *Chrysops*. (d) Wing venation of Tabanidae. (From Smart, 1943.)

FAMILY TABANIDAE

Species of Tabanidae are often known as horse flies, deer flies or clegs. The pain caused by their bites leads to interrupted feeding and, as a consequence, flies may feed on a succession of hosts and are therefore important in the mechanical transmission of pathogens such as trypanosomes.

These are large flies with stout antennae often consisting of only three segments, the last segment frequently bearing annulations (see Fig. 3.14). The maxillary palps are usually held forwards and cross-veins are present on the wings. The females use their slashing-sponging mouthparts to pierce the skin of their host and then feed on the pool of blood created. The eggs are laid on vegetation overhanging mud or shallow water, and hatch into large carnivorous larvae with ill-defined but usually retractile heads. Like the Nematocera, both larvae and pupae are mobile and aquatic, and are usually found in mud.

Tabanus, *Chrysops* and *Haematopota*

Description, adult: These are medium to large biting flies, up to 25 mm in length, with wingspans of up to 65 mm. The head is large and the proboscis prominent. They are generally dark coloured, but may have various stripes or patches of colour on the abdomen or thorax and even the large eyes, which are dichoptic in the female and holoptic in the male, may be coloured. The coloration of the wings and the short, stout, three-segmented antennae, which have no arista, are useful in differentiating the three major genera of Tabanidae (Fig. 3.26).

The mouthparts, which are adapted for slashing/sponging, are short and strong and always point downwards (Fig. 3.27). Most

prominent is the stout labium, which is grooved dorsally to incorporate the other mouthparts, collectively termed the biting fascicle. The labium is also expanded terminally as paired large labella, which carry tubes called pseudotracheae, through which blood or fluid from wounds is aspirated. The biting fascicle, which creates the wound, consists of six elements: the upper sharp labrum, the hypopharynx with its salivary duct, paired rasp-like maxillae and paired broad-pointed mandibles. Male flies have no mandibles and therefore cannot feed on blood. They instead feed on honeydew and the juice of flowers.

Description, larvae: Larvae are spindle-shaped and off-white in colour and clearly segmented. The cuticle has distinct longitudinal striations. Mature larvae may be 15–30 mm in length. There

Fig. 3.27 Slashing and sponging mouthparts of a female tabanid fly.

is a distinct head capsule and strong biting mandibles. Abdominal segments have unsegmented leg-like structures (pseudopods) for locomotion (four pairs in *Tabanus* and three pairs in *Chrysops*). A distinct posterior respiratory siphon is usually present, which may be greatly elongated.

Life cycle: After a blood meal the female lays batches of 100–1000 creamy white or greyish cigar-shaped eggs, 1–2.5 mm long, on the underside of vegetation or on stones, generally in muddy or marshy areas. The eggs hatch in 1–2 weeks, using a special spine to exit the egg case, and the cylindrical, poorly differentiated larvae drop into the mud or water. The larvae are 1–60 mm in length, and have 11 segments. They are recognised as tabanids by their small black retractable heads and the prominent raised rings around the segments, most of which bear pseudopods. They also have a structure in the last segment, unique to tabanid larvae, known as Graber's organ, the function of which may be sensory. They are sluggish and feed either by scavenging on decaying organic matter or by predation on small arthropods including other tabanid larvae. Optimally, larval development takes 3 months but, if overwintering occurs, may extend for up to 3 years. The sub-cylindrical pupa is brown, the abdominal segments are movable and the anterior part of the appendages of the adult can be distinguished. Mature larvae pupate while partially buried in mud or soil and the adult fly emerges after 1–3 weeks. In most species, males complete their pupation before females. After emergence the male pursues the female and mating, initiated in the air, is completed on the ground. Adults are strong fliers and are usually diurnal. The whole life cycle takes a minimum of 4–5 months, or longer if larval development is prolonged.

Populations of adult flies show seasonal fluctuations in both temperate and tropical areas. In temperate climates adults die in the autumn and are replaced by new populations the following spring and summer, whereas in tropical areas their numbers are merely reduced during the dry season with an increase at the start of the rainy season.

Although the female flies feed mostly on blood from their hosts, if a suitable host is unavailable they will consume honeydew and plant sap (the major food source of males which lack mandibles). They typically bite a number of times in different places before they are replete and the wounds created continue to bleed and may attract other flies. Adults feed approximately every 3 hours during the day and between feeding rest on the underside of leaves or on stones or trees.

***Tabanus* (horse flies)**

Species of the genus *Tabanus* have transparent wings. Also useful in generic differentiation are the characteristics of the short, stout, three-segmented antennae, which have no arista. The first two antennal segments are small and the terminal segment has a tooth-like projection on its basal part and four annulations (Fig. 3.26a).

***Chrysops* (horse flies, deer flies)**

Chrysops have dark banded wings, which are divergent when at rest. The wing venation is characteristic, especially the branching of the fourth longitudinal vein (Fig. 3.26d).

***Haematopota* (horse flies, clegs)**

Haematopota have characteristically mottled wings that are held divergent when at rest. The first antennal segment is large and the second segment narrower, while the terminal segment has three annulations (Fig. 3.26b).

FAMILY MUSCIDAE

This family comprises many biting and non-biting genera, the latter commonly referred to as nuisance flies. As a group they may be responsible for 'fly-worry' in livestock and a number of species are vectors of important bacterial, helminth and protozoal diseases of animals. The major genera of veterinary importance include *Musca* (house flies and related flies), *Stomoxys* (stable fly), *Haematobia* (horn flies, buffalo flies) and *Hydrotaea* (sweat and head flies).

Musca

The genus *Musca* contains about 60 species, of which the house fly, *Musca domestica*, and the face fly, *Musca autumnalis*, are of particular importance. *Musca sorbens*, the bazaar fly, is widespread throughout Africa and Asia, and *Musca vetustissima*, the bush fly, is an important pest in Australia. Adults are non-metallic, dull black, grey or brown flies. The detailed wing venation is of taxonomic importance in the differentiation of *Musca* from similar flies belonging to other genera such as *Fannia*, *Morellia* and *Muscina* and in the identification of different *Musca* species. In flies of this genus, the wing vein M is deflected forward at a strong bend and ends at the wing edge near to the end of wing vein R₄₊₅, with the distance between the two ends not more than the length of cross-vein r-m (Fig. 3.28b).

***Musca domestica* (house fly)**

Description: Female adults of *Musca domestica* are 6–8 mm in length, male adults are 5–6 mm, and they vary in colour from light to dark grey. The thorax is usually grey with four dark longitudinal stripes, and there is a sharp upward bend in the fourth longitudinal wing vein (Fig. 3.28a). The abdomen has a yellow-brown background colour with a black median longitudinal stripe. The eyes are reddish and the space between them can be used to determine the sex of a specimen, since in females it is almost twice as broad as in males. The arista are bilaterally plumose at the tip.

Life cycle: Female flies lay batches of up to 150 creamy white, approximately 1 mm long, banana-shaped eggs in wet faeces or rotting organic material. The dorsal surface of the eggs has two curved, rib-like thickenings. Batches of eggs are laid at 3–4 day intervals throughout life. The eggs hatch (under optimal temperatures) in 12–24 hours to produce whitish coloured, segmented, cylindrical larvae with a pair of small anterior mouth hooks. High manure moisture favours their survival. At the posterior end of the larvae there are paired respiratory spiracles, the shape and structure of which allow generic and specific differentiation (Fig. 3.28c). The three larval stages feed on decomposing organic material and mature to 10–15 mm in length in 3–7 days under suitable conditions. Optimal temperatures for larval development are 30–37°C,

Fig. 3.28 (a) Female house fly, *Musca domestica*. (b) Wing venation typical of species of *Musca*, showing the strongly bent vein M ending close to R_{4+5} . (c) Posterior spiracles of a third-stage larva. (Adapted from Smart, 1943.)

although as the larvae mature their temperature tolerance increases. Mature larvae then move to drier areas around the larval habitat and pupate, forming a rigid and dark-brown barrel-shaped puparium or 'pupal case'. The adult fly emerges after 3–26 days, depending on temperature. Mating and oviposition take place a few days after emergence. Total development time from egg to adult fly may be as little as 8 days at 35°C, but is extended at lower temperatures. In temperate areas, a small proportion of pupae or larvae may survive the winter, but more frequently the flies overwinter as hibernating adults.

***Musca autumnalis* (face fly)**

Description: *Musca autumnalis* is very similar to *M. domestica* in size and appearance, although the abdomen of the female is darker, while in the male tergite 2 and 3 are typically yellowish-orange along the sides. Female adults of *Musca autumnalis* are 6–8 mm in length, male adults 5–6 mm, and they vary in colour from light to dark grey. The thorax is usually grey with four dark longitudinal stripes, and there is a sharp upward bend in the fourth longitudinal wing vein. The abdomen is a yellowish-brown background colour with a black median longitudinal stripe. The eyes are reddish and the space between them can be used to determine the sex of a specimen, since in females it is almost twice as broad as in males. The arista are bilaterally plumose at the tip. The eggs of *M. autumnalis* bear a terminal respiratory horn.

Life cycle: The face fly, *Musca autumnalis*, congregates in large numbers around the faces of cattle. It feeds on secretions from the eyes, nose and mouth as well as from blood in wounds left by other flies, such as tabanids. It lays its eggs just beneath the surface of fresh cattle manure within about 15 minutes of the dung pats being deposited. The eggs of *M. autumnalis* are about 3 mm in length and possess a short respiratory stalk. They are arranged so that the respiratory stalk of each egg projects above the surface of the pat. Like *M. domestica*, the larvae pass throughout three stages within approximately 1 week, before entering the surrounding soil and pupariating to form a whitish-coloured puparium. Summer generations require about 2 weeks to complete a life cycle. This allows several generations in any one season. Face flies prefer bright sunshine and usually do not follow cattle into barns or heavy shade. Adults are strong fliers and can move between widely separated herds. Face flies overwinter as adults, in response to short photoperiods, aggregating in overwintering sites such as farm buildings.

Musca sorbens* and *Musca vetustissima

Description: Adult flies have two broad longitudinal stripes on the thorax and the first abdominal segment is black.

Musca crassirostris

Description: Adult flies are about 5.5–7.5 mm in length and vary in colour from light to dark grey. There are four distinct dark longitudinal stripes on the thorax and the greyish abdomen has various light and dark markings.

Life cycle: *Musca crassirostris* is not an obligatory parasite, but can feed on a wide variety of animal secretions and is especially attracted to wounds. Female flies lay batches of up to 100 eggs in faeces or rotting organic material. Eggs hatch to produce whitish, segmented, cylindrical larvae (maggots). The three larval stages feed on decomposing organic material and mature within 3–7 days under suitable conditions. These then move to drier areas around the larval habitat and pupate. The adult fly emerges after 3–26 days, depending on temperature.

Stomoxys

This genus contains about 18 species, of which the most common is *Stomoxys calcitrans*. *Stomoxys niger* and *Stomoxys sitchensis* may replace *S. calcitrans* as important pests in Afro-tropical regions and parts of Asia. Although they can be localised pests, they are not of great significance as vectors of disease. Nonetheless, their bites are painful and they pester dogs and can have a huge economic impact on the health and productivity of cattle, being one of the most widespread and economically important pests to attack cattle.

Life cycle: Both male and female flies feed on blood. The female lays batches of 25–50 eggs, resembling those of house flies, in manure and moist decaying vegetable matter, such as hay and straw contaminated with urine. The eggs are yellowish-white with a longitudinal groove on one side, and measure approximately 1 mm in length. Eggs hatch in 1–4 days, or longer in cold weather, and the larvae develop in 6–30 days. Pupation occurs in the drier parts of the breeding material and takes 6–9 days or longer in cold weather.

Optimal conditions for pupariation involve complete darkness and a temperature of about 27°C. The puparia are brown and about 6 mm in length. The complete life cycle from egg to adult fly may take 12–60 days depending mainly on temperature.

After emergence the adult females require several blood meals before the ovaries mature and egg-laying can start (usually after about 9 days). If deprived of a blood meal in the first few days after emergence, ovarian development is delayed and females produce fewer, smaller eggs. In temperate areas flies may overwinter as larvae or pupae, whereas in tropical climates breeding is continuous throughout the year.

Stable flies may double their body weight during feeding. After a blood meal, flies move to a resting site on structures such as barn walls, fences or trees.

Stomoxys calcitrans (stable fly)

Description, adult: Superficially, *Stomoxys calcitrans* resembles the house fly *M. domestica*, being similar in size (about 7–8 mm in length) and grey with four longitudinal dark stripes on the thorax. Its abdomen, however, is shorter and broader than that of *M. domestica*, with three dark spots on the second and third abdominal segments. The wing vein M_{1+2} curves gently forwards and the R-cell is open, ending at or behind the apex of the wing. Probably the simplest method of distinguishing stable flies from *M. domestica* and other genera of non-biting muscid flies is by examination of the proboscis, which in *Stomoxys* is conspicuous and forward projecting (Fig. 3.29a). Stable flies can be distinguished from biting muscid flies of the genus *Haematobia* by the larger size and the much shorter palps of the former.

Description, larvae: Larvae of *Stomoxys* can be identified by examination of the posterior spiracles, which are relatively well separated; each has three S-shaped slits.

Haematobia

Grey-black blood-sucking flies which resemble the stable fly in appearance. There are two common species in temperate areas, the horn fly, *Haematobia irritans* (syn. *Lyperosia irritans*), found in

Europe and the USA, and *Haematobia stimulans* in Europe only. *Haematobia irritans exigua* (the buffalo fly) occurs in Asia, China and Australia, and *Haematobia minuta* in Africa. The genus *Lyperosia* is synonymous. They can have a huge economic impact on the health and productivity of cattle, and are one of the most widespread and economically important pests of cattle.

Life cycle: In contrast to other muscids these flies generally remain on their hosts, leaving only to fly to another host or, in the case of females, to lay eggs in freshly passed faeces. Eggs are laid in groups of four to six, usually in the fresh faeces or in the soil immediately beneath it. These hatch quickly if the humidity is sufficiently high; larvae may mature in as little as 4 days given adequate moisture and temperatures of around 27°C. Low temperatures and dry conditions delay larval development and kill the eggs. The pupal period is around 6–8 days and on emergence the adult flies seek and remain on their cattle hosts. Horn flies overwinter as pupae in the soil below cowpats, emerging as adults the following spring.

Haematobia irritans

Subspecies: *Haematobia irritans irritans*, *Haematobia irritans exigua*

Synonym: *Lyperosia irritans*

Description, adult: The adults are 3–4 mm in length and are usually grey, often with several dark stripes on the thorax. Unlike *Musca* the proboscis is held forwards and unlike *Stomoxys* the palps are stout and as long as the proboscis (Fig. 3.29c). In *Haematobia irritans* the palps are dark greyish. Eggs are 1–1.5 mm long and are laid in fresh faeces.

Description, larvae: The cylindrical larvae are yellow-white and generally about 7 mm long with two D-shaped posterior spiracles. Puparia are dull reddish-brown and 3–4 mm long.

Haematobia minuta

Synonym: *Lyperosia minuta*

Description: The adults are up to 4 mm in length. They are usually grey, often with several dark stripes on the thorax.

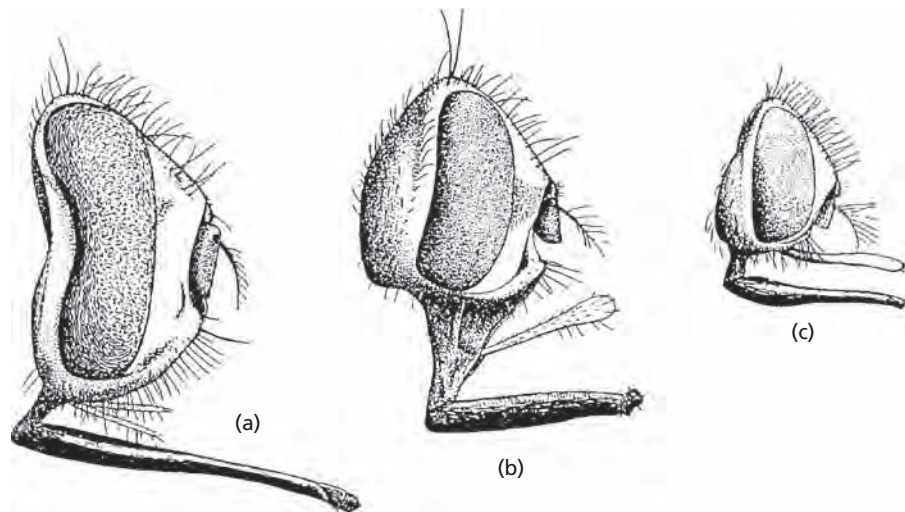

Fig. 3.29 Lateral views of the heads of blood-sucking Muscidae: (a) *Stomoxys calcitrans*; (b) *Haematobia stimulans*; (c) *Haematobia irritans*. (From Edwards et al., 1939.)

Haematobia stimulans

Synonym: *Haematobosca irritans*

Description: As for *Haematobia irritans* except the palps are yellow (Fig. 3.29b).

Hydrotaea

The sweat or head flies closely resemble *Musca*. The genus contains one important species, *Hydrotaea irritans*, the sheep head fly.

Life cycle: Adult flies prefer still conditions and are found near woodlands and plantations, with peak numbers occurring in midsummer. Eggs are laid in decaying vegetation or faeces; they hatch and develop into mature larvae by the autumn. Each female produces one or two batches of about 30 eggs in its lifetime. Third-stage larvae may be predatory on other larvae. These larvae then go into diapause (a temporary cessation of development) until the following spring when pupation and development is completed, with emergence of a new generation of adults in early summer. Thus there is only one generation of head flies each year, with peak numbers occurring in midsummer.

***Hydrotaea irritans* (head fly)**

Description: *Hydrotaea irritans* is generally similar in size and appearance to the various species of *Musca*, with adults measuring 4–7 mm in length. It is characterised by an olive-green abdomen and an orange–yellow coloration at the base of the wings. The thorax is black with grey patches.

FAMILY FANNIIDAE

The family contains about 250 species, of which species of the genus *Fannia* are of importance as nuisance pests of livestock.

Fannia

Species of *Fannia* generally resemble house flies in appearance but are more slender and smaller at about 4–6 mm in length. The fourth longitudinal vein is straight (not bent as in the house fly) (Fig. 3.30a).

Life cycle: *Fannia* breed in a wide range of decomposing organic material, particularly the excrement of chickens, humans, horses and cows. The life cycle is typical, with three larval stages, followed by the pupa and adult. The complete life cycle requires 15–30 days.

Fannia canicularis

Description: *Fannia canicularis* is greyish to almost black in colour, possessing three dark longitudinal stripes on the dorsal thorax. The palps are black. The arista are bare.

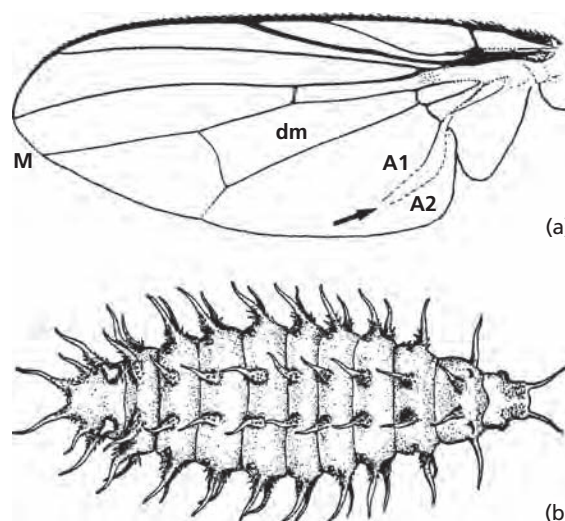

Fig. 3.30 (a) Wing venation typical of species of *Fannia* showing the characteristic convergence of the anal veins. (b) Third-stage larva of the lesser house fly *Fannia canicularis*. (From Zumpt, 1965.)

Fannia scalaris

Description: As for *F. canicularis* except the halteres are yellow.

Fannia benjamini

Description: As for *F. canicularis* except the palps are yellow.

FAMILY HIPPOBOSCIDAE

The Hippoboscidae (keds and forest flies) are unusual in being flattened dorsoventrally and having an indistinctly segmented abdomen, which is generally soft and leathery. They have piercing blood-sucking mouthparts, are parasitic on mammals and birds and have strong claws on the feet, which allow them to cling to hair or feathers. There are about 200 species in the family and they tend to be either permanent ectoparasites or remain on their hosts for long periods. The four major genera of veterinary importance are *Hippobosca*, *Melophagus*, *Lipoptena* and *Pseudolynchia*. The hippoboscids have relatively robust legs, consisting of an enlarged femur, a flattened tibia and short compact tarsi with one or more basal teeth. Species that parasitise mammals can be distinguished from those that parasitise birds by their shorter and stouter legs and heavier tarsal claws.

Hippobosca

Several species of this genus are common parasites of cattle and horses in many parts of the world, where their biting and blood-feeding may be extremely damaging. The flies are about 1 cm long and have a reddish-brown colour. There are two wings, the veins of which are crowded together towards the anterior border.

Hippobosca species of veterinary importance

| Species | Common name | Hosts |
|-------------------------------|-----------------------------|--|
| <i>Hippobosca equina</i> | Forest fly, horse louse fly | Mainly horses and cattle, but other domestic animals and birds may be attacked |
| <i>Hippobosca camelina</i> | Camel fly | Camels |
| <i>Hippobosca maculata</i> | Horse and cattle louse fly | Mainly horses and cattle |
| <i>Hippobosca variegata</i> | Horse louse fly | Horses and cattle |
| <i>Hippobosca rufipes</i> | Cattle louse fly | Cattle |
| <i>Hippobosca longipennis</i> | Dog fly | Dogs and wild carnivores |

***Hippobosca equina* (forest fly, louse fly)**

Description: Adult flies are approximately 10 mm in length and are generally pale reddish-brown with yellow spots on the indistinctly segmented abdomen. They have one pair of wings, the veins of which are crowded together towards the anterior margin (Fig. 3.31). The major part of the piercing proboscis is usually retracted under the head, except during feeding. Forest flies remain on their hosts for long periods and their preferred feeding sites are the perineum and between the hindlegs. Both sexes of adult are blood feeders. The larvae are rarely seen and measure about 5 mm in length.

Life cycle: Gravid female flies leave their hosts and deposit mature larvae singly in dry soil or humus. Each female can produce only five or six larvae in its lifetime. These larvae pupate almost immediately. When pupation is completed, the newly emerged winged adults locate a suitable host animal on which they blood-feed, remaining on the host for long periods. In temperate areas, flies are most abundant in the summer months.

Hippobosca camelina

Description: Adult flies are approximately 10 mm in length and are generally pale reddish-brown with yellow spots on the indistinctly segmented abdomen. They have one pair of wings, the veins of which are crowded together towards the anterior margin. Both sexes of adult are blood feeders.

Life cycle: Gravid female flies mature a single larva within the oviduct. When fully developed the mature third-stage larva is larviposited on the host. These larvae drop to the ground and pupate almost immediately. When pupation is completed, the newly emerged winged adults locate a suitable host animal on which they

Fig. 3.31 Wing venation typical of species of *Hippobosca* showing the characteristic crowding of the veins into the leading half of the wings. (From Smart, 1943.)

blood-feed, remaining on the host for long periods. Each female can produce only five or six larvae in its lifetime.

Melophagus

Members of the genus *Melophagus* are wingless biting flies, of which *Melophagus ovinus* (the sheep ked) is the most important species.

Life cycle: Keds are permanent ectoparasites and live for several months feeding on the blood of sheep and sometimes goats. A single egg is ovulated at a time. The egg hatches inside the body of the female and the larva is retained and nourished within the female during its three larval stages, until it is fully developed. The mature larvae produced by the females adhere to the wool. These are immobile and pupate immediately, the 3–4 mm long, brown pupae easily visible on the fleece. The pupae are fully formed within 12 hours of larviposition and are resistant to treatment. Adult keds emerge in approximately 3 weeks in summer, but this period may be extended considerably during winter. Copulation occurs 3–4 days after emergence from the pupa, and females are able to produce offspring 14 days after emergence. Although one mating provides sufficient sperm for a lifetime, repeated matings usually occur when multiple males are present. A female produces between 10 and 20 larvae in its lifetime. Ked populations build up slowly since each female produces only one larva every 10–12 days, up to a total of 15. Adults can only live for short periods off their hosts.

***Melophagus* species of veterinary importance**

| Species | Common name | Hosts |
|--------------------------|-------------|-------|
| <i>Melophagus ovinus</i> | Sheep ked | Sheep |

***Melophagus ovinus* (sheep ked)**

Description: Hairy, brown, wingless 'degenerate' fly, approximately 5–8 mm long with a short head and broad, dorsoventrally flattened, brownish thorax and abdomen (Fig. 3.32; see also Fig. 9.68). The

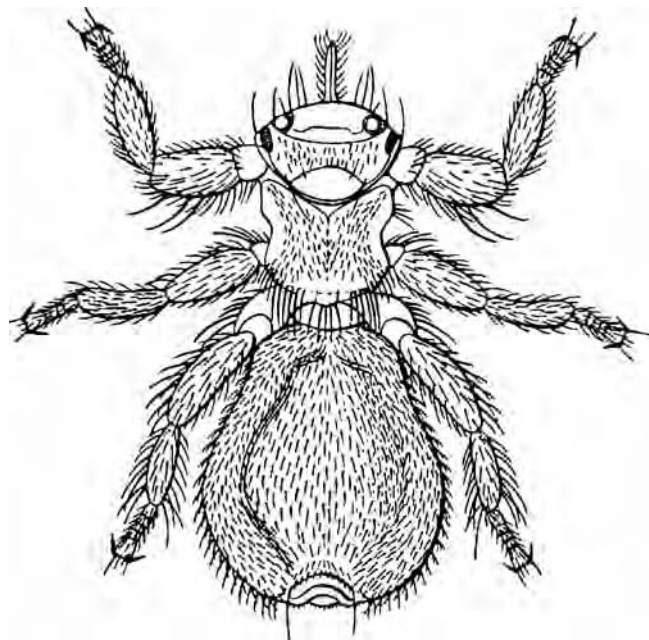

Fig. 3.32 The sheep ked, *Melophagus ovinus*.

abdomen is indistinctly segmented and is generally soft and leathery. Both sexes are completely wingless and even the halteres are absent. They have piercing blood-sucking mouthparts and strong legs provided with claws that enable them to cling on to wool and hair.

Lipoptena

The deer keds, *Lipoptena cervi* in Europe and *Lipoptena depressa* in North America, are common parasites of deer. Adults are winged on emergence but shed their wings on finding a suitable host (see Fig. 17.4). The wingless adults can be differentiated from *Melophagus* by the presence of halteres.

Life cycle: Like all hippoboscids, adult female flies larviposit single, fully developed third-stage larvae while on the host. Pupae fall to the ground. Following pupation the newly emerged adult must find a suitable host, feed and mate. Both sexes are blood feeders.

Pseudolynchia

A genus of louse flies, which are parasites of birds.

Life cycle: Gravid female flies mature larvae singly. Each female can produce only five or six larvae in its lifetime. These larvae pupate almost immediately after larviposition. When pupation is completed, the newly emerged winged adults locate a suitable host animal on which they blood-feed, remaining on the host for long periods. In temperate areas, flies are most abundant in the summer months.

Pseudolynchia species of veterinary importance

| Species | Common name | Hosts |
|----------------------------------|------------------|-----------------------------|
| <i>Pseudolynchia canariensis</i> | Pigeon louse fly | Pigeons, doves, other birds |

Pseudolynchia canariensis

Description: Adult flies are approximately 10 mm in length and are generally pale reddish-brown with yellow spots on the indistinctly segmented abdomen. They have one pair of wings, the veins of which are crowded together towards the anterior margin. Both sexes of adult are blood feeders.

FAMILY GLOSSINIDAE

The sole genus in the family Glossinidae is *Glossina*, species of which are known as tsetse flies. Tsetse flies are entirely restricted to sub-Saharan Africa, and both sexes feed exclusively on the blood of vertebrates and are of importance as vectors of trypanosomiasis in animals and humans.

The 23 known species and eight subspecies of tsetse can be divided into three groups, each with different habits and requirements. The *Glossina palpalis* group are riverine species that feed primarily on reptiles and ungulates. Flies of the *G. morsitans* group are savannah and dry thorn-bush species and feed mainly on large animals. Members of the *G. fusca* group occur in the rainforest, preferring dense shade and riverine thickets. Key species in the *fusca* and *palpalis* groups include *G. palpalis*, *G. austeni*, *G. fuscipes* and *G. tachinoides*, while key species in the *morsitans* group include *G. morsitans* and *G. palidipes*.

Glossina spp. (tsetse flies)

Description: In general, adult tsetse are narrow-bodied, yellow to dark-brown flies, 6–15 mm in length, and have a long, rigid, forward-projecting proboscis (Fig. 3.33; see also Fig. 17.5). When at rest, the wings are held over the abdomen like a closed pair of scissors. The thorax is a dull greenish-brown colour and is marked with inconspicuous stripes and spots. The abdomen is brown, with six segments that are visible from the dorsal aspect (see Fig. 17.5). Tsetse flies are easily distinguished from all other flies by the characteristic hatchet-shaped medial cell in the wings (Fig. 3.33b). The antenna has a large third segment, with an arista that bears 17–29 dorsal branching hairs.

There are no maxillae or mandibles in the mouthparts of tsetse flies and the long proboscis is adapted for piercing and sucking. The proboscis is composed of a lower U-shaped labium with rasp-like labella terminally and an upper, narrower labrum, which together creates a food channel. Within this food channel sits the slender hypopharynx that carries saliva and anticoagulant down into the wound formed during feeding. The proboscis is held horizontally between long palps, which are of an even thickness throughout.

Fig. 3.33 (a) Male tsetse fly, *Glossina longipennis*. (b) Wing venation typical of species of *Glossina* showing the characteristic hatchet shape of the cell dm. (From Smart, 1943.)

Life cycle: Both male and female flies suck blood and although the various species of tsetse may have some host preferences, generally they will feed on a wide variety of animals.

The females, in contrast to other muscids, are viviparous. They ovulate a single egg at a time. The fertilised egg is retained in the oviduct, where it hatches after about 4 days at 25°C. The larva is retained in the common oviduct (uterus) where it is nourished with secretions from the highly specialised accessory glands. Maturation in the uterus from fertilised egg to the mobile, 8–10 mm long, third-stage larva takes approximately 10 days. At this stage the larva is creamy white, segmented and posteriorly has a pair of prominent dark ear-shaped protruberances known as polypneustic lobes. During the development of the third-stage larva these lobes protrude from the posterior abdomen of the adult female and have a respiratory function similar to the posterior spiracles of other muscid larvae.

When mature, the larva is deposited on the ground by the adult female, usually into characteristic areas of bare sandy soil under shade. After deposition the larva wriggles into loose soil to a depth of a few centimetres and forms a rigid, dark-brown, barrel-shaped puparium within 1–2 hours. The pupal period is relatively long, taking 4–5 weeks, or even more in cool weather. On emergence the adult is unable to fly until its wings have expanded. It takes at least a week for the complete endocuticle to be secreted and for the exocuticle to harden fully. The female fly may require several blood meals over a period of 16–20 days before producing her first larva. Once fully active the adult flies feed every 2–3 days and the first larviposition occurs 9–12 days after emergence.

Breeding generally continues throughout the year, with peak fly numbers occurring at the end of the rainy season. The longevity of adult flies in nature is variable, ranging from a few days to several months.

***Glossina fusca* group**

Description: Males are characterised by free superior claspers, without a membrane between them. Females have five genital plates, one dorsal pair, one anal pair and a single median sternal plate.

***Glossina palpalis* group**

Description: The superior claspers in the males are connected by a thin membrane deeply divided medially. Females have six genital plates, one dorsal pair, one anal pair, one single median sternal plate and a small mediodorsal plate.

***Glossina morsitans* group**

Description: The superior claspers in the male are completely joined by a membrane and are fused distally. In the female, there is a pair of fused anal plates and a median sternal plate, but the dorsal plates are usually absent.

FAMILY CALLIPHORIDAE

The Calliphoridae, known as blowflies, are a large family, composed of over 1000 species divided between 150 genera. At least 80 species have been recorded as causing traumatic myiasis (the infestation

of the tissues of a living vertebrate host). These species are found largely in five important genera: *Cochliomyia*, *Chrysomya*, *Cordylobia*, *Lucilia* and *Calliphora*. The genera *Protophormia* and *Phormia* also each contain a single species of importance. Most of these species are either primary or secondary facultative invaders. The screwworms, *Chrysomya bezziana* and *Cochliomyia hominivorax*, and the flies of the genus *Cordylobia* (*Cordylobia anthropophaga* and *Cordylobia rodhaini*) are the only species that are obligate agents of myiasis.

Members of this family are medium to large flies, almost all of which have a metallic blue or green sheen. The larvae are usually clearly segmented, pointed anteriorly and truncated posteriorly. However, this shape may be modified, with the larvae of some species being barrel-like or, occasionally, flattened. The cuticle is typically pale and soft, but is often covered by spines or scales arranged in circular bands. Although legless, in some species the body may have a number of fleshy protruberances, which aid in locomotion. The true head is completely invaginated into the thorax. The functional mouth is at the inner end of the pre-oral cavity, from which a pair of darkened mouth hooks protrudes. The mouth hooks are part of a complex structure known as the cephalopharyngeal skeleton, to which muscles are attached. There is a pair of anterior spiracles on the prothoracic segment, immediately behind the head, and a pair of posterior spiracles on the 12th segment. The structure of the posterior spiracles is of great taxonomic importance. They usually consist of a pair of sclerotised spiracular plates with slits or pores in the surface for gaseous exchange.

Life cycle: A small number of species are obligate agents of myiasis, i.e. they require a living host for larval development. Adult females deposit approximately 200 eggs at a time on the host and the larvae hatch after 12–24 hours, moult once after 12–18 hours and a second time about 30 hours later. They feed for 3–4 days and then move to the soil to pupate for 7 days to several weeks depending on temperature. However, the vast majority of species are facultative agents of myiasis. In the latter case adult flies oviposit primarily in carrion, but may also act as secondary invaders of myiasis on live mammals. The life cycle is identical to the obligate species, with three larval stages and the final larval stage migrating from the feeding site prior to pupation.

Cochliomyia hominivorax

Synonym: *Callitroga hominivorax*

Description, adult: The adult fly has a deep greenish-blue metallic colour with a yellow, orange or reddish face and three dark stripes on the dorsal surface of its thorax (see Fig. 17.10).

Description, larvae: The mature larvae measure 15 mm in length and have bands of spines around the body segments. The tracheal trunks leading from the posterior spiracles have a dark pigmentation extending forwards as far as the ninth or tenth segment (Fig. 3.34). This pigmentation is most conspicuous in fresh specimens.

Life cycle: *Cochliomyia hominivorax* is an obligate parasite and cannot complete its life cycle on carrion. Female flies oviposit at the edge of wounds or in body orifices, in clusters of 150–300 eggs. Shearing, castration or dehorning wounds are common oviposition sites, as are the navels of newly born calves. Even wounds the

Fig. 3.34 (a) Pigmented dorsal tracheal trunks of larvae of *Cochliomyia hominivorax*. (b) Unpigmented dorsal tracheal trunks and (c) Posterior spiracles of *Cochliomyia macellaria*. (From Zumpt, 1965.)

size of a tick bite are reported to be sufficient to attract oviposition. The flies lay batches of this size every 2–3 days during adult life, which is on average 7–10 days in length. The larvae hatch in 10–12 hours and penetrate into the tissues, which they liquefy, and extend the lesion considerably. The wound may begin to emit a foul-smelling liquid attracting other female *C. hominivorax* and secondary agents of myiasis. The larvae become mature in 5–7 days, after which they leave the host to pupate in the ground. The pupal period lasts for between 3 days and several weeks, depending on temperature. There is no true diapause stage and *C. hominivorax* cannot survive over winter in cool temperate habitats. The entire life cycle may be completed in 24 days in optimum conditions.

Cochliomyia macellaria

Synonym: *Callitroga macellaria*

Description, adult: These blue–green flies have longitudinal stripes on the thorax and orange–brown eyes. Adults are extremely similar in appearance to *C. hominivorax*, but possess a number of white spots on the last segment of the abdomen.

Description, larvae: The larvae may be distinguished from those of *C. hominivorax* by the absence of pigmented tracheal trunks leading from small posterior spiracles (Fig. 3.34).

Life cycle: *Cochliomyia macellaria* is a ubiquitous carrion breeder. However, it can act as a secondary invader of myiasis, and is known as the secondary screwworm fly.

Chrysomya bezziana

Description, adult: These stout blue–green flies have four longitudinal black stripes on the prescutum, orange–brown eyes and a pale coloured face (see Fig. 17.11). The flies have dark legs and white thoracic squamae. The anterior spiracle is dark orange or black–brown. The adult flies measure 8–10 mm in length.

Description, larvae: The first-stage larvae are creamy white and measure about 1.5 mm in length. The second- and third-stage larvae are 4–9 mm and 18 mm in length, respectively, and are similar in appearance, each segment carrying a broad encircling belt of strongly developed spines (Fig. 3.35).

Life cycle: *Chrysomya bezziana* is an obligate agent of myiasis. Gravid females are attracted to fresh open wounds and body orifices on any warm-blooded animal. Even small wounds resulting from thorn scratches and tick bites may be sufficient to attract oviposition. *Chrysomya bezziana* commonly infest the umbilicus of newborn calves. The female lays batches of 100–300 eggs on the dry perimeter around the wound. Each female produces several batches of eggs in her lifetime of about 9 days. The eggs hatch within 10–20 hours at 37°C and first-stage larvae begin to feed in the open wound or moist tissue, often penetrating deep into the host tissue.

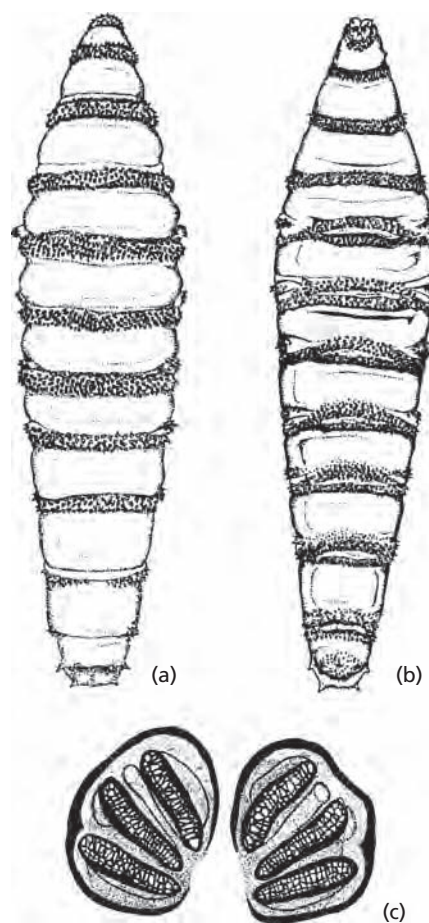

Fig. 3.35 Third-stage larva of *Chrysomya bezziana*: (a) dorsal view; (b) ventral view; (c) posterior peritremes. (From Zumpt, 1965.)

Fig. 3.36 Adult male of *Chrysomya megacephala*. (From Shtakelbergh, 1956.)

Chrysomya megacephala

Description, adult: Adults are medium-sized, stout, blue-green flies with longitudinal stripes on the thorax and orange-brown eyes. *Chrysomya megacephala* can be distinguished from *Lucilia* by the broad bands on its rounder abdomen and by its black forelegs (Fig. 3.36). The face is pale-coloured. The anterior spiracle of the thorax of adults is dark-coloured.

Description, larvae: The larvae are about 18 mm in length. They have hooked mouthparts and bands of small spines on each segment. There are four to six projections on the anterior spiracle with fleshy projections on the last segment only.

Life cycle: Flies oviposit primarily in carrion but may also act as secondary invaders of myiases on live mammals. Females lay batches of up to 250–300 eggs on carcasses, faeces and other decomposing matter. The entire egg-to-adult life cycle takes about 8 days at 30°C. *Chrysomya megacephala* is commonly called the Oriental latrine fly because of its habit of breeding in faeces as well as on carrion and other decomposing organic matter. It may occur in large numbers around latrines and may also become a nuisance in slaughterhouses, confined animal facilities and open-air meat and fish markets.

Chrysomya rufifacies

Description, adult: These bluish-green flies have longitudinal stripes on the thorax and orange-brown eyes. The hind margins of the abdominal segments have blackish bands and the anterior spiracle is white or pale yellow.

Description, larvae: The larvae bear a number of thorn-like fleshy projections on most of the body segments, which give these species their common name of 'hairy maggot blowflies'. These projections become longer on the dorsal and lateral parts of the body. The larvae of *Chrysomya rufifacies* may be distinguished from those of *C. albiceps* by the presence of small spines on the stalks of the projections (Fig. 3.37).

Life cycle: Flies oviposit primarily in carrion, but may also act as secondary invaders of myiases on live mammals. The larvae of this species will actively feed on other larvae in carcasses.

Fig. 3.37 Third-stage larva of *Chrysomya rufifacies*. Inset shows presence of small spines on the stalks of the projections. (From Zumpt, 1965.)

Chrysomya albiceps

Description, adult: These bluish-green flies have longitudinal stripes on the thorax and orange-brown eyes. The hind margins of the abdominal segments have blackish bands and the anterior spiracle is white or pale yellow.

Description, larvae: The larvae are similar to those of *C. rufifacies* but can be distinguished by the absence of small spines on the stalks of the projections.

Life cycle: Flies oviposit primarily in carrion, but may also act as secondary invaders of myiases on live mammals. This species thrives in warm humid conditions, at temperatures above 17°C but below 38°C.

Cordylobia anthropophaga

Description, adult: The adult fly (known as the tumbu, mango or putzi fly) is stout, yellow-brown and 8–12 mm in length. It has a yellow face and legs and two black marks on the thorax. Adult flies feed on decaying fruits, carrion and faeces and have large, fully developed mouthparts. The arista of the antenna has setae on both sides. The thoracic squamae are without setae and the stem vein of the wing is without bristles.

Description, larvae: Third-stage larvae are 12–28 mm in length and are densely, but incompletely, covered with small, backwardly directed, single-toothed spines. The posterior spiracles have three slightly sinuous slits and a weakly sclerotised peritreme (Fig. 3.38).

Fig. 3.38 Third-stage larva of *Cordylobia anthropophaga*. (From Zumpt, 1965.)

Life cycle: The eggs are deposited singly in dry, sandy, shaded areas where animals lie, particularly areas contaminated with host urine or faeces. Females may also be attracted to dry, urine-soiled clothing. Eggs are laid in early morning or late evening. Up to 500 eggs are laid per female over their lifespan of 2–3 weeks. The eggs hatch after 2–4 days and the first-stage larvae wait in the dry substrate for a host. The larvae can remain alive, without feeding, for 9–15 days, hidden just beneath the soil surface. A sudden rise in temperature, vibration or carbon dioxide, which might signify the presence of a host, activates the larvae. They attach to the host and immediately burrow into the skin. Larvae develop beneath the skin and produce a swelling approximately 10 mm in diameter at the point of entry. The swelling has a hole in the centre through which the larva breathes. The swellings may be found anywhere on the host animal's body but are most commonly found on ventral parts. The three larval stages are completed in the host and, when mature (7–15 days after infection), the larvae emerge out of this hole and pupate on the ground in surface debris. Adult flies emerge from the pupae after 3–4 weeks.

Cordylobia rodhaini

Description, adult: The Lund fly closely resembles *C. anthropophaga* but is larger, measuring 12.5 mm in length. The adult is a stout yellow-brown fly with a yellow face and legs and two black marks on the thorax. Adult flies feed on decaying fruits, carrion and faeces and have large, fully developed mouthparts. The arista of the antenna has setae on both sides. The thoracic squamae are without setae and the stem vein of the wing is without bristles.

Description, larvae: Third-stage larvae are 12–28 mm in length and are densely, but incompletely, covered with small, backwardly directed, single-toothed spines. The posterior spiracles are markedly tortuous.

Lucilia

There are at least 27 species of *Lucilia*, known colloquially as 'green-bottles'; however, only two species are of major clinical significance as primary agents of cutaneous myiasis, particularly in sheep.

Lucilia sericata and *Lucilia cuprina*

Description, adult: Adult *Lucilia* blowflies measure up to 10 mm in length and are characterised by a metallic greenish to bronze sheen (Fig. 3.39; see also Fig. 17.6b). The adults are characterised by the presence of a bare stem vein, bare squamae and the presence of three pairs of post-sutural, dorso-central bristles on the thorax. The sexes are very similar in appearance, but may be distinguished by the distance between the eyes, which are almost touching anteriorly in males and separated in females.

Adult *Lucilia sericata* and *L. cuprina* may be distinguished from most other species of *Lucilia* by the presence of a pale creamy-white basicostal scale at the base of the wing, three post-sutural acrostichal bristles on the thorax and one anterodorsal bristle on the tibia of the middle leg. However, definitive identification to species can only be confirmed using a small number of subtle morphological

Fig. 3.39 (a) Adult *Lucilia sericata* (from Shtakelbergh, 1956). (b, c) Male genitalia (aedeagus in lateral view and forceps in dorsal view) of (b) *Lucilia sericata* and (c) *Lucilia cuprina* (from Aubertin, 1933. Reproduced with permission from John Wiley & Sons.)

Fig. 3.40 *Lucilia sericata*: (a) posterior peritremes; (b) cephalopharyngeal skeleton. (From Zumpt, 1965.)

features, such as the colour of the fore femur, the number of paravertical setae present on the back of the head and, most reliably, the shape of the male genitalia (Fig. 3.39).

Description, larvae: Larvae are smooth, segmented and measure 10–14 mm in length (see Fig. 17.7). They possess a pair of oral hooks at the anterior extremity, and at the posterior peritremes bearing spiracles (Fig. 3.40).

Life cycle: *Lucilia* are anautogenous and females must obtain a protein meal before maturing their eggs. When protein is freely available the gravid female blowfly lays clusters of 225–250 yellowish-cream eggs on wounds, soiled fleece or dead animals, attracted by the odour of the decomposing matter. The eggs hatch into larvae in about 12 hours. The larvae then feed, grow rapidly and moult twice to become fully mature maggots in 3 days. The larvae usually feed superficially on the epidermis and lymphatic exudates, or on necrotic tissue. They will only begin to feed on healthy tissue in crowded conditions. The mouth hooks are used to macerate the tissues, and digestion occurs extra-orally by means of amylase in the saliva and proteolytic enzymes in the larval excreta. Mature larvae drop to the ground and pupate. The pupal stage is completed in 3–7 days in summer. Adult flies can live for about 7 days. The time required to complete the life cycle from egg to adult is highly dependent on the ambient temperature but is usually between 4 and 6 weeks.

Calliphora

There are numerous species in this genus, known colloquially as 'bluebottles'. The two most important species are *Calliphora vicina* and *Calliphora vomitoria*.

Life cycle: Flies oviposit primarily in carrion, but may also act as secondary invaders of myiasis on live mammals. The gravid female lays clusters of 100–200 yellowish-cream eggs. The eggs hatch into larvae and the larvae then feed, grow rapidly and moult twice to become fully mature maggots. When they have completed feeding, third-stage larvae migrate to the ground and pupate. Following pupation the adult female fly must obtain a protein meal and mate.

Calliphora vicina

Synonym: *Calliphora erythrocephala*

Description, adult: Bluebottles are stout and characterised by a metallic blue sheen on the body (see Fig. 17.6a). The thoracic

squamae have long dark hair on the upper surface. *Calliphora vicina* has yellow–orange jowls with black hairs.

Description, larvae: Larvae are smooth, segmented and measure 10–14 mm in length. The posterior spiracles are in a closed peritreme (Fig. 3.41a).

Calliphora vomitoria

Description, adult: As for *Calliphora vicina* but distinguished by having black jowls with predominantly reddish hairs (see Fig. 17.9).

Calliphora augur

Description, adult: The adult *Calliphora augur* is predominantly brown or brown–yellow in colour with a patch of metallic-coloured blue on the medial abdomen. The adult body is approximately 11 mm in length.

Calliphora albifrontalis

Synonym: *Calliphora australis*

Description, adult: In the adult *Calliphora albifrontalis* the thorax is non-metallic blue–black in colour but the abdomen is predominantly brown or brown–yellow.

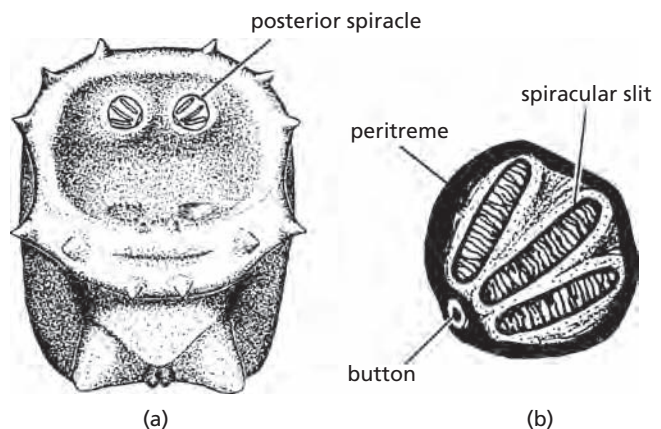

Fig. 3.41 (a) Posterior view of the last abdominal segment of *Calliphora vicina* and (b) detail of the posterior spiracles of a third-stage larva of *Calliphora vomitoria*. (From Zumpt, 1965.)

Calliphora nociva

Synonym: *Calliphora dubia*

Description, adult: The adult *Calliphora nociva* is predominantly brown or brown–yellow in colour and closely resembles *C. augur* except for the colour patch on the abdomen, which is a much brighter blue on *C. nociva* than on *C. augur*. *Calliphora nociva* displaces *C. augur* in Western Australia.

Calliphora stygia

Synonyms: *Pollenia stygia*, *Calliphora laemica*

Description, adult: The adult *Calliphora stygia* is a large native Australasian blowfly with a grey thorax and yellow–brown mottled abdomen.

Phormia and *Protophormia*

These two genera are closely related and each contains a single species of interest, *Phormia regina* and *Protophormia terraenovae*. Adult flies are black in colour with an overlying metallic blue–green sheen and may be known colloquially as ‘blackbottles’. The third-stage larvae of both species are characterised by strongly developed, fairly pointed tubercles on the posterior face of the last segment.

Phormia regina

Description, adult: *Phormia regina* is a black-coloured blowfly, with an overlying metallic blue–green sheen. This species is very similar to *Protophormia terraenovae* in appearance. In *Phormia regina* the anterior spiracle is yellow or orange and stands out clearly against the dark background colour of the thorax.

Description, larvae: The third-stage larvae of *P. regina* are characterised by strongly developed, fairly pointed tubercles on the posterior face of the last segment. In third-stage larvae of *P. regina*, the tubercles on the upper margin of the last segment are shorter than

those of *P. terraenovae*, and are less than half the width of the posterior spiracle in length (Fig. 3.42b). There are no dorsal spines on the posterior margins of segment 10.

Life cycle: Flies oviposit primarily in carrion, but may also act as secondary invaders of myiasis on live mammals. The gravid female lays clusters of 100–200 yellowish-cream eggs. The eggs hatch into larvae; the larvae then feed, grow rapidly and moult twice to become fully mature maggots. These then migrate to the ground and pupate. Following pupation the adult female fly must obtain a protein meal and mate. Adult flies can live for approximately 30 days.

Protophormia terraenovae

Description, adult: *Protophormia terraenovae* is a black-coloured blowfly with an overlying metallic blue–green sheen. This species is very similar to *Phormia regina* in appearance. In *P. terraenovae* the anterior thoracic spiracle is black or black–brown and is difficult to distinguish from the general body colour.

Description, larvae: The third-stage larvae of *P. terraenovae* (as with *P. regina*) are characterised by strongly developed, fairly pointed tubercles on the posterior face of the last segment. In third-stage larvae of *P. terraenovae*, the tubercles on the upper margin of the last segment are longer than half the width of a posterior spiracle (Fig. 3.42a). The larvae of *P. terraenovae* also possess dorsal spines on the posterior margins of segment 10 (Fig. 3.42c).

FAMILY SARCOPHAGIDAE

The family Sarcophagidae, known as flesh flies, contains over 2000 species in 400 genera. Most species of Sarcophagidae are of no veterinary importance, breeding in excrement, carrion and other decomposing organic matter. The principal genus containing species which act as important agents of veterinary myiasis is *Wohlfahrtia*. Members of the genus *Sarcophaga* may occasionally infest wounds, the more widely distributed species of which is *Sarcophaga haemorrhoidalis*.

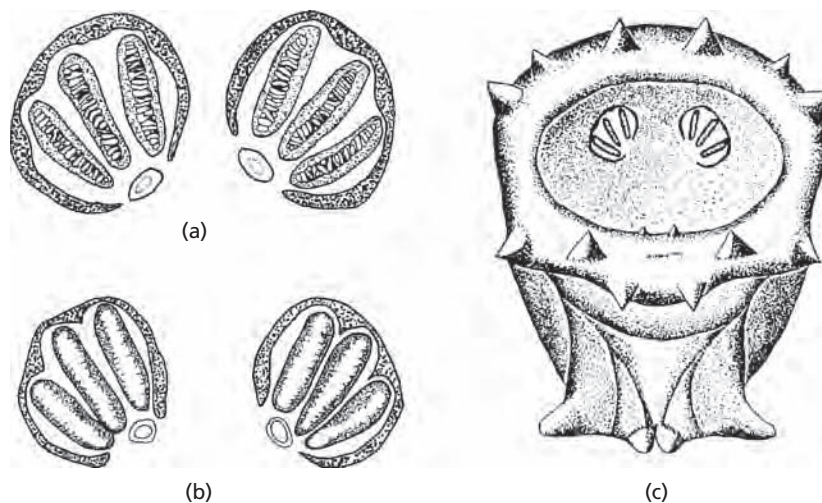

Fig. 3.42 Posterior spiracles of third-stage larvae of (a) *Protophormia terraenovae* and (b) *Phormia regina*. (c) Tubercles on the posterior face of the last segment of third-stage *Protophormia terraenovae*. (From Zumpt, 1965.)

Wohlfahrtia

The most economically important species is *Wohlfahrtia magnifica* found throughout the Mediterranean basin, eastern and central Europe and part of Asia. This is an obligate agent of traumatic myiasis. Other species include *Wohlfahrtia vigil* in North America and *Wohlfahrtia nubia*, which is a facultative species that breeds in carrion or living hosts in North Africa and the Middle East where it can be locally important, particularly in camels. *Wohlfahrtia opaca* (formerly *W. meigeni*) behaves in North America in a similar manner to *W. vigil*, causing a furuncular, boil-like, myiasis in smaller animals.

Wohlfahrtia magnifica

Description, adult: The adult flies are large, measuring 8–14 mm in length, with elongated bodies. They are grey in colour and have three distinct longitudinal thoracic stripes. The abdomen is clearly marked with black spots (Fig. 3.43c). The flies have numerous bristles covering the body and long black legs. The arista of the antennae does not possess setae.

Description, larvae: Larvae possess strongly developed oral hooks.

Life cycle: *Wohlfahrtia magnifica* is an obligate agent of myiasis. Female flies deposit 120–170 first-stage larvae on the host, in wounds or next to body orifices. The larvae feed and mature in 5–7 days, moulting twice, before leaving the wound and dropping to the ground where they pupate.

Wohlfahrtia nubia

Description, adult: The adult flies are large, 8–14 mm in length, with elongated bodies, longitudinal black thoracic stripes and a grey and black tessellated abdomen.

Life cycle: *Wohlfahrtia nubia* oviposits primarily in carrion but may also act as a secondary invader of myiasis on live mammals in North Africa and the Near East. Females deposit live first-stage larvae rather than eggs. When fully mature, the third-stage larvae leave the feeding site to pupate in the ground.

Wohlfahrtia vigil

Description, adult: The adult flies are large, 8–14 mm in length, with elongated bodies, longitudinal black thoracic stripes and a grey and black tessellated abdomen.

Life cycle: The adult female of *Wohlfahrtia vigil* deposits active maggots on the host, often in wounds, body orifices or existing myiasis. However, the larvae can penetrate intact skin if it is thin and tender; hence young animals tend to be most affected. Groups of larvae may be observed in boil-like swellings under the skin. The larvae feed and grow, moulting twice, before leaving the host and dropping to the ground where they pupate.

Wohlfahrtia meigeni

Description, adult: The adult flies are large, 8–14 mm in length, with elongated bodies, longitudinal black thoracic stripes and a grey and black tessellated abdomen.

Fig. 3.43 (a) Adult of the flesh fly *Sarcophaga carnaria* (from Castellani and Chalmers, 1910). (b, c) *Wohlfahrtia magnifica*: posterior spiracles deeply sunk in a cavity (b) and abdomen of adult (c) (from Smart, 1943).

Sarcophaga

There are over 2000 species in the family, divided into 400 genera. Most species of the genus *Sarcophaga* are of no veterinary importance, breeding in excrement, carrion and other decomposing organic matter, but some species may occasionally infest wounds. One of the more widely distributed species is *Sarcophaga haemorrhoidalis*.

Life cycle: All Sarcophagidae are larviparous: the ovulated eggs are retained within the oviduct of the adult female and batches of 30–200 larvae are deposited shortly after the eggs hatch. The larvae of *Sarcophaga* are normally associated with carrion but may occasionally infest wounds. They may extend the injury, increasing the severity of the infestation.

Sarcophaga haemorrhoidalis

Description, adult: Adults flies are grey–black, non-metallic, medium to large flies with prominent stripes on the thorax and a checkered abdominal pattern.

FAMILY OESTRIDAE

This is an important family consisting of several genera of large, usually hairy, flies whose larvae are obligatory parasites of animals. All are obligate agents of myiasis, showing a high degree of host specificity. The adults have primitive non-functional mouthparts. However, their larvae spend their entire period of larval growth and development feeding within their vertebrate hosts, causing nasopharyngeal, digestive tract or dermal–furuncular myiasis. The larvae are characterised by posterior spiracular plates containing numerous small pores.

The Oestridae contains about 150 species, known as the bots and warbles. There are four subfamilies of importance: **Oestrinae**, **Gasterophilinae**, **Hypodermatinae** and **Cuterebrinae**.

SUBFAMILY OESTRINAE

The subfamily Oestrinae contains one genus of major importance, *Oestrus*, and four genera of lesser importance, *Gedoelestia*, *Rhinoestrus*, *Cephenomyia* and *Cephalopina*.

Oestrinae species of veterinary importance

| Species | Hosts | Site |
|-------------------------------|---|----------------|
| <i>Oestrus ovis</i> | Sheep and goat, ibex, camel, rarely humans | Nasal passages |
| <i>Gedoelestia hassleri</i> | Wild ruminants, occasionally sheep, cattle | Nasopharynx |
| <i>Rhinoestrus purpureus</i> | Horse, donkey, rarely human | Nasal passages |
| <i>Pharyngomyia picta</i> | Red deer (<i>Cervus elaphus</i>), sika deer (<i>Cervus nippon</i>), fallow deer (<i>Dama dama</i>), roe deer (<i>Capreolus capreolus</i>) | Nasal passages |
| <i>Cephenemyia trompe</i> | Reindeer (<i>Rangifer tarandus</i>), moose, caribou | Nasopharynx |
| <i>Cephenemyia auribarbis</i> | Reindeer, caribou, red deer; fallow deer; mule deer (<i>Odocoileus hemionus</i>), white-tailed deer (<i>Odocoileus</i> spp.) | Nasopharynx |
| <i>Cephenemyia phobifer</i> | Mule deer | Nasopharynx |
| <i>Cephenemyia stimulator</i> | Roe deer | Nasopharynx |
| <i>Cephenemyia jellisoni</i> | Moose (<i>Alces alces</i>), elk (<i>Cervus elaphus</i>) | Nasopharynx |
| <i>Cephalopina titillator</i> | Camel | Nasopharynx |

Oestrus ovis (nasal bot fly)

Description, adult: Greyish-brown flies about 12 mm long, with small black spots on the abdomen and a covering of short brown hairs (Fig. 3.44; see also Fig. 9.41). The head is broad, with small eyes, and the frons, scutellum and dorsal thorax bear small wart-like protruberances. The segments of the antennae are small and

Fig. 3.44 (a) Adult female *Oestrus ovis* and (b) wing venation typical of *Oestrus* showing the strongly bent vein M joining the R_{4+5} vein before the wing margin. (From Castellani and Chalmers, 1910.)

the arista bare. The mouthparts are reduced to small knobs. The characteristic wing venation has a strongly bent M vein joining the R_{4+5} vein before the wing margin.

Description, larvae: Mature larvae in the nasal passages are about 30 mm long, yellowish-white and tapering anteriorly. Each segment has a dark transverse band dorsally (Fig. 3.45). They have large black oral hooks, connected to an internal cephalopharyngeal skeleton. The ventral surface bears rows of small spines.

Life cycle: The females are viviparous and infect the sheep by squirting a jet of liquid containing larvae at the nostrils during flight, which delivers up to 25 larvae at a time. The newly deposited L_1 are about 1 mm long, and migrate through the nasal passages to the frontal sinuses, feeding on the mucus that is secreted in response to the stimulation of larval movement. Larvae attach themselves to the mucous membrane using oral hooks, which cause irritation. The first moult occurs in the nasal passages, and the L_2 crawl into the frontal sinuses where the final moult to third-stage larvae takes place. In the sinuses, the larvae complete their growth and then migrate back to the nostrils, from where they are sneezed to the ground. Larvae pupate in the ground and pupation lasts for 3–9 weeks.

The larvae remain in the nasal passages for a variable period, ranging from 2 weeks in summer to 9 months during colder seasons. Where flies are active throughout the year, two or three generations are possible, but in cool or cold weather the small L_1 and L_2 become dormant and remain in recesses of the nasal passages over winter. They move to the frontal sinuses only in the warmer spring weather, and then complete their development into the L_3 , which emerge from the nostrils and pupate on the ground to give a further generation of adults. The females survive only 2 weeks, but during this time each can deposit up to 500 larvae in the nasal passages of sheep.

Fig. 3.45 *Oestrus ovis*: (a) dorsal view and (b) ventral view of third-stage larva; (c) posterior view of third-stage larva; (d) first-stage larva; (e) mouthparts of first-stage larva in lateral view. (From Zumpt, 1965.)

Gedoeelstia hassleri* and *Gedoeelstia cristata

Description, adult: Large robust flies of up to 18 mm in length. The head of the adult is reddish-yellow with dark brown spots. The thorax is rusty-brown in colour with a pattern of glossy black lines. The abdomen is brown with large black lateral patches and a series of large tubercles with sharply pointed tips.

Description, larvae: The third-stage larvae are ovoid, up to 20 mm in length and may be distinguished from all other oestrids by a vertical slit in the posterior peritremes or a vertical suture if the spiracle is closed.

Life cycle: The larvae are deposited by the adult flies in the orbit of the natural hosts, which are antelopes, and travel by a vascular route to the nasopharynx where they mature, thus showing some affinity with *Cephenemyia*. Some larvae appear to include the lungs in this migration.

Rhinoestrus purpureus

Description, adult: A relatively small fly, 8–11 mm in length. The anterior thorax is characterised by a number of glossy black stripes. The head, thorax and abdomen are covered with small wart-like protruberances and a covering of short yellow–brown hairs. The head is broad, with small eyes. The legs are red and yellow–brown. The mouthparts are reduced to small knobs.

Description, larvae: The larvae resemble those of *Oestrus ovis* except that they have strongly recurved mouth hooks and a single row of 8–12 terminal hooklets. There are three larval stages, approximately 1, 3.5 and 20 mm in length respectively.

Life cycle: The female fly produces 700–800 larvae which are expelled in batches of up to 40 into the nostrils of the hosts. First-stage larvae remain in the nasal cavities before moving to the pharyngeal area where they moult to become second- and then third-stage larvae. The rate of development varies considerably depending on location. Third-stage larvae are expelled and pupate in the ground.

***Cephenemyia trompe* (reindeer throat bot)**

Description, adult: The adult is bee-like in appearance, 14–16 mm in length and covered in long yellowish and black hairs overlying a shining black body.

Description, larvae: Developing larvae are white, while fully developed larvae are about 25–40 mm long and yellowish-brown. The entire larval body is covered by bands of short spines on both sides and narrows posteriorly.

Life cycle: The adult flies are active from June to September and, like *Oestrus*, the females are viviparous. The fly hovers close to the animal, then darts in and ejects larvae in fluid into the nostrils of the host animal. The larvae migrate to the retropharyngeal pouches.

There they become attached in clusters and develop. Further development occurs in the nasopharynx, as the larvae migrate to and crowd in the retropharyngeal pouches that lie on either side of the throat at the base of the tongue. Fully developed third-stage larvae, which may be 40 mm in length, crawl to the anterior nasal passages and are sneezed out. Pupation occurs on the ground under surface debris. The pupation period is about 4 weeks. The adult flies have no mouthparts for feeding so they are short-lived and mate shortly after emerging.

Cephalopina titillator

Description, adult: The adult fly measures 8–10 mm in length. It is relatively robust and has a powdery grey appearance. The head is large, orange above and yellow below. The eyes are broadly separated, especially in the female. The thorax is reddish-brown, with a black pattern. The abdomen has irregular black blotches and white hair and the legs are yellow.

Description, larvae: The first-stage larvae are about 0.7 mm in length and have long spines on the lateral edges of the segments. Third instars are about 25–35 mm in length, and characterised by smooth fleshy lobes on each segment and large mouth hooks.

Life cycle: Eggs are laid around the nasal area. Larvae hatch and migrate into the nasal cavity, frontal sinus and pharynx of their host, where they take several months to feed and moult. When mature, the larvae make their way back to the nose, considerably irritating the host (usually a camel), in the process. As a result they are sneezed out onto the ground, and from here the larvae burrow into the ground and pupate. Pupation takes about 25 days.

SUBFAMILY GASTEROPHILINAE

The subfamily Gasterophilinae contains a single genus of importance, *Gasterophilus*, which are obligate parasites of horses, donkeys, zebras, elephants and rhinoceroses. Eight species are recognised in total, six of which are of interest as veterinary parasites of equids.

Description, adult: Bot flies are robust dark flies 10–15 mm in length. The body is densely covered with yellowish hairs. In the female the ovipositor is strong and protruberant. The wings of adult *Gasterophilus* characteristically have no cross-vein dm-cu (Fig. 3.46).

Description, larvae: When mature and present in the stomach or passed in faeces, the larvae are cylindrical, 16–20 mm long and reddish-orange with posterior spiracles (Fig. 3.47). Differentiation of mature larvae of the various species can be made on mouth hooks and the numbers and distribution of the spines present on various segments (Fig. 3.48).

Life cycle: The life cycles of the various species differ only slightly; key differences are highlighted in the following sections.

Gasterophilus haemorrhoidalis

Description, larvae: The spines on the ventral surface of the larval segments are arranged in two rows. The head segment has only

Fig. 3.46 Adult female *Gasterophilus intestinalis*. (From Castellani and Chalmers, 1910.)

lateral groups of denticles and the dorsal row of spines on the eighth segment is not broadly interrupted medially. The mouth hooks are uniformly curved dorsally and directed laterally, and the body spines are sharply pointed (Fig. 3.48d).

Life cycle: *Gasterophilus haemorrhoidalis* lays batches of 150–200 eggs around the lips. The adult flies have a short lifespan and females can

Fig. 3.47 (a) Third-stage larva of *Gasterophilus intestinalis*. (b) Ventral view of pseudocephalon of *G. pecorum*. Eggs of (c) *G. nasalis*; (d) *G. intestinalis*; (e) *G. haemorrhoidalis*; (f) *G. inermis*. (From Zumpt, 1965.)

Fig. 3.48 Mouth hooks (top) and ventral spines (bottom) of the fifth segment of (a) *Gasterophilus intestinalis*; (b) *G. inermis*; (c) *G. nasalis*; (d) *G. haemorrhoidalis*; (e) *G. pecorum*. (From Zumpt, 1965.)

deposit all of their eggs within 2–3 hours if the weather is mild and a suitable host is available. The eggs are easily seen (length 1–2 mm) and are usually black in colour (Fig. 3.47e). They either hatch spontaneously in about 5 days or are stimulated to do so by warmth, which may be generated during licking and self-grooming. Larvae either crawl into the mouth or are transferred to the tongue during licking. The larvae can burrow into the epidermis of the lips and from there migrate into the mouth. These then penetrate the tongue or buccal mucosa and burrow through these tissues for several weeks while feeding, before moulting and passing via the pharynx and oesophagus to the stomach where they attach to the gastric epithelium.

The larvae remain and develop in the stomach for periods of 10–12 months. When mature in the following spring or early summer, they detach and are passed in the faeces. In this species, the larvae reattach in the rectum for a few days before being passed out. Pupation takes place on the ground and after 1–2 months the adult flies emerge. These do not feed, and live for only a few days or weeks, during which time they mate and lay eggs. If suitable hosts are unavailable the flies move to high points to aggregate and mate, following which the females initiate a longer-distance search for hosts. There is therefore only one generation of flies per year in temperate areas.

Gasterophilus inermis

Description, larvae: Spines on the ventral surface of the larval segments are arranged in two rows. The head segment has only lateral groups of denticles and the dorsal row of spines on the eighth segment are not broadly interrupted medially. The mouth hooks are strongly curved, with their tips directed backwards and approaching the base; body spines are sharply pointed (Fig. 3.48b). Body segment 3 has three complete rows of spines, and body segment 11 has one row of spines interrupted by a broad median gap.

Life cycle: The adult female lays up to 300 eggs on the cheeks and around the mouth of the host animal. These are each attached individually to the base of a hair in these regions. The eggs are 1–2 mm in length and usually creamy white in colour (Fig. 3.47f). The life cycle is essentially similar to that of *G. haemorrhoidalis*.

Gasterophilus intestinalis

Description, larvae: The mouth hooks are not uniformly curved dorsally, and have a shallow depression. The body spines have blunt tips (Fig. 3.48a).

Life cycle: *Gasterophilus intestinalis* eggs are laid on the hairs of the forelegs and shoulders. Several eggs may be glued to each hair and up to 1000 eggs may be deposited by a female *G. intestinalis* during its lifetime of only a few days. The eggs are 1–2 mm in length and usually creamy white in colour (Fig. 3.47d). Larvae penetrate the tongue or buccal mucosa at the anterior end of the tongue where they excavate galleries in the subepithelial layer of the mucous membrane. The larvae wander in these tissues for several weeks before exiting the tongue and moulting. Second-stage larvae attach for a few days to the sides of the pharynx, before moving to the oesophageal portion of the stomach where they cluster at the boundary of glandular and non-glandular epithelium. The larvae remain and develop in this site for periods of 10–12 months.

Gasterophilus nasalis

Description, larvae: *Gasterophilus nasalis* larvae have spines on the ventral surface of the larval segments arranged in a single row. The first three body segments are more or less conical and the third segment has a dorsal row of spines and sometimes ventral spines (Fig. 3.48c).

Life cycle: The throat bot fly, *G. nasalis*, lays its eggs in the intermandibular area. Eggs are laid in batches of up to 500, usually with one egg attached per hair (Fig. 3.47c). The larvae burrow into the spaces around the teeth and between the teeth and gums. This may result in the development of pus-sockets and necrosis in the gums. The first larval stage lasts 18–24 days, following which larvae moult and second-stage larvae move via the pharynx and oesophagus to the stomach, where they attach to the gastric epithelium. In the stomach, the yellow *G. nasalis* larvae attach around the pylorus and sometimes the duodenum, where they remain for 10–12 months.

Gasterophilus nigricornis

Description, larvae: Spines on the ventral surface of the larval segments are arranged in a single row. The first three body segments are more or less cylindrical, showing sharp constrictions posteriorly, and the third segment is without spines dorsally or ventrally.

Life cycle: Female flies alight on the host's cheek to oviposit. The larvae hatch in 3–9 days and burrow directly into the skin. They then burrow to the corner of the mouth and penetrate the mucous membranes inside the cheek. Once they have reached the central part of the cheek (about 20–30 days after hatching) they moult and leave the mucous membranes. The second-stage larvae are then swallowed, following which they attach themselves to the wall of the duodenum and remain there for 10–12 months.

Gasterophilus pecorum

Description, larvae: Larvae have spines on the ventral surface of the larval segments, which are arranged in two rows. The head segment has two lateral groups of denticles and one central group, the latter situated between the antennal lobes and mouth hooks. The dorsal rows of spines are broadly interrupted medially on the seventh and eighth segments. Segments 10 and 11 have no spines (Fig. 3.48e).

Life cycle: Adult *G. pecorum* are most active in late summer and, unlike other species, the dark-coloured eggs are laid on pasture and

are ingested by horses during grazing. Up to 2000 eggs are laid in batches of 10–115. The eggs are highly resistant and the developed larva may remain viable for months within its egg until ingested by horses. In the mouth, the eggs hatch within 3–5 minutes. First-stage larvae immediately penetrate the mucous membrane of the lips, gums, cheeks, tongue and hard palate and burrow towards the root of the tongue and soft palate where they may remain for 9–10 months until fully developed. They may also be swallowed and settle in the walls of the pharynx, oesophagus or stomach. When mature in the following spring or early summer, the larvae detach and are passed in the faeces.

SUBFAMILY HYPODERMATINAE

The subfamily Hypodermatinae contains one genus of major importance, *Hypoderma* (warble flies or cattle grubs), and a second less widespread genus, *Przhevalskiana* (goat warbles). The Hypodermatinae contains six species of veterinary importance within the genus *Hypoderma*. Two species, *H. bovis* and *H. lineatum*, are parasites primarily of cattle, whereas *H. diana*, *H. actaeon*, *H. tarandi* and *H. sinense* affect roe deer, red deer, reindeer and yak, respectively.

Hypoderma

Description, adult: The adults are large and the abdomen is covered with yellow–orange hairs giving them a bee-like appearance (Fig. 3.49; see also Fig. 8.48). The adults have no functioning mouthparts.

Fig. 3.49 (a) Adult female of *Hypoderma bovis* (from Castellani and Chalmers, 1910). (b) Wing venation typical of *Hypoderma* showing the strongly bent vein M not joining R_{4+5} before the wing margin and vein A_1+CuA_2 reaching the wing margin.

Fig. 3.50 (a) Third-stage larva of *Hypoderma bovis*. Eggs of (b) *H. lineatum* and (c) *H. bovis*. Posterior spiracles of third-stage larvae of (d) *H. bovis* and (e) *H. lineatum*. (From Zumpt, 1965.)

Description, larvae: Mature larvae are thick and somewhat barrel-shaped, tapering anteriorly. When mature they are 25–30 mm long, and most segments bear short spines. The colour is dirty white when newly emerged from the host, but rapidly turns to dark brown; the pupa is almost black. The third-stage larvae of the two species of *Hypoderma* that commonly parasitise cattle (*H. bovis* and *H. lineatum*) may be distinguished from other species of *Hypoderma* by examination of the posterior spiracular plate, which is completely surrounded by small spines. The cattle species may be further distinguished as follows: in *H. bovis*, the posterior spiracular plate surrounding the button has a narrow funnel-like channel, whereas in *H. lineatum* it has a broad channel (Fig. 3.50 and Table 3.2).

Life cycle: The adult flies are active only in warm weather, and in the northern hemisphere the peak period is usually in June and July. The females attach their eggs to hairs on the lower parts of the body and on the legs above the hocks. The eggs are 1 mm long and are fixed to the hairs using small terminal clasps (Fig. 3.50). One female may lay 100 or more eggs on an individual host. There is no fly activity below approximately 18°C.

The first-stage larvae, which are less than 1 mm long, hatch in a few days and crawl down the hairs, penetrate the hair follicles and migrate in the body, following species-specific pathways (see following sections). The use of paired mouth hooks and the secretion of proteolytic enzymes aids migration. The larvae feed as they travel to the species-specific resting sites, which are reached in late autumn, where they spend the winter. The moult to the second stage occurs at this resting site. During this stage they grow to 12–16 mm. In February and March migration is resumed and the L_2 arrive under the skin of the back. Here they moult to the L_3 stage, which can be

Table 3.2 Summary of differences between the *Hypoderma* which parasitise cattle.

| Feature | <i>Hypoderma bovis</i> | <i>Hypoderma lineatum</i> |
|--------------------|--|---|
| Adult length | 15 mm | 13 mm |
| Eggs laid | Singly | In batches |
| Larval morphology | Posterior spiracular plate surrounding the button has a narrow funnel-like channel | Posterior spiracular plate surrounding the button has a broad channel |
| Migration path | Along nerves | Between the fascial planes of muscles and along connective tissue |
| Overwintering site | Epidural fat of the spinal cord | Submucosa of the oesophagus |

palpated as distinct swellings ('warbles'). The L₃ makes a cutaneous perforation and the larvae breathe by applying their spiracles to the aperture. A fully grown third-stage larva measures 27–28 mm in length. After about 4–6 weeks in this site they emerge in May–June and fall to the ground, where they pupate under leaves and loose vegetation for about 5 weeks. The adults then emerge, copulate, and the females lay their eggs and die, all within 1–2 weeks. Oviposition can take place as soon as 24 hours after emergence from the puparium. The precise timings and duration of events in the life cycle will vary depending on latitude and ambient temperature.

Hypoderma of veterinary importance

| Species | Hosts | Site |
|--|--------------------------------------|---|
| <i>Hypoderma bovis</i> | Cattle | L ₁ , epidural fat; L ₃ , subcutaneous skin |
| <i>Hypoderma lineatum</i> | Cattle | L ₁ , oesophagus; L ₃ , subcutaneous skin |
| <i>Hypoderma diana</i> | Deer, occasionally horse, sheep | L ₁ , epidural fat; L ₃ , subcutaneous skin |
| <i>Hypoderma tarandi</i> (syn. <i>Oedemagena tarandi</i>) | Reindeer, caribou, rarely dog, horse | All larval stages in subcutaneous connective tissue |
| <i>Hypoderma actaeon</i> | Deer | Not known |
| <i>Hypoderma sinense</i> | Yak | Not known |

Hypoderma bovis (warble fly)

Description, adult: Adult female *Hypoderma bovis* are about 15 mm in length and bee-like in appearance; the abdomen is covered with yellow–orange hairs with a broad band of black hairs around the middle. The hairs on the head and the anterior part of the thorax are greenish-yellow.

Life cycle: Characteristic features of the life cycle of *H. bovis* are that it attaches its eggs singly to hairs on the lower parts of the body (Fig. 3.50c). Following penetration through the skin, the larvae migrate along nerves until they reach the epidural fat of the spine in the region of the thoracic and lumbar vertebrae, where they overwinter.

Hypoderma lineatum (warble fly, heel fly)

Description, adult: Adult female *Hypoderma lineatum* are about 13 mm in length and bee-like in appearance; the abdomen is

covered with yellow–orange hairs with a broad band of black hairs around the middle. The hairs on the head and the anterior part of the thorax are yellowish-white.

Life cycle: Characteristic features of the life cycle of *H. lineatum* are that it attaches its eggs in rows of six or more on individual hairs below the hocks (Fig. 3.50b). Following penetration of the skin, the larvae migrate between the fascial planes of muscles and along connective tissue, towards the region of the diaphragm. Eventually they reach the submucosa of the oesophagus where they spend the winter. Adult *H. lineatum* also usually emerge about 1 month before *H. bovis*.

Hypoderma diana

Description, adult: Adult female *Hypoderma diana* are about 15 mm and similar in appearance to cattle warble flies.

Description, larvae: The larvae are relatively host-specific and live as subcutaneous parasites of deer. Mature larvae are thick, and somewhat barrel-shaped, tapering anteriorly and are 25–30 mm in length. Most segments bear short spines and the inner margins of the channels of the posterior peritremes are divergent. Larvae are dirty white in colour when newly emerged from the host, but rapidly turn dark brown. The pupa is almost black.

Life cycle: Females emerge with all their eggs fully developed. They have a relatively short lifespan in which they do not feed, and are able to mate and oviposit soon after emergence. Mating takes place off the host at aggregation points where females are intercepted in flight. The female flies lay between 300 and 600 eggs on the lower regions of the legs and lower body of the host animal, where they are glued to the hairs.

The first-stage larvae are less than 1 mm in length, hatch within a week and crawl down the hairs, either burrowing directly into the skin or into the hair follicles. The larvae then continue to burrow beneath the skin. *Hypoderma diana* migrates below the skin along nerves to the spinal cord. After about 4 months, usually by autumn, larvae reach the epidural fat of the spine in the region of the thoracic and lumbar vertebrae, where they overwinter.

The following spring, migration is not resumed until about 9 months after oviposition when the larvae reach the skin of the back. A characteristic small swelling (the 'warble') is formed and a small hole is cut to the surface. A cystic nodule then begins to form around each larva. The larva reverses its position and rests with its two posterior spiracles close to the opening in the warble, allowing the larva to breathe. In this location the larva moults twice, during which time it grows rapidly, more than doubling in length. Larval migration and growth take place in the host until April. The larvae then drop off the host animal and pupate in soil. The fly emerges after approximately 36 days. The duration of pupation depends on ambient temperature and ground cover; higher pupal survival occurs when there is at least some grass cover and where the ground does not freeze.

Hypoderma tarandi (reindeer warble fly)

Synonym: *Oedemagena tarandi*

Description, adult: Large flies, about 15–18 mm, similar in appearance to *H. bovis*.

Description, larvae: Mature larvae are up to 3 cm in length. The posterior peritremes are heavily sclerotised, and have a broad interior channel leading to the lumen.

Life cycle: The life cycle of *Hypoderma tarandi* resembles that of other species in the genus *Hypoderma*. They are active in July and August, each female laying between 500 and 700 eggs, which are attached to the downy undercoat rather than the outer hair. The flanks, legs and rump are preferential laying sites. After approximately 6 days the egg hatches on the skin, and the larva then burrows into and under the skin. Unlike other *Hypoderma*, however, the L₁ migrates directly to the back in the subcutaneous connective tissue via the spine. When the larva comes to rest in about September to October, a swelling (warble) is created around it where it feeds on the animal's blood and body fluids. The L₃ makes a cutaneous perforation and the larvae breathe by applying their spiracles to the aperture. When growth is completed in the spring, the larva leaves the reindeer through its air hole and drops to the ground to pupate. It then emerges as an adult fly, completing the cycle.

Przhevalskiana

The goat warble, *Przhevalskiana silenus* is common in Mediterranean countries.

Przhevalskiana silenus

Description, adult: The adult flies are 8–14 mm in length, have large eyes, a grey thorax and grey tessellated abdomen.

Description, larvae: The third-stage larvae are large (up to 25 mm in length), club-shaped, tapering towards the posterior end, with a pair of posterior spiracles. The body is composed of 11 segments with small spines at the conjunction of segments.

Life cycle: The life cycle of this species is similar in many ways to that of *Hypoderma*, the third-stage larva occurring under the skin of the back. After mating, the adult females lay about 100 black oval eggs that are about 0.8 mm in length. One to four eggs are glued on each hair. The first-stage larvae hatch from the eggs in 5–6 days and penetrate the skin into the subcutaneous tissue. The larvae then migrate in the subcutis directly to the back. However, there is no resting site as seen with *Hypoderma*. Larvae reach the subcutaneous tissue of the host's back and flanks between the end of December and the beginning of February. Here they feed, grow and moult into their second and third stages, causing the characteristic warble swelling at the skin surface. The third-stage larva may be 15–18 mm in length and dark-coloured. The L₃ makes a cutaneous perforation, through which the larvae breathe by applying their spiracles to the aperture. When fully mature, in about February to April, the L₃ drops to the ground and pupates. The period required for pupation depends on weather conditions. The adults are active from April to June, lack mouthparts and survive only 5–10 days on resources accumulated during the larval period.

SUBFAMILY CUTEREBRINAE

The subfamily Cuterebrinae contains two genera of interest, *Cuterebra* and *Dermatobia*.

Cuterebra spp.

Species of the genus *Cuterebra* are largely parasites of rodents and rabbits but occasionally infest dogs and cats.

Description, adult: The adults are large flies (up to 30 mm in length) covered by dense short hairs, and have a blue–black abdomen. They have small non-functional mouthparts and do not feed as adults.

Description, larvae: Larvae have strongly curved mouth hooks and numerous strong body spines.

Life cycle: Females lay eggs on the ground near or within the entrance of host nests, or on grass near trails used by hosts. These are picked up by the passing host. The larvae enter the body, directly through the skin or through one of the orifices such as the nose, and then migrate subdermally. At their final, species-specific resting site the larvae eventually form a warble-like swelling. In rodents the warble is often formed near the anus, scrotum or tail. Larval development may require between 3 and 7 weeks. When mature, the larvae leave the host and drop to the ground where they pupate.

Dermatobia

The genus *Dermatobia* contains a single species of importance, *Dermatobia hominis*, which infests domestic animals and humans. This is a neotropical species, distributed from southern Mexico through Argentina, and inhabits wooded areas along forest margins of river valleys and lowlands. It is variously known as torsalo, the human bot fly or the American warble fly.

Dermatobia hominis (torsalo fly)

Description, adult: The adult *Dermatobia* fly resembles *Calliphora* in appearance, the short broad abdomen having a bluish metallic sheen, but there are only vestigial mouthparts covered by a flap. The female measures approximately 12 mm in length. Adults have a yellow–orange head and legs, and the thorax possesses a sparse covering of short setae. The arista of the antennae has setae on the outer side only.

Description, larvae: Mature larvae measure up to 25 mm long and are somewhat oval. They have two to three rows of strong spines on most of the segments. Larvae are narrowed at the posterior end, particularly the second-stage larva. The third-stage larva is more oval in shape with prominent flower-like anterior spiracles and posterior spiracles located in a small deep cleft (Fig. 3.51).

Life cycle: *Dermatobia* is most common in forest and bush regions, the latter known in many parts of South America as the 'monte'. The adult flies do not feed; instead nourishment is derived from food stores accumulated during the larval stages. The female has a sedentary habit, resting on leaves until oviposition is imminent, when she catches an insect (usually a mosquito) and attaches a batch of up to 25 eggs to the underside of its abdomen or thorax. While attached to this transport host the L₁ develop within the eggs in about a week, but do not hatch until the carrier insect lands on a warm-blooded animal to feed. The first-stage larvae hatch in response to the sudden temperature rise near the host's body. The larvae then penetrate the skin (often through the

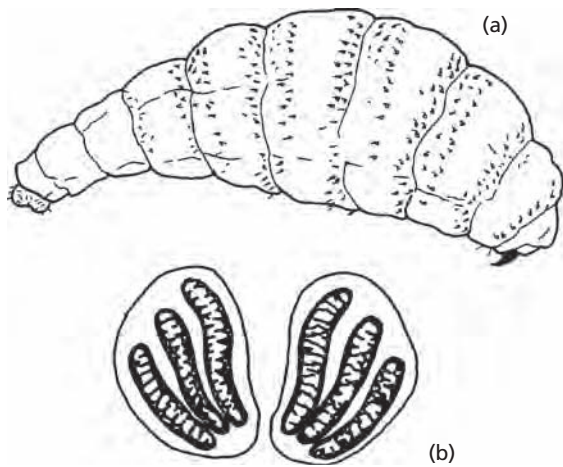

Fig. 3.51 *Dermatobia hominis*: (a) third-stage larva; (b) posterior spiracles.

opening made by the transport fly) and migrate to the subcutis, where they develop to the L₃ and breathe through a skin perforation in the fashion of *Hypoderma*. The larvae do not wander. The mature larvae emerge after about 3 months and pupate on the ground for a further month before the adult flies emerge. There may be up to three generations each year.

ORDER PHTHIRAPTERA

The lice (order Phthiraptera) are permanent obligate ectoparasites that are highly host-specific, many species even being localised on specific anatomical areas of their host. They usually only leave their host to transfer to a new one. They are small insects, about 0.5–8 mm in length, dorsoventrally flattened and possess stout legs and claws for clinging tightly to fur, hair and feathers. All lice are wingless, but this is a secondary adaptation to the parasitic lifestyle, and lice are thought to be derived originally from winged ancestors. They feed on epidermal tissue debris, parts of feathers, sebaceous secretions and blood. They usually vary in colour from pale beige to dark grey, but they may darken considerably on feeding. Most are blind, but a few species have simple photosensitive eye spots.

The Phthiraptera is a small order with about 3500 described species, of which only about 20–30 are of major economic importance. The order is divided into four suborders: **Anoplura**, **Amblycera**, **Ischnocera** and **Rhynchophthirina**. However, the Rhynchophthirina is a very small suborder, including just two African species, one of which is a parasite of elephants and the other a parasite of warthogs.

The Anoplura, known as the sucking lice, are usually large, up to 5 mm, with small pointed heads and terminal mouthparts (Fig. 3.52). They are generally slow moving, and have powerful legs, each with a single large claw. They occur exclusively on mammals.

In the veterinary literature, the Amblycera and Ischnocera are usually discussed together and described as the **Mallophaga** which, in older textbooks, is accorded status as a suborder in its own right. However, Mallophaga is not a monophyletic group. Mallophaga literally means 'wool eating' and together the Amblycera and Ischnocera are known as **chewing lice**. The description 'biting lice' is a misnomer and should be avoided, because all lice bite.

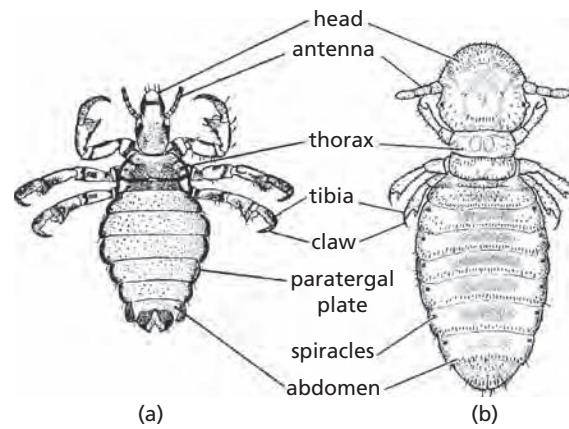

Fig. 3.52 Dorsal view of adult female (a) sucking louse *Haematopinus* (from Smart, 1943) and (b) chewing louse *Bovicola* (from Gullan and Cranston, 1994).

LOUSE LIFE CYCLES

Sucking and chewing lice have very similar life cycles. During a lifespan of about 1 month the female lays 20–200 operculate eggs ('nits'). These are usually whitish, and are glued to the hair or feathers where they may be seen with the naked eye (Fig. 3.53). From the egg hatches a nymph, which is similar to, though much smaller than, the adult. After three moults the fully grown adult is present. The whole cycle from egg to adult usually takes 2–3 weeks.

Sucking lice, with their piercing mouthparts, feed on blood, but the chewing lice are equipped with mouthparts for cutting and grinding and have a wider range of diets. Those on mammals ingest the outer layers of the hair shafts, dermal scales and blood scabs; the bird lice also feed on skin scales and scabs, but unlike the mammalian species they can digest keratin so that they also eat feathers and down.

Heavy louse infestation is generally known as **pediculosis** (although originally this term refers specifically to human infestation with lice of the genus *Pediculus*). Some species of lice may act as intermediate hosts to the tapeworm *Dipylidium caninum*. However, despite this, lice are predominantly of veterinary interest because of the direct damage they can cause to their hosts, rather than as vectors. Hence, the effect of lice infestation is usually a function of their density. A small number of lice may present no problem and in fact

Fig. 3.53 Anopluran louse, *Haematopinus*: detail of (a) the tarsus and claw and (b) an egg attached to a hair. (From Smart, 1943.)

may be considered as a normal part of the skin fauna. However, louse populations can increase dramatically, reaching high densities. Such heavy louse infestations may cause pruritus, alopecia, excoriation and self-wounding. The disturbance caused may result in lethargy and loss of weight gain or reduced egg production in birds. Severe infestation with sucking lice may cause anaemia. Heavy infestations are usually associated with young animals or older animals in poor health, or those kept in unhygienic conditions.

Transfer of lice from animal to animal or from herd to herd is usually by direct physical contact. Because lice do not survive for long off their host, the potential for animals to pick up infestations from dirty housing is limited, although it cannot be ignored. Occasionally, lice may also be transferred between animals by attachment to flies (phoresy).

In temperate habitats, louse populations are dynamic and exhibit pronounced seasonal fluctuations. The seasonal increase in louse populations may be exacerbated by winter housing, if the animals are in poor condition and particularly if animals are deprived of the opportunity to groom themselves properly. Louse infestation may also be indicative of some other underlying problem, such as malnutrition or chronic disease.

SUBORDER ANOPLURA

Anoplura are small insects, ranging from less than 0.5 to 8 mm in length in the adult; about 2 mm is an average length. The antennae are usually five-segmented; the eyes are reduced and usually absent, and there are no ocelli. The three thoracic segments are fused. The legs have only a single tarsal segment and a single claw; when the claw is retracted it makes contact with a thumb-like process on the tibia (the enclosed space having the diameter of the hairs of the host) and enables the louse to maintain firm attachment to an active host. There is one pair of spiracles (mesothoracic) on the thorax, and six pairs (segments 3–8) on the abdomen, which has nine segments in all.

The mouthparts are highly specialised and are not visible externally. They are highly adapted for piercing the skin of hosts. They are composed of three stylets in a ventral pouch which form a set of fine cutting structures. During feeding, the stylets are used to puncture the skin and blood is sucked into the mouth. The mouthparts have no palps and are usually retracted into the head when not in use so that all that can be seen of them is their outline in the head or their tips protruding.

The suborder Anoplura contains several families, two of which are of major importance in veterinary medicine, the Haematopinidae and the Linognathidae. The Microthoraciidae contains species that are of importance in camelids. The Polyplacidae and Hoploperidae contain species which are parasites of rodents. The Echinophthiridae contains species which are parasites of marine mammals and the Neolinagnathidae, of which there are only two species, are parasites of elephant shrews. Two other families of medical interest are the Pediculidae and Pthiridae.

FAMILY HAEMATOPINIDAE

The family Haematopinidae contains the genus *Haematopinus*, which is one of the primary genera of veterinary importance, species of which are among the largest lice of domestic mammals, up to 0.5 cm in length, found in cattle, pigs and horses.

Haematopinus

Twenty-six species have been described in the genus *Haematopinus*. All species are large lice, about 4–5 mm and possess prominent angular processes (ocular points or temporal angles) behind the antennae. The legs are of similar size, each terminating in a single large claw that opposes the tibial spur. Distinct sclerotised paratergal plates are visible on abdominal segments 2 or 3 to 8.

Haematopinus species of veterinary importance

| Species | Hosts | Site |
|---|-----------------|--|
| <i>Haematopinus eurysternus</i> | Cattle | Skin, poll, base of horns, ears, eyes and nostrils, occasionally tail switch |
| <i>Haematopinus quadripertusus</i> | Zebu, cattle | Tail and perineum |
| <i>Haematopinus tuberculatus</i> (syn. <i>Haematopinus bufalieuropaei</i>) | Buffalo, cattle | Skin, back, neck and horn base |
| <i>Haematopinus suis</i> | Pig | Skin, skin folds of the neck and jowl, the flanks, insides of the legs |
| <i>Haematopinus asini</i> | Horse, donkey | Skin of head, neck, back, brisket and between the legs |

Haematopinus eurysternus (short-nosed louse)

Description: *Haematopinus eurysternus* is one of the largest lice of domestic mammals, measuring 3.4–4.8 mm in length. The louse is broad in shape with a short pointed head (Fig. 3.54). The head and thorax are yellow or greyish-brown, and the abdomen blue-grey with a dark stripe on each side. The hard-shelled eggs are opaque and white and are pointed at their base.

Fig. 3.54 Dorsal view of adult *Haematopinus*. (From Séguy, 1944.)

Life cycle: Adult lice live for 10–15 days and when mature, females lay one egg per day for approximately 2 weeks. The eggs are glued to the hairs or bristles of the host and hatch in 1–2 weeks. The emerging nymphs resemble the adult louse except in size. Nymphs moult to become adults about 14 days after hatching. The female lice begin to lay eggs after feeding and mating.

***Haematopinus quadripertusus* (tail louse)**

Description: *Haematopinus quadripertusus* is a large eyeless louse about 4–5 mm in length. It has a dark, well-developed thoracic sternal plate. The legs are of similar sizes, each terminating in a single large claw that opposes the tibial spur.

Life cycle: During a lifespan of about a month the female lays 50–100 operculate eggs ('nits') at a rate of one to six eggs per day. These are usually whitish, and are glued to the hair or feathers where they may be seen with the naked eye. The eggs of this louse are usually deposited on the tail hairs, which become matted with eggs in severe infestations. In very severe cases the tail head may be shed. The eggs hatch after 9–25 days depending on the climatic conditions. Nymphs disperse over the entire body surface of the host, but adults are most commonly found on the tail head. After three nymphal moults, over a period of about 12 days, the fully mature reproductive adult is present. Within 4 days, after feeding and mating, the adult female begins to lay eggs. The whole cycle from egg to adult takes 2–3 weeks.

***Haematopinus tuberculatus* (buffalo louse)**

Synonym: *Haematopinus bufalieuropaei*

Description: A large louse measuring about 5.5 mm in length, with prominent ocular points but without eyes.

***Haematopinus suis* (hog louse)**

Description: *Haematopinus suis* is a large greyish-brown louse with brown and black markings, measuring 5–6 mm in length (see Fig. 11.19). The head is long and with long mouthparts adapted for sucking blood. It has prominent angular processes, known as ocular points or temporal angles, located behind the antennae. Eyes are absent. The thoracic sternal plate is dark and well developed.

Life cycle: Female lice lay one to six eggs per day. These are deposited singly, and are glued to the hairs on the lower parts of the body and in skin folds on the neck, and on or in the ears, where they may be seen with the naked eye. The eggs hatch within 13–15 days. The emerging nymphs resemble the adult louse except in size. In about 12 days, the nymphs mature into adults and within 4 days, after feeding and mating, the female lice begin to lay eggs. The entire life cycle, from egg to adult, takes place on the host and is completed in 2–3 weeks. Adults may live for up to 40 days but cannot survive for more than a few days off the host. Between six and fifteen generations may be completed per year, depending on environmental conditions.

***Haematopinus asini* (horse sucking louse)**

Description: *Haematopinus asini* is 3–3.5 mm long and yellow-brown as an adult. The lice have three pairs of legs and a long narrow head with piercing mouthparts adapted for sucking blood and tissue fluids. The lice are found only on equines.

Life cycle: The lifespan of the adult louse is about 1 month, during which time the female lays operculate eggs at a rate of one to six eggs per day. These are usually whitish, and are glued to the hair where they may be seen with the naked eye. They hatch in 1–2 weeks. Nymphs grow and moult over a period of about 12 days until the fully grown adult is present. After feeding and mating, the female lice may begin to lay eggs. Adults die after approximately 10–15 days of oviposition, and an average of around 24 eggs are laid per female. The whole cycle from egg to adult takes 3–4 weeks.

FAMILY LINOGNATHIDAE

There are two genera of veterinary importance in the family Linognathidae, *Linognathus* and *Solenopotes*. Members of this family are distinguished by the absence of eyes and ocular points. Most species of *Linognathus* are found on Artiodactyla, and a few on carnivores.

Linognathus

More than 60 species of *Linognathus* have been described, of which six are found on domestic animals. Lice belonging to this genus do not have eyes or ocular points. The second and third pairs of legs are larger than the first pair and end in stout claws. The thoracic sternal plate is weakly developed or absent. Species differentiation is generally based on host and location on the body.

***Linognathus* species of veterinary importance**

| Species | Hosts | Site |
|------------------------------|--------------------------|------------------------------------|
| <i>Linognathus vituli</i> | Cattle | Skin, head, neck and dewlap |
| <i>Linognathus africanus</i> | Goat, occasionally sheep | Skin, face |
| <i>Linognathus ovis</i> | Sheep | Skin, mainly on face |
| <i>Linognathus pedalis</i> | Sheep | Skin, abdomen, legs, feet, scrotum |
| <i>Linognathus stenopsis</i> | Goat | Skin, head, neck, body |
| <i>Linognathus setosus</i> | Dog | Skin, head, neck, ears |

***Linognathus vituli* (long-nosed cattle louse)**

Description: Bluish-black medium-sized lice with an elongated pointed head and body, approximately 2.5 mm in length (Fig. 3.55). There are no eyes or ocular points. Forelegs are small. Midlegs and hindlegs are larger with a large claw and tibial spur. There are two rows of setae on each segment. The thoracic sternal plate is weakly developed or absent. These lice are gregarious in habit, forming dense isolated clusters. While feeding they extend their bodies in an upright position.

Life cycle: During a lifespan of about a month the female lays a number of operculate eggs at a rate of about one egg per day. These

Fig. 3.55 Dorsal view of adult female *Linognathus*. (From Séguy, 1944.)

are usually whitish, and are glued to the hair where they may be seen with the naked eye. The eggs hatch within 10–15 days. The nymph is similar in appearance to the adult though much smaller. The nymph increases in size as it moults through three instars, to eventually become an adult. The whole cycle from egg to adult takes 2–3 weeks.

***Linognathus ovillus* (long-nosed sheep louse)**

Description: This sucking louse is bluish-black with a long narrow head and slender body. It measures approximately 2.5 mm in length.

Life cycle: Adult females lay a single egg per day. Eggs hatch in 10–15 days, giving rise to nymphs that require about 2 weeks to pass through three nymphal stages. The egg-to-adult life cycle requires about 20–40 days.

***Linognathus pedalis* (sheep foot louse)**

Description: The foot louse *Linognathus pedalis* is bluish-grey, with a long pointed head and can reach up to 2 mm in length when fully engorged.

Life cycle: See *L. ovillus*.

***Linognathus stenopsis* (goat sucking louse)**

Description: *Linognathus stenopsis* is up to 2 mm long when fully fed, with a long pointed head.

Life cycle: See *L. ovillus*.

***Linognathus africanus* (African sheep louse)**

Description: Female lice are around 2.2 mm long and males 1.7 mm.

***Linognathus setosus* (dog sucking louse)**

Description: This species of louse is up to 2 mm long when fully fed, with a long pointed head. It does not have eyes or ocular points. The second and third pairs of legs are larger than the first pair and end in stout claws. The thoracic sternal plate is absent or if present is weakly developed. Paratergal plates are absent from the abdomen.

Life cycle: Adult females lay a single egg per day. Eggs hatch in 10–15 days, giving rise to nymphs that require about 2 weeks to pass through three nymphal stages. The egg-to-adult life cycle requires about 20–40 days.

Solenopotes

Description: Eyes and ocular points are absent, and the lice have a short rostrum. There are no paratergal plates on the abdomen. The second and third pairs of legs are larger than the first pair and end in stout claws. These lice may be distinguished from the genus *Linognathus* by the presence of abdominal spiracles set on slightly sclerotised tubercles, which project slightly from each abdominal segment (Fig. 3.56). Also, in contrast to species of *Linognathus*, the thoracic sternal plate is distinct.

Fig. 3.56 Dorsal view of adult female *Solenopotes*. (From Séguy, 1944.)

Solenopotes species of veterinary importance

| Species | Hosts | Site |
|--------------------------------|------------------------------|---|
| <i>Solenopotes capillatus</i> | Cattle | Skin, neck, head, shoulders, dewlap, back, tail |
| <i>Solenopotes burmeisteri</i> | Red deer, sika deer | Skin, head, neck, shoulders |
| <i>Solenopotes ferrisi</i> | Elk | Skin, head, neck, shoulders |
| <i>Solenopotes capreoli</i> | Roe deer | Skin, head, neck, shoulders |
| <i>Solenopotes muntiacus</i> | Muntjac deer | Skin, head, neck, shoulders |
| <i>Solenopotes tarandi</i> | Reindeer, caribou | Skin, head, neck, shoulders |
| <i>Solenopotes binipilosus</i> | White-tailed deer, mule deer | Skin, head, neck, shoulders |

Solenopotes capillatus

Description: Small bluish lice which tend to occur in clusters on the neck, head, shoulders, dewlap, back and tail. At 1.2–1.5 mm in length, *Solenopotes capillatus* is the smallest of the anopluran lice found on cattle.

Life cycle: Females lay one to two eggs per day, and oviposition usually causes the hairs on which eggs are laid to bend. Eggs hatch after about 10 days and lice moult three times before reaching adulthood 11 days later. The egg-to-adult life cycle requires about 5 weeks.

FAMILY MICROTHORACIIDAE

This family contains four species of the genus *Microthoracius*. Three species parasitise llamas, and a fourth species is a parasite of camels.

Microthoracius

Members of this family have a long spindle-shaped head with clypeal segments much shorter than the antenna–ocular segments. Eyes are evident and the antennae generally have five segments. Legs are similar in shape and size with pointed claws and a thick apical bristle.

Life cycle: The life cycle is typical, with eggs giving rise to three nymphal stages followed by the reproductive adult. The life cycle may be completed in as little as 2 weeks, and adults may live for up to 6 weeks.

Microthoracius species of veterinary importance

| Species | Hosts | Site |
|-------------------------------------|------------------------|-----------------------------------|
| <i>Microthoracius mazzai</i> | Llama, alpaca | Skin, neck |
| <i>Microthoracius animor</i> | Guanaco, llama, vicuna | Skin, neck |
| <i>Microthoracius praelongiceps</i> | Guanaco, llama, vicuna | Skin, neck |
| <i>Microthoracius cameli</i> | Camel | Skin, flanks, head, neck, withers |

***Microthoracius mazzai* (llama louse)**

Description: *Microthoracius mazzai* has a very characteristic elongated, spindle-shaped head that is almost as long as its swollen rounded abdomen. The entire body is 1–2 mm in length.

Life cycle: The life cycle is typical, with eggs giving rise to three nymphal stages followed by the reproductive adult. The life cycle

may be completed in as little as 2 weeks, and adults may live for up to 6 weeks.

***Microthoracius cameli* (camel sucking louse)**

Description: *Microthoracius cameli* has a very characteristic elongated, spindle-shaped head that is almost as long as its swollen rounded abdomen. The entire body is 1–2 mm in length.

Life cycle: The life cycle is typical, with eggs giving rise to three nymphal stages followed by the reproductive adult. However, little precise detail is known.

FAMILY POLYPLACIDAE

Lice of the genus *Polyplax* infest rodents and may cause problems in laboratory colonies. *Haemodipsus* is found on rabbits and hares and may be involved in the transmission of tularaemia in wild lagomorphs.

Polyplax

These lice are slender, 0.6–1.5 mm in length and yellow–brown in colour (Fig. 3.57). The head bears prominent five-segmented antennae, no eyes and no ocular points. There is a distinct sternal plate on the ventral surface of the thorax. The forelegs are small and the hindlegs are large with large claws and tibial spurs. The abdomen has 7–13 dorsal plates and approximately seven lateral plates on each side.

Life cycle: The lice spend their entire life cycle in the host and transmission occurs by direct contact. The eggs hatch in about 5–6 days

Fig. 3.57 Adult female *Polyplax* in dorsal view.

to give rise to three nymphal stages, followed by the reproductive adult. The first nymphal stage is found on the entire body, while older stages are found predominantly on the front of the body. The entire life cycle is completed in about 2 weeks.

Polyplax species of veterinary importance

| Species | Hosts | Site |
|---------------------------|-------|------|
| <i>Polyplax spinulosa</i> | Rat | Fur |
| <i>Polyplax serrata</i> | Mouse | Fur |

Polyplax spinulosa and Polyplax serrata

Description: The species are differentiated on the shape of the ventral thoracic plate. In *P. spinulosa* the ventral plate is triangular while in *P. serrata* it is pentagonal in shape.

FAMILY PEDICINIDAE

Lice of the genus *Pedicinus* are found on species of Old World monkeys.

FAMILY PEDICULIDAE

Lice of the genus *Pediculus*, which includes the human body louse (*P. humanus humanus*) and head louse (*P. humanus capitis*), are found on primates.

FAMILY PTHIRIDAE

Lice of the genus *Pthirus*, which includes the human crab louse (*P. pubis*), are found on primates.

SUBORDER AMBLYCERA

Amblycera are ectoparasites of birds, marsupials and New World mammals. Adults are medium-sized or relatively large lice, usually 2–3 mm in length. They have large rounded heads on which the eyes are reduced or absent. They are chewing lice with mouthparts consisting of distinct mandibles on the ventral surface and a pair of two- to four-segmented maxillary palps. The four-segmented antennae are protected in antennal grooves, so that only the last segment is visible. The Amblycera contains six families, of which the Menoponidae, Boopidae, Gyropidae and Trimenoponidae are of relevance to veterinary medicine.

FAMILY MENOPONIDAE

Several genera are of veterinary importance on birds. *Menacanthus* can cause severe anaemia and is the most pathogenic louse of adult domestic hens and cage birds, in particular canaries. *Menopon* is found mainly on the domestic hen, but it will spread to other fowl, such as turkeys and ducks, which are in contact. *Holomenopon*, *Ciconiphilus* and *Trinoton* are found on ducks; *Amyrsidea* and *Mecanthus* are found on gamebirds.

Menacanthus

The taxonomy of this genus is highly uncertain, with over 100 species described, although recent studies have synonymised dozens of species. This genus includes the chicken body louse or yellow body louse, *Menacanthus stramineus*, which is a relatively large pathogenic species.

Menacanthus species of veterinary importance

| Species | Hosts | Site |
|-------------------------------|---|--|
| <i>Menacanthus stramineus</i> | Chicken, turkey, guinea fowl, peafowl, pheasant, quail, cage birds (canary) | Skin, breast, thighs, vent, wings and head |
| <i>Menacanthus layali</i> | Gamebirds | Skin, body |

Menacanthus stramineus (yellow body louse, chicken body louse)

Description: Adult males measure approximately 2.8 mm in length and the female 3.3 mm. The head is almost triangular in shape and the ventral portion of the front of the head is armed with a pair of spine-like processes. The palps and four-segmented antennae are distinct. The antennae are club-shaped and mostly concealed beneath the head. The flattened abdomen is elongated and broadly rounded posteriorly with two dorsal rows of setae on each abdominal segment. There are three pairs of short, two-clawed legs (Fig. 3.58). The eggs have characteristic filaments on the anterior half of the shell and on the operculum.

Menopon

Species of the genus *Menopon* are feather lice found on chickens and other domestic birds.

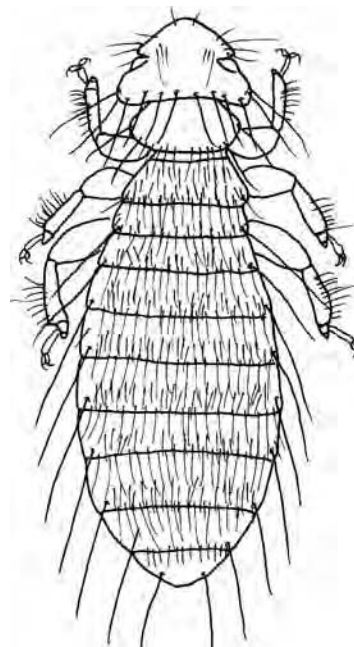

Fig. 3.58 Adult *Menacanthus stramineus* (dorsal view).

Menopon species of veterinary importance

| Species | Hosts | Site |
|---|-------------------------------|----------------------------------|
| <i>Menopon gallinae</i> | Chicken, turkey, duck, pigeon | Thigh and breast feathers |
| <i>Menopon leucoxanthum</i> (syn. <i>Holomenopon leucoxanthum</i>) | Duck | Feathers, especially preen gland |
| <i>Menopon pallens</i> | Gamebirds | Thigh and breast feathers |

***Menopon gallinae* (shaft louse)**

Description: Pale yellow, rapidly moving louse. It is a small louse; adults measure approximately 2 mm in length. *Menopon gallinae* has small palps and a pair of four-segmented antennae, folded into grooves in the head. The abdomen is tapered posteriorly in the female but rounded in the male and has a sparse covering of small to medium-length setae on its dorsal surface (Fig. 3.59).

Menopon leucoxanthum

Description: A small, rapidly moving louse that especially favours the preen gland, inhibiting production of the oily secretion and causing 'wet feather'.

Life cycle: The nymph moults three times over 2–3 weeks before giving rise to the reproductive adult. Individuals are highly mobile and move rapidly.

FAMILY BOOPIDAE

Members of this family occur on marsupials. *Heterodoxus* may be of importance on dogs and other Canidae.

Fig. 3.59 Adult *Menopon gallinae* (dorsal view).

Fig. 3.60 Adult female *Heterodoxus* in ventral view. (From Séguéy, 1944.)

Heterodoxus

Species in the genus *Heterodoxus* are primarily parasites of kangaroos and wallabies in Australia and New Guinea. The ancestor of the dog louse, *Heterodoxus spiniger*, presumably colonised dingos after their transport to Australia by early humans. From the dingo, the louse transferred to domestic dogs and from there the louse spread to other parts of the world.

***Heterodoxus* species of veterinary importance**

| Species | Hosts | Site |
|-----------------------------|-------------------|------------|
| <i>Heterodoxus spiniger</i> | Dog, other canids | Skin, body |

Heterodoxus spiniger

Description: *Heterodoxus spiniger* is a large, slender, yellowish-coloured louse. Adults are about 5 mm in length, with a dense covering of thick, medium and long setae (Fig. 3.60). It can easily be distinguished from other lice infesting domestic mammals since the tarsi end in two claws, as opposed to one in the Anoplura and Trichodectidae.

Life cycle: The life cycle is typical, with eggs giving rise to three nymphal stages followed by the reproductive adult. However, little detail is known.

FAMILY GYROPIDAE

Gyropus and *Gliricola* may be important in guinea pigs; *Aotiella* is found on primates. Species of this family may be distinguished from other families of chewing lice because the tarsi of the midlegs and hindlegs have either one or no claws.

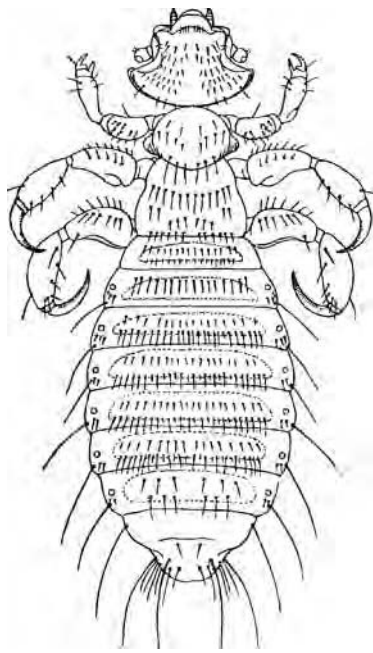

Fig. 3.61 Adult female *Gyropus ovalis*. (From Séguy, 1944.)

Fig. 3.62 Adult female *Gliricola porcelli*. (From Séguy, 1944.)

Gyropus

Gyropus species of veterinary importance

| Species | Hosts | Site |
|-----------------------|------------|--------------------------------|
| <i>Gyropus ovalis</i> | Guinea pig | Skin, especially ears and neck |

Gyropus ovalis (guinea pig louse)

Description: *Gyropus ovalis* is a chewing louse with club-shaped antennae positioned within grooves in the head. The head is broad and rounded with four-segmented maxillary palps and stout mandibles. The body is pale yellow in colour, oval in shape and 1–1.5 mm in length and has eight abdominal segments (Fig. 3.61).

Life cycle: The life cycle is typical, with eggs giving rise to three nymphal stages followed by the reproductive adult. However, little precise detail is known.

Gliricola

Gliricola species of veterinary importance

| Species | Hosts | Site |
|---------------------------|------------|----------|
| <i>Gliricola porcelli</i> | Guinea pig | Body fur |

Gliricola porcelli (guinea pig louse)

Description: A very similar species to *Gyropus ovalis*. However, *G. porcelli* is a slender yellow louse, typically measuring 1–2 mm in length and 0.3–0.4 mm in width (Fig. 3.62). The head is longer than it is wide and is rounded posteriorly. The maxillary palps have two

segments. Antennae are four-segmented with pedicellate terminal segments and are almost concealed by the antennal fossae. The five pairs of abdominal spiracles are located ventrally within distinct sclerotised spiracular plates. The stout legs are modified for grasping hair but have no tarsal claws. A ventral furrow on the abdomen aids attachment to hair.

FAMILY TRIMENOPONIDAE

Trimenopon is found on guinea pigs.

Trimenopon

Trimenopon species of veterinary importance

| Species | Hosts | Site |
|----------------------------|------------|----------|
| <i>Trimenopon hispidum</i> | Guinea pig | Body fur |

Trimenopon hispidum

Description: Similar in appearance to *Gyropus ovalis* but *Trimenopon hispidum* has five abdominal segments compared to *G. ovalis* with eight.

SUBORDER ISCHNOCERA

The Ischnocera includes five families, three of which, the Philopteridae on domestic birds and mammals and the Trichodectidae and Bovicolidae on mammals, are of major veterinary importance.

FAMILY PHILOPTERIDAE

The family Philopteridae contains the genera *Cuclotogaster*, *Lipeurus*, *Goniodes*, *Goniocotes* and *Columbicola*, species of which are important parasites of domestic birds. Other species of lesser importance belong to the genera *Anaticola*, *Acidoproctus*, *Anatoecus* and *Ornithobius*, which are found on ducks, geese and other waterfowl; *Lagopoecus*, which are found on gamebirds; *Struthiolipeurus* found on ostrich; *Tricholipeurus* found on deer; and *Trichophilopterus* found on primates. The Philopteridae have five-segmented antennae and paired claws on the tarsi.

Cuclotogaster

Head lice of birds and includes the poultry head louse, *Cuclotogaster heterographus*.

Cuclotogaster species of veterinary importance

| Species | Hosts | Site |
|------------------------------------|------------------------|-------------------------------|
| <i>Cuclotogaster heterographus</i> | Chicken, other poultry | Skin, feathers, head and neck |
| <i>Cuclotogaster obsuricor</i> | Gamebirds | Skin, feathers, head and neck |

Cuclotogaster heterographus (head louse)

Description: *Cuclotogaster heterographus* has a rounded body with a large slender head that is rounded at the front (Fig. 3.63). Adult males measure approximately 2.5 mm and females 2.6 mm in length. The first segment of the antennae of males is long and thick and bears a posterior process. The abdomen is elongate in the male and barrel-shaped in the female, with dark brown lateral tergal plates. Three long bristles project from each side of the

Fig. 3.63 Adult female *Cuclotogaster heterographus* (dorsal view).

dorsal surface of the head and the five-segmented antennae are fully exposed. Each leg has two tarsal claws.

Lipeurus

Grey, slow-moving lice found close to the skin on the underside of the large wing feathers.

Lipeurus species of veterinary importance

| Species | Hosts | Site |
|---------------------------|-------------------|------------------------------|
| <i>Lipeurus caponis</i> | Chicken, pheasant | Skin, wing and tail feathers |
| <i>Lipeurus maculosus</i> | Gamebirds | Skin, wing and tail feathers |

Lipeurus caponis (wing louse)

Description: *Lipeurus caponis* is an elongated narrow species, about 2.2 mm in length and 0.3 mm in width (Fig. 3.64). The head is long and rounded at the front, and the antennae are five-segmented and fully exposed. The legs are narrow and bear two tarsal claws. Characteristically the hindlegs are about twice as long as the first two pairs of legs. There are characteristic small angular projections on the head in front of the antennae. There are relatively few dorsal hairs on the abdomen.

Struthiolipeurus

Lice found close to the skin on the underside of the large wing feathers of ostrich.

Life cycle: The biology of these lice has not been fully studied, but is thought to be typical: egg, several nymphal stages and adult requiring about 1 month for completion. Eggs are deposited on feather barbs.

Fig. 3.64 Adult *Lipeurus caponis* (dorsal view).

Struthiolipeurus species of veterinary importance

| Species | Hosts | Site |
|-------------------------------------|---------|------------------------------|
| <i>Struthiolipeurus struthionis</i> | Ostrich | Skin, wing and tail feathers |
| <i>Struthiolipeurus nandu</i> | Ostrich | Skin, wing and tail feathers |
| <i>Struthiolipeurus stresmanni</i> | Ostrich | Skin, wing and tail feathers |
| <i>Struthiolipeurus rhea</i> | Ostrich | Skin, wing and tail feathers |

Struthiolipeurus struthionis

Description: Narrow-bodied lice with large heads.

Meinertzhageniella
Meinertzhageniella species of veterinary importance

| Species | Hosts | Site |
|-------------------------------------|-------|------------------------------|
| <i>Meinertzhageniella lata</i> | Rhea | Skin, wing and tail feathers |
| <i>Meinertzhageniella schubarti</i> | Rhea | Skin, wing and tail feathers |

Dahlehornia
Dahlehornia species of veterinary importance

| Species | Hosts | Site |
|--------------------------------|-------|------------------------------|
| <i>Dahlehornia asymmetrica</i> | Emu | Skin, wing and tail feathers |

Goniodes

Description: These are very large brown lice, with males measuring 3–4 mm and females around 5 mm in length. They have a broad head, which is concave posteriorly, producing marked angular corners at the posterior margins. The head bears two large bristles, which project from each side of its dorsal surface. The antennae have five segments and are fully exposed. Each leg has two tarsal claws.

Life cycle: During a lifespan of about a month the female lays 200–300 operculate eggs. These are usually whitish, and are glued to the hair or feathers, where they may be seen with the naked eye. The eggs hatch within 4–7 days and the lice spend their entire life cycle on the host, feeding on feather debris. The nymph that hatches from the egg is similar to, though much smaller than, the adult. The nymph moults three times over 2–3 weeks before giving rise to the reproductive adult.

Goniodes species of veterinary importance

| Species | Hosts | Site |
|-----------------------------|--------------------------------|------------------------|
| <i>Goniodes gigas</i> | Chicken, pheasant, guinea fowl | Skin and body feathers |
| <i>Goniodes dissimilis</i> | Chicken | Skin and body feathers |
| <i>Goniodes meleagridis</i> | Turkey | Skin and body feathers |
| <i>Goniodes colchici</i> | Gamebirds | Skin and body feathers |
| <i>Goniodes dispar</i> | Gamebirds | Skin and body feathers |
| <i>Goniodes pavonis</i> | Peafowl | Skin and body feathers |

***Goniodes gigas* (large chicken louse)**

Description: Very large brown lice occurring on the body and feathers of the fowl. Males measure 3–4 mm and females 5 mm in length.

Fig. 3.65 Adult female *Goniodes dissimilis* (dorsal view).

***Goniodes dissimilis* (brown chicken louse)**

Description: *Goniodes dissimilis* is a large louse about 3 mm in length and brown in colour (Fig. 3.65).

Goniodes meleagridis

Description: These lice are characterised by broad mandibles located ventrally on the head, short antennae (three to five segments) and a dorsoventrally flattened body. They are large lice, the adults reaching up to 5 mm in length.

Goniocotes

This genus includes the poultry fluff louse, *Goniocotes gallinae*.

Goniocotes species of veterinary importance

| Species | Hosts | Site |
|---------------------------------|-----------|----------|
| <i>Goniocotes gallinae</i> | Chicken | Feathers |
| <i>Goniocotes chryocephalus</i> | Gamebirds | Feathers |
| <i>Goniocotes obscurus</i> | Gamebirds | Feathers |
| <i>Goniocotes microthorax</i> | Gamebirds | Feathers |

***Goniocotes gallinae* (fluff louse)**

Description: *Goniocotes gallinae* is one of the smallest lice found on poultry, at about 0.7–1.3 mm in length. It has a pale yellow, almost circular body (Fig. 3.66). The head is rounded and carries two large bristles projecting from each side of its dorsal surface. The antennae are five-segmented, fully exposed and the same in both sexes.

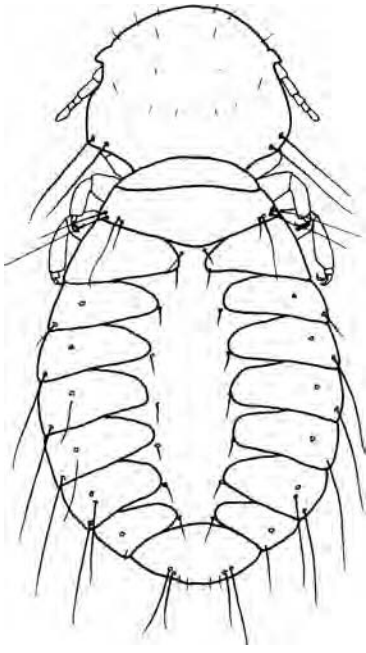

Fig. 3.66 Adult female *Gonicotes gallinae* (dorsal view).

There are two tarsal claws on each leg and few hairs on the dorsal abdomen.

Columbicola

The genus *Columbicola* includes 82 species affecting pigeons and doves. Members of this genus are slender elongate lice, with most species showing sexual dimorphism of the antennae, with males having a much enlarged scape and distally expanded third segment. The head has a distinct bilobed dorso-anterior head plate with a pair of forward-directed broad medio-anterior setae.

Life cycle: Eggs of this species are usually attached to the feathers close to the skin. There are three nymphal stages similar to, though much smaller than, the adult. Development of the final stage gives rise to the fully mature reproductive adult.

Columbicola species of veterinary importance

| Species | Hosts | Site |
|-----------------------------|--------------|-------------------------|
| <i>Columbicola columbae</i> | Pigeon, dove | Skin, wings, head, neck |

Columbicola columbae

Description: A pale-yellow slender louse usually 2–3 mm in length. The head of the male has a long pair of medio-posterior setae extending beyond the posterior margin.

FAMILY TRICHODECTIDAE

The family Trichodectidae contains the genera *Felicola*, the sole species of louse found on cats; *Trichodectes*, found on dogs and primates; and *Eutrichophilus* and *Cebidicola*, found on primates.

Felicola

Species belonging to this genus are found on members of the cat family and include *Felicola subrostratus*, the only species that commonly occurs on cats.

Life cycle: Eggs are laid on the cat fur and hatch in 10–20 days. The adult stage is reached within 2–3 weeks and the egg-to-adult life cycle requires about 30–40 days.

Felicola species of veterinary importance

| Species | Hosts | Site |
|------------------------------|-------|--------------------------|
| <i>Felicola subrostratus</i> | Cat | Skin, face, pinnae, back |

Felicola subrostratus (cat biting louse)

Description: This louse is beige or yellow in colour, with transverse brown bands. Adults are an average of 1–1.5 mm in length. The shape of the head is very characteristic, being triangular and pointed anteriorly (Fig. 3.67). Ventrally there is a median longitudinal groove on the head, which fits around the individual hairs of the host. The antennae have three segments, are fully exposed and are similar in both sexes. The legs are small, slender and end in single claws. The abdomen has only three pairs of spiracles and is smooth with few setae.

Trichodectes

Species belonging to this genus are found on members of the dog family. The single species of veterinary importance, *Trichodectes canis*, is commonly found on domestic dogs.

Fig. 3.67 Adult female *Felicola* in ventral view. (From Séguy, 1944.)

Fig. 3.68 Adult female *Trichodectes* in ventral view. (From Séguy, 1944.)

Trichodectes species of veterinary importance

| Species | Hosts | Site |
|---------------------------|------------------|-----------------------------------|
| <i>Trichodectes canis</i> | Dog, wild canids | Skin, head, neck and tail regions |

Trichodectes canis (dog biting louse)

Description: *Trichodectes canis* is a small, broad, yellowish-coloured louse (Fig. 3.68). It is 1–2 mm in length, with dark markings. The head is broader than long and the antennae are three-segmented, short and exposed. The legs are stout and their tarsi bear single claws, with which they tightly grasp the hair of their host. The abdomen has six pairs of spiracles on segments 2–6, and many rows of large thick setae.

Life cycle: *Trichodectes canis* commonly infests the head, neck and tail regions, where it attaches to the base of a hair using its claws or mandibles. The female lays several eggs per day for approximately 30 days. Eggs hatch in 1–2 weeks and give rise to three nymphal stages. The nymphs mature into reproductive adults within about 2 weeks. The egg-to-adult life cycle requires about 30–40 days.

FAMILY BOVICOLIDAE

The family Bovicolidae contains the genus *Bovicola* (formerly *Damalinia*), found on cattle, sheep, horses and deer. *Werneckiella*, sometimes described as a genus, but here described as a subgenus of *Bovicola*, contains the species *Bovicola* (*Werneckiella*) *ocellatus* found on donkeys.

Bovicola

This genus includes a number of morphologically similar host-specific species of lice on domestic animals.

Bovicola species of veterinary importance

| Species | Hosts | Site |
|--|----------------|---|
| <i>Bovicola ovis</i> (syn. <i>Damalinia ovis</i>) | Sheep | Skin, mainly on the back and upper parts of the body |
| <i>Bovicola caprae</i> (syn. <i>Damalinia caprae</i>) | Goat | Skin, head, back and flanks |
| <i>Bovicola limbata</i> (syn. <i>Damalinia limbata</i>) | Goat (angora) | Skin, back and flanks |
| <i>Bovicola bovis</i> (syn. <i>Damalinia bovis</i>) | Cattle | Skin, head, poll, forehead, neck, shoulders, back, rump, and occasionally the tail switch |
| <i>Bovicola equi</i> (syn. <i>Damalinia equi</i> , <i>Trichodectes parumpilosus</i> , <i>Werneckiella equi equi</i>) | Horse | Skin, neck, flank, tail base |
| <i>Bovicola</i> (<i>Werneckiella</i>) <i>ocellatus</i> | Donkey | Skin, face, neck, back, flanks |
| <i>Bovicola tibialis</i> | Deer (fallow) | Skin, neck, back, flanks |
| <i>Bovicola mayeri</i> | Deer (roe) | Skin, neck, back, flanks |
| <i>Bovicola maai</i> | Deer (sika) | Skin, neck, back, flanks |
| <i>Bovicola forticula</i> | Deer (muntjac) | Skin, neck, back, flanks |

Bovicola ovis

Synonym: *Damalinia ovis*

Description: These chewing lice are up to 3 mm long, reddish-brown in colour, with a relatively large head that is as wide as the body and rounded anteriorly. The mouthparts are ventral. *Bovicola* have three-segmented antennae and a single claw on each tarsus.

Life cycle: Female lice live about 1 month and lay one to three operculate eggs per day. The eggs are usually whitish, and are glued to the hair where they may be seen with the naked eye. *Bovicola ovis* prefers areas close to the skin such as the back, neck and shoulder, but is highly mobile and severe infestations will spread over the whole body. It is estimated to take about 20 weeks for a population of *B. ovis* on a sheep to increase from 5000 to half a million, under favourable conditions. A nymph hatches from the egg; nymphs are similar to, though much smaller than, the adult. The nymph moults twice, at 5–9 day intervals, until eventually moulting to become an adult. The whole cycle from egg to adult takes 2–3 weeks.

The mouthparts of these lice are adapted for biting and chewing the outer layers of the hair shafts, dermal scales and blood scabs. *Bovicola ovis* is capable of rapid population expansion and this is thought to be aided by their ability to change from sexual to asexual reproduction by parthenogenesis (although this has not yet been demonstrated definitively). Hence, highly female-biased sex ratios may be common in a growing population.

Bovicola bovis (red louse, cattle chewing louse)

Synonym: *Damalinia bovis*

Description: *Bovicola bovis* are a reddish-brown in colour with dark transverse bands on the abdomen. Adult lice are up to 2 mm long and 0.35–0.55 mm in width. The head is relatively large, as wide as the body, and is rounded anteriorly (Fig. 3.69). The mouthparts are ventral and are adapted for chewing. The legs are slender

Fig. 3.69 Dorsal view of adult female *Bovicola*. (From Séguy, 1944.)

and are adapted for moving among the hair. The claws, on each leg, are small. The nymphs also have lighter sclerotisation and less distinct banding than adult lice. The nymph is similar in appearance though much smaller than the adult.

Life cycle: During a lifespan of about a month the female lays an egg every 2 days on average. These eggs are usually whitish, and are glued singly to the hair shaft where they may be seen with the naked eye. The eggs hatch after 7–10 days and each nymphal instar lasts 5–6 days. After three nymphal stages, the nymph moults again to become an adult. The whole cycle from egg to adult takes 2–3 weeks. Adults may live for up to 10 weeks. *Bovicola bovis* is also believed to be capable of increasing its rate of population growth by parthenogenesis. As a result, highly female-biased sex ratios may be commonly found in a growing population.

***Bovicola equi* (horse louse)**

Synonyms: *Damalinia equi*, *Trichodectes parumpilosus*, *Werneckiella equi equi*

Description: These lice are up to 1–2 mm long and reddish-brown in colour. The relatively large head is as wide as the wingless body, and rounded anteriorly. The mouthparts are ventral. This species has a three-segmented antenna and a single claw on the tarsi.

Life cycle: Female lice lay one egg approximately every day, glued singly on to a hair shaft. The eggs are usually whitish and may be seen with the naked eye. Females avoid ovipositing on the coarse hairs of the mane and tail, instead preferring finer hairs on the side of the neck, the flanks and the tail base. In severe cases the infestation may cover most of the body. The egg hatches into a nymph that is similar in appearance to the adult, though the nymph is much smaller, with lighter sclerotisation and less distinct banding. The cycle from egg to adult takes 3–4 weeks.

SUBORDER RYNCOPHTHIRINA

The Rhynchophthirina is a very small suborder including just two species, which are parasites of elephants and warthogs.

ORDER SIPHONAPTERA

Fleas (Siphonaptera) are small, wingless, obligate blood-feeding insects. Both sexes are blood feeders and only the adults are parasitic. The order is relatively small with about 2500 described species, almost all of which are morphologically extremely similar. Over 95% of flea species are ectoparasites of mammals, while the others are parasites of birds.

Fleas (Fig. 3.70) are dark-brown wingless insects, usually between 1 and 6 mm in length, with females being larger than males. The body colour may vary from light brown to black. The body is laterally compressed with a glossy surface, allowing easy movement through hairs and feathers. Eyes, when present, are simply dark photosensitive spots, and the antennae, which are short and club-like, are recessed into the head. The third pair of legs is much longer than the others, an adaptation for jumping. The head and first segment of the thorax (pronotum) may bear ventral (genal) or posterior (pronotal) rows of dark spines called ctenidia or 'combs', and these are important features used in identification (Table 3.3).

Many species of flea are able to parasitise a range of hosts. This, combined with their mobility, which allows them to move easily between hosts, makes them parasites of considerable medical and veterinary importance and makes them difficult to control. Once on their host, fleas feed daily or every other day. Females require

Fig. 3.70 Morphological features of an adult flea. (From Gullan and Cranston, 1994.)

Table 3.3 Morphological differentiation of fleas based on presence or absence of pronotal and genal combs.

| No combs present | Pronotal combs only | Both pronotal and genal combs | |
|--------------------------------|-------------------------------|-------------------------------|---|
| | | Few combs | Several combs |
| <i>Xenopsylla cheopis</i> | <i>Nosopsyllus fasciatus</i> | <i>Archaeopsylla erinacei</i> | <i>Ctenocephalides felis</i> |
| <i>Pulex irritans</i> | <i>Ceratophyllus gallinae</i> | | <i>Ctenocephalides canis</i> |
| <i>Echidnophaga gallinacea</i> | | | <i>Spilopsyllus cuniculi</i> <i>Leptopsylla segnis</i> |

significantly more blood than males and an initial blood meal is required to start egg production. Blood-feeding may have a range of damaging effects on the host animal, causing inflammation, pruritus or anaemia. Fleas may also act as vectors of bacteria, protozoa, viruses and tapeworms. However, in veterinary entomology fleas are probably of most importance as a cause of cutaneous hypersensitivity reactions. Though most important in dogs, cats and poultry, their readiness to parasitise humans as alternative hosts gives the fleas of these domestic animals a relevance in public health. Ruminants, horses and pigs do not have their own species of fleas.

FLEA LIFE CYCLES

Fleas are holometabolous and go through four life-cycle stages: egg, larva, pupa and adult (Fig. 3.71). The ovoid eggs have smooth surfaces, and may be laid on the ground or on the host from which they soon drop off. Hatching occurs in 2 days to 2 weeks, depending on the temperature of the surroundings. The larvae are maggot-like, with a distinct, brownish head, and body segments bear a cirlet of backwardly directed bristles that, together with the anal struts on the last segment, enable the larva to move. There are no appendages. They have chewing mouthparts and feed on organic debris (skin, fur or feathers) but also particularly on the faeces of the adult fleas, which contain blood and give the larvae a reddish colour. The larva moults twice, the final stage being about 5–10 mm long, and then spins a cocoon, from which the adult emerges. Moulting and pupation are dependent on the ambient temperature and humidity. Under ideal conditions, the entire cycle may take only 18 days to complete, although it can range from 6 to 12 months.

Two broad trends in flea life cycles can be seen. A simple association with the nest habitat is preserved in many groups of the family Ceratophyllidae, characterised by infrequent and brief associations with the host and often considerable adult movement between hosts and nests. In contrast, many groups of the family Pulicidae show prolonged adult associations with the host. However, within these broad categories, a high degree of variation may exist. A few genera remain permanently attached throughout adult life. These are the burrowing, or 'stickfast', fleas, whose females are embedded in the skin, within nodules. Only the posterior part of these fleas

communicates with the surface, allowing the eggs or larvae to drop to the ground and develop in the usual manner.

There are generally considered to be 15 or 16 families and 239 genera. Only two families contain species of veterinary importance: the **Ceratophyllidae** and the **Pulicidae**.

FAMILY CERATOPHYLLIDAE

The Ceratophyllidae is a large family containing over 500 species, of which about 80 species are parasites of birds and the remainder are parasites of rodents.

Nosopsyllus

Species in this genus are parasites of rodents, including squirrels, with the one cosmopolitan species of veterinary significance, the northern rat flea *Nosopsyllus fasciatus*.

Nosopsyllus species of veterinary importance

| Species | Hosts | Site |
|------------------------------|-------------------|--------------|
| <i>Nosopsyllus fasciatus</i> | Rat, mouse, human | Fur and skin |

Nosopsyllus fasciatus (northern rat flea)

Description: The flea is elongated, about 3–4 mm in length and has a pronotal comb with 18–20 spines. A genal comb is absent (Fig. 3.72). Eyes are present, and the head carries a row of three setae below the eye. The frontal tubercle on the head of both sexes is conspicuous. There are three or four bristles on the inner surface of the hind femur.

Fig. 3.71 Life cycle of a typical flea: (a) adult; (b) egg; (c) larva; (d) pupa. (Adapted from Séguy, 1944.)

Fig. 3.72 The northern rat flea, *Nosopsyllus fasciatus*, male head. (Adapted from Smart, 1943.)

Life cycle: The life cycle is typical: egg, three larval stages, pupa and adult. Life-cycle development may be completed at temperatures as low as 5°C. Larval stages are found only in the nest or burrow. The larvae of this species may pursue and solicit faecal blood meals from adult fleas. The larvae grasp the adult in the region of the sensillum using their large mandibles. Adults respond by defecating stored semi-liquid blood, which is then imbibed by the larvae directly from the anus.

Ceratophyllus

Ceratophyllus parasitise mainly squirrels and other rodents, but contains two species of veterinary importance because they feed on poultry and other birds.

Life cycle: The life cycle is typical: egg, three larval stages, pupa and adult. Unlike most other fleas, which often remain on the host and feed for long periods, chicken and pigeon fleas spend most of their time in the nest of the host, and only move on to the birds to feed for short periods. The larvae feed on detritus among the nest material, droppings and on undigested blood from the adult faeces. The larval stages are completed in a few weeks, before the pupal cocoon is spun. The flea overwinters in the cocoon and emerges in an old nest in spring as temperatures rise. Large numbers may occur in the nests of passerine birds and they may complete their life cycle during the period of nest occupation by these birds. Work has shown a negative correlation between flea abundance and mean body mass of the brood being parasitised.

If the nest is reused by birds the following year, the newly emerged adults will locate the new hosts, feed and continue the cycle. If the nest is not reused, the newly emerged adults will make their way to the nest entrance, where they may be able to attach to a bird that is examining the old nest as a potential nest site. Alternatively, they may climb up trees and bushes, where they stop periodically and face the brightest source of light, jumping in response to a shadow passing in front of the light.

Ceratophyllus species of veterinary importance

| Species | Hosts | Site |
|-------------------------------|-------------------------------|------|
| <i>Ceratophyllus gallinae</i> | Poultry, wild birds | Skin |
| <i>Ceratophyllus niger</i> | Poultry, dog, cat, rat, human | Skin |
| <i>Ceratophyllus columbae</i> | Pigeon | Skin |

Ceratophyllus gallinae

Description: Adults of *Ceratophyllus gallinae* are typically 2–2.5 mm long with no antennal fossae. Eyes are present. There is a pronotal comb, carrying more than 24 spines, while the genal comb is absent (Fig. 3.73). There is a lateral row of four to six bristles on the inner surface of the hind femur and there are no spines on the basal section of the legs.

Ceratophyllus niger

Description: The genal comb is absent and the pronotal comb has more than 24 spines. Eyes are present and the head bears a row of three strong setae below the eye.

Fig. 3.73 Head and pronotum of a female chicken flea, *Ceratophyllus*. (Adapted from Smart, 1943.)

FAMILY PULICIDAE

The Pulicidae are parasites of a range of mammals with worldwide distribution. Genera of veterinary importance include *Ctenocephalides* (dog and cat fleas), *Spilopsyllus*, *Echidnophaga*, *Pulex*, *Xenopsylla*, *Archaeopsylla* and *Tunga*.

Ctenocephalides

The genus contains 11 species which are primarily parasites of carnivores, though some species are found on hares and ground squirrels. *Ctenocephalides* fleas can be vectors of plague and are intermediate hosts of the tapeworm *Dipylidium caninum*.

Ctenocephalides species of veterinary importance

| Species | Hosts | Site |
|------------------------------|-----------------------------------|------------|
| <i>Ctenocephalides felis</i> | Cat, dog, human | Skin, hair |
| <i>Ctenocephalides canis</i> | Dog, cat, rat, rabbit, fox, human | Skin, hair |

Ctenocephalides felis

Subspecies: *Ctenocephalides felis felis*, *Ctenocephalides felis strongylus*, *Ctenocephalides felis damarensis*, *Ctenocephalides felis orientalis*

Description: Cat fleas are dark brown/black, with laterally compressed bodies which have a glossy surface. Females typically measure 2.5 mm in length; males are smaller, sometimes less than 1 mm in length. Eyes are simply dark photosensitive spots, and the antennae, which are short and club-like, are recessed into the head. In the female *C. f. felis*, the head is twice as long as high and pointed anteriorly (Fig. 3.74). In the male *C. f. felis*, the head is as long as wide but is also slightly elongate anteriorly. The third pair of legs

Fig. 3.74 The cat flea, *Ctenocephalides felis felis*: (a) front of male head; (b) female head and pronotum; (c) hind tibia.

is much longer than the others and, coupled to elaborate internal musculature, provide an adaptation for jumping to locate their host. The genal comb consists of seven to eight spines and the pronotal comb about 16 spines. The teeth of the genal comb are all about the same length. On the dorsal border of the hind (metathoracic) tibia in both sexes of *C. f. felis* there are only six notches bearing setae. Between the post-median and apical long setae there is a short sub-apical spine.

Life cycle: Both sexes are blood feeders, and only the adults are parasitic. Once on its host *C. f. felis* tends to become a permanent resident. Within 24–48 hours of the first blood meal females begin to oviposit. The pearly white ovoid eggs (Fig. 3.75), which measure 0.5 mm in length, have smooth surfaces and may be laid on the ground or on the host, from which they soon drop off. In the laboratory, an adult female *C. f. felis* can produce an average of about 30 eggs per day and a maximum of 50 eggs per day, over a lifespan of about 50–100 days. However, on a cat, the average lifespan is probably substantially lower than this, possibly less than 1 week. The

rate of oviposition is highest at times of day when cats normally rest, in the early morning and late afternoon. As a result, flea eggs are concentrated at host resting sites rather than over the large areas they roam. The eggs cannot withstand major climatic variations, particularly in temperature and humidity. Only those eggs that fall into an appropriate environment will ultimately develop into adults. At 70% relative humidity and 35°C, 50% of eggs hatch within 1.5 days. At 70% relative humidity and 15°C it takes 6 days for 50% of eggs to hatch. Eggs cannot survive below 50% relative humidity.

Hatching occurs in 2 days to 2 weeks, depending on the temperature of the surroundings. The creamy yellow larvae are elongate, slender and maggot-like (Fig. 3.76); each segment carries a ring of bristles. The last abdominal segment bears two hooked processes called anal struts, which are used for gripping in locomotion. They have chewing mouthparts and feed on debris and on the faeces of the adult fleas, which contain blood and give the larvae a reddish colour.

Within the host's bedding, den or lair the larvae of *C. f. felis* exist in a protected environment, with relatively high humidity, buffered

Fig. 3.75 Flea egg.

Fig. 3.76 Flea larva.

from the extreme fluctuations of ambient temperatures and provided with detritus and a source of adult flea faecal blood. The larvae have limited powers of movement (probably less than 20 cm before pupation) and crawl about their environment largely at random, but they are negatively phototactic and positively geotactic. In the domestic environment this behaviour often takes them to the base of carpets where they can encounter food and are sheltered from light and mechanical damage. The larva moults twice, the final stage being about 5 mm long. At 24°C and 75% relative humidity, the duration of the three larval stages is about 1 week, but in unfavourable conditions larvae may develop more slowly. At 13°C and 75% relative humidity larval development takes about 5 weeks, though the larval cycle can take up to 200 days. Larvae will only survive at temperatures between 13 and 35°C. The larvae are extremely susceptible to desiccation and mortality is high below 50% relative humidity.

When fully developed, the mature third-stage larva empties its gut and spins a thin silk cocoon. This process requires a vertical surface against which they can align themselves. Fragments of detritus adhere to the cocoon giving it some degree of camouflage. The larva pupates within the cocoon. At 24°C and 78% relative humidity the duration of the pupal stage is about 8–9 days. If the pupal stage is disturbed the larvae will either spin another cocoon or develop into naked pupae, showing that the cocoon is not essential for development into an adult. When fully developed, adults emerge from the pupal cuticle but may remain within the cocoon. Adults may remain in this state for up to 140 days at 11°C and 75% relative humidity. At cooler temperatures, fully formed fleas may remain in their cocoons for up to 12 months.

The areas within a building with the necessary humidity for egg and larval development are limited. Sites outdoors are even less common and flea larvae cannot develop in arid areas exposed to the hot sun. If found outside they typically inhabit the top few millimetres of soil.

Emergence of the adult from the cocoon is triggered by stimuli such as mechanical pressure, vibrations or heat. Adult emergence may be extremely rapid, when provided with appropriate conditions. The ability to remain within the cocoon for extended periods is essential for a species such as *C. f. felis* since its mobile hosts may

only return to the lair or bedding at infrequent intervals. The fully formed adults begin to feed almost as soon as they are on their host, though they can survive for several days without feeding, provided the relative humidity is above about 60%. Within 36 hours of adult emergence most females will have mated. Females will mate with several males and egg-laying begins 24–48 hours after the first blood meal.

Within 10 minutes of feeding adults begin to produce faeces. Partially digested host blood forms a large component of the flea faeces. The faeces quickly dry into reddish-black faecal pellets known as 'flea dirt'.

It is important to recognise that most of the flea's life cycle is spent away from the host. This includes not only the eggs, larvae and cocoon, but also, if necessary, the adult flea.

Ctenocephalides canis

Description: The dog flea, *C. canis*, is closely related and is morphologically very similar to the cat flea *C. f. felis*, although they cannot interbreed and are therefore truly distinct species. The head of the female dog flea is more rounded on its upper and anterior surface than that of the cat flea and less than twice as long as high. Like *C. f. felis*, the dog flea has both genal and pronotal combs. The genal comb consists of seven to eight spines and the pronotal comb about 16 spines. However, in both female and male *C. canis* the first spine of the genal comb is shorter than the rest. On the dorsal border of the hind (metathoracic) tibia in both sexes of *C. canis* there are eight notches bearing stout setae (Fig. 3.77).

Life cycle: The life cycle of *C. canis* (egg, vermiform larva, pupa and adult) is very similar to that of *C. f. felis*. Egg production commences 2 days after the male and female arrive on the dog. Eggs and larvae do not survive at temperatures of over 35°C, preferring a temperature range between 13 and 32°C and relative humidity between 50 and 90%. In these conditions even unfed adults can survive for many weeks. Pupae may remain dormant for a year or more, yet are able to hatch in 30 seconds when cues, such as vibration, indicate the presence of a suitable host. In an appropriate environment the total life cycle may take as little as 3 weeks.

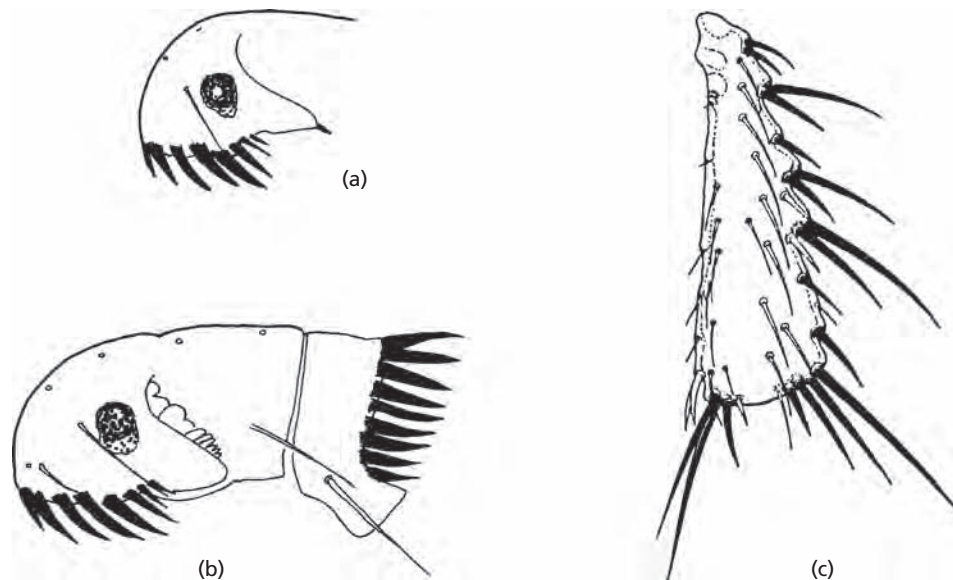

Fig. 3.77 The dog flea, *Ctenocephalides canis*: (a) front of male head; (b) female head and pronotum; (c) hind tibia.

Spilopsyllus

This genus includes the rabbit flea, *Spilopsyllus cuniculi*, which is a common vector of myxomatosis.

Spilopsyllus species of veterinary importance

| Species | Hosts | Site |
|------------------------------|------------------------|------|
| <i>Spilopsyllus cuniculi</i> | Rabbit, hare, dog, cat | Ears |

Spilopsyllus cuniculi (rabbit flea)

Description: The rabbit flea, *S. cuniculi*, has both pronotal and genal combs, the latter being composed of four to six oblique spines. Adults are dark brown, and females are, on average, 1 mm in length; males are slightly smaller. Eyes are present and the frons at the front of the head is rounded with the frontal tubercle conspicuous. There are two stout spines beneath the eye (Fig. 3.78).

Life cycle: The rabbit flea, *S. cuniculi*, occurs largely on the ears. It is more sedentary than most other species of flea and remains for long periods with its mouthparts embedded in the host. The life cycle of this species is believed to be mediated by host hormones imbibed with the host blood. The presence of progesterones inhibits or delays flea maturation. Following mating, the adult female rabbit ovulates and, about 10 days before parturition, the levels of oestrogens and corticosteroids in the blood increase. These hormones cause the fleas to attach tightly to their host and stimulate development of the eggs of the female flea. Reproductive hormones of the pregnant female host stimulate maturation of the ovaries and oocytes of feeding female fleas and testicular development in males. These fleas can only reproduce after feeding on a pregnant doe. This serves to synchronise the life cycles of the flea and its host and results in the emergence of adult fleas at the same time as a new litter of host animals are born. The adult fleas become ready to mate when the litter is born: an airborne kairomone emanating from the newborn

Fig. 3.78 Head and pronotum of the rabbit flea, *Spilopsyllus cuniculi*.

rabbits and their urine boosts copulation. The hormones of the host also cause adult fleas to increase the rate of feeding and defecation by about five times. This provides an abundance of food in the burrow for the newly hatched larvae. Oviposition occurs soon after adults have transferred onto the newborn young. The larvae feed on organic matter in the nest debris and mature 15–45 days later when they infest the host littermates before they disperse from the burrow. Populations of *S. cuniculi* may increase dramatically during the rabbit breeding season. Adult female fleas on bucks or non-pregnant does are more mobile and will move to pregnant does if able. The rise in ear temperature during rabbit mating will also stimulate movement of fleas from one rabbit to another.

Echidnophaga

The genus *Echidnophaga* includes some 21 species of fleas and includes the cosmopolitan sticktight flea, *Echidnophaga gallinacea*, which occurs on a wide range of birds and mammals.

Echidnophaga species of veterinary importance

| Species | Hosts | Site |
|--------------------------------|---|------|
| <i>Echidnophaga gallinacea</i> | Poultry, also cat, dog, rabbit, horse and human | Skin |

Echidnophaga gallinacea (sticktight flea)

Description: The sticktight flea, *E. gallinacea*, is a burrowing flea important mainly in domestic poultry. The adult sticktight flea is small: females are commonly about 2 mm in length and the males are less than 1 mm in length. The head is sharply angled at the front (frons). There are no genal or pronotal combs (Fig. 3.79). On the head behind the antenna there are two setae and, in the female,

Fig. 3.79 The sticktight flea, *Echidnophaga gallinacea*, female head and thorax (arrow marks angulation of the frons). (Adapted from Smart, 1943.)

usually a well-developed occipital lobe. The thoracic segments are narrowed dorsally. Spiracles are present on the second and third abdominal segments. The mouthparts appear large, extending the length of the forecoxae, and project from the head conspicuously. The maxillary laciniae are broad and coarsely serrated. On the anteroventral surface of each hind coxa, there are three rows of minute spiniform bristles.

Life cycle: After host location, females aggregate on bare areas, often the head, comb or wattles. Newly emerged adults are active and move towards sunlight, which helps them accumulate on the wattles of cocks or hens. After feeding, females burrow into the skin where they attach firmly with their mouthparts. Each female may remain attached for between 2 and 6 weeks. Copulation then takes place. The skin around the point of attachment may become ulcerated. The female begins oviposition an average of 6–10 days after attachment, at a rate of about one to four eggs per day. Eggs are laid in the ulceration or dropped to the ground. If laid in the ulceration, larvae hatch, emerge from the skin and drop to the ground to complete their development. The incubation period may last 4–14 days, though typically it takes 6–8 days. Eggs fail to survive temperatures of 43°C and above. The larvae feed on chicken manure and develop through three larval stages over a period of 14–31 days. The pupal period generally requires around 9–19 days and the entire life cycle may be completed in 30–60 days. Adults generally locate a new host and attach within about 5–8 days after emergence.

Fig. 3.80 The human flea, *Pulex irritans*, male head and pronotum. (Adapted from Smart, 1943.)

Pulex

This genus contains six species of which the most important is *Pulex irritans*, the human flea, which is common on pigs.

Pulex species of veterinary importance

| Species | Hosts | Site |
|-----------------------|---|------|
| <i>Pulex irritans</i> | Humans and pigs; may also occur on dog, cat, rat and badger | Skin |
| <i>Pulex simulans</i> | Dog, cat, wild mammals | Skin |

Pulex irritans

Description: The human flea, *Pulex irritans*, has neither genal nor pronotal combs. The outer margin of the head is smoothly rounded and there is a pair of eyes (Fig. 3.80). This species can be distinguished from *Xenopsylla cheopis* by the presence of the single ocular bristle below the eye and the absence of a row of bristles along the rear margin of the head. The metacoxae have a patch of short spines on the inner side. The maxillary laciniae extend about half-way down the forecoxae.

Life cycle: The life cycle is typical: egg, three larval stages, pupa and adult. It is thought that originally the principal hosts of this species were pigs. Each adult female *P. irritans* lays around 400 eggs.

Pulex simulans

Description: Similar to *P. irritans* but the laciniae extend for at least three-quarters the length of the forecoxae.

Xenopsylla

The genus *Xenopsylla* contains over 77 species, which are fleas of rats. The Oriental rat flea, *Xenopsylla cheopis*, is the chief vector of *Yersinia pestis*, the causative agent of plague in humans.

Xenopsylla species of veterinary importance

| Species | Hosts | Site |
|---------------------------|--------------------------|------|
| <i>Xenopsylla cheopis</i> | Rodents, primates, human | Skin |

Xenopsylla cheopis (Oriental rat flea)

Description: *Xenopsylla cheopis* resembles *Pulex irritans* in that both genal and pronotal combs are absent (Fig. 3.81). The head is smoothly rounded anteriorly. The flea has a light amber coloration. The maxillary laciniae reach nearly to the end of the forecoxae. Eyes are present, yet it can only see very bright light. Immediately behind the eyes are two short antennae. The segments of the thorax appear relatively large and the pleural ridge is present in the mesopleuron of the thorax. There is a conspicuous row of bristles along the rear margin of the head and a stout ocular bristle in front of the eye.

Life cycle: The life cycle of *X. cheopis* is typical: egg, three larval stages, pupa and adult. Eggs are usually laid in the environment rather than on the animal host. Eggs are laid in batches of about 3–25 a day, with a female laying 300–1000 eggs over a lifespan that may range from 10 days to more than a year. Eggs hatch after about 5 days (range 2–14 days depending on local conditions). The larva that emerges avoids light and feeds actively on organic debris. The duration of the larval stage depends on local conditions. The most important environmental variable is humidity and larvae may die if

Fig. 3.81 The Oriental rat flea, *Xenopsylla cheopis*, male head. (Adapted from Smart, 1943.)

they move outside a narrow range. Humidities above 60–70% and temperatures above 12°C are required for life-cycle development in this species. The larval period may last 12–84 days, and the pupal and pharate adult period in the cocoon 7–182 days, depending on the availability of a suitable host. Adults may survive for up to 100 days if a host is available, and up to 38 days without food, if humidity is high. Adult males and females can take several blood meals a day. If the host dies, the flea moves almost immediately to find a new one.

Archaeopsylla

The single species *Archaeopsylla erinacei* is a common species on hedgehogs and can transfer to dogs and cats.

Archaeopsylla species of veterinary importance

| Species | Hosts | Site |
|-------------------------------|--------------------|------|
| <i>Archaeopsylla erinacei</i> | Hedgehog, dog, cat | Skin |

Archaeopsylla erinacei (hedgehog flea)

Description: Adults are easily recognised, being 2–3.5 mm long with a genal comb of one to three short spines and a pronotal comb of one short spine (Fig. 3.82).

Life cycle: The life cycle is typical: egg, three larval stages, pupa and adult. Before the female can begin ovipositing she needs to feed on the host several times. Once on its host, *A. erinacei* tends to become a permanent resident.

Fig. 3.82 The hedgehog flea, *Archaeopsylla erinacei*, female head. (Adapted from Smart, 1943.)

Tunga

Species of this genus, often assigned their own family Tungidae in the superfamily Pulicoidea, are parasites of edentates (armadillos, anteaters), livestock, rodents and humans. *Tunga penetrans*, the jigger or chigger flea, causes tungosis in humans.

Tunga species of veterinary importance

| Species | Hosts | Site |
|------------------------|---|------|
| <i>Tunga penetrans</i> | Human, pig, cattle, sheep, horse, mule, rat, mouse, dog, and other wild animals | Skin |

Tunga penetrans

Description: *Tunga penetrans* has no combs and no spiniform bristles on the metathoracic coxae. The head is angular and has an acute frontal angle. The thorax is short and reddish-brown. The female is about 1 mm long before a blood meal but may increase to a length of up to 7 mm when gravid. The male flea is smaller, about 0.5 mm long, and never embeds in the host.

Life cycle: The fertilised female slashes the skin of the host with her mouthparts and then burrows into the wound, inserting her head and body until only the last two abdominal segments are exposed. Host skin proliferates and covers the flea, all but the last abdominal segments. A free-living, mobile, adult male mates with the embedded female. The male possesses one of the longest intromittent organs relative to body size in the animal kingdom and mates from an inverted position. The female remains attached, feeding on host fluids and greatly expanding the size of the abdomen. The female often expands 80-fold to reach the size of a pea after 8–10 days. The embedded female produces a nodular swelling leaving only a small opening to the outside through which up to 200 eggs are passed and drop to

the ground. The eggs hatch in 3 or 4 days, and the fleas moult through two larval stages. The entire life cycle requires about 17 days.

FAMILY LEPTOPSYLLIDAE

Leptopsylla

The European mouse flea, *Leptopsylla segnis*, is found on house mice, rats and other wild rodents and has occasionally been reported on cats and dogs.

Leptopsylla species of veterinary importance

| Species | Hosts | Site |
|---------------------------|-----------------------------|------|
| <i>Leptopsylla segnis</i> | Mouse, rat, rarely dog, cat | Fur |

Leptopsylla segnis (mouse flea)

Description: In the adult fleas there are both genal and pronotal combs and the genal comb contains only four spines.

Life cycle: The life cycle is typical: egg, three larval stages, pupa and adult. Eggs and larvae are found in the host's nest and the adults are obligate blood feeders on the host animal. The adult fleas live for approximately 20 days on the host. The entire life cycle may be completed in 3–4 weeks under ideal conditions or 2 years under adverse conditions.

CLASS ARACHNIDA

Members of the class Arachnida are a highly diverse group of largely carnivorous terrestrial arthropods. The arachnids do not possess antennae or wings and they have only simple eyes. In this class there is only one group of major veterinary importance, the subclass Acari (sometimes also called Acarina), containing the mites and ticks.

The subclass Acari is an extremely diverse and abundant assembly; over 25,000 species have been described to date. They are usually small, averaging about 1 mm in length. However, some ticks may be over 3 cm in length. Segmentation is inconspicuous or absent and the sections of the body are broadly fused, so that the body appears simple and sack-like.

The first pair of appendages, called **chelicerae**, is positioned in front of the mouth and is used in feeding. The second pair of appendages appears behind the mouth and is composed of **palps**. Their precise structure and function varies from order to order. The palps are usually short sensory structures associated with the chelicerae. Together the chelicerae and palps form a structure called the **gnathosoma**. The body posterior to the gnathosoma is known as the **idiosoma** (Fig. 3.83). In the adult, the idiosoma is subdivided into the region that carries the legs, the **podosoma**, and the area behind the last pair of legs, the **opisthosoma**. The legs are six-segmented and each is attached to the podosoma at the **coxa**, also known as the epimer. This is then followed by the trochanter, femur, genu, tibia and tarsus, ending in a pair of claws and a pad-like pulvillus (Fig. 3.84).

THE MITES

There are three main lineages of extant mites: the Opilacariformes, the Parasitiformes and the Acariformes. The Opilocariformes are

Fig. 3.83 Divisions of the body of a generalised mite.

thought to be the most primitive of the living mites and are not parasitic. The Parasitiformes possess one to four pairs of lateral stigmata posterior to the coxae of the second pair of legs and the coxae are usually free. The Parasitiformes include the ticks, described as the Ixodida or Metastigmata, and the gamesid mites or Mesostigmata. The Acariformes do not have visible stigmata posterior to the coxae of the second pair of legs and the coxae are often fused to the ventral body wall. The Acariformes include the mite-like mites, the Sarcoptiformes and Trombidiformes, often described as the Astigmata and Prostigmata, respectively. The terms 'metastigmata', 'mesostigmata', 'astigmata' and 'prostigmata' relate to the position of the respiratory openings on the body and provide a convenient way of distinguishing the four suborders of parasitic importance.

The ectoparasitic mites of mammals and birds largely inhabit the skin, where they feed on blood, lymph, skin debris or sebaceous secretions, which they ingest by puncturing the skin, scavenging from the skin surface or imbibing from epidermal lesions. Most ectoparasitic mites spend their entire lives in intimate contact with

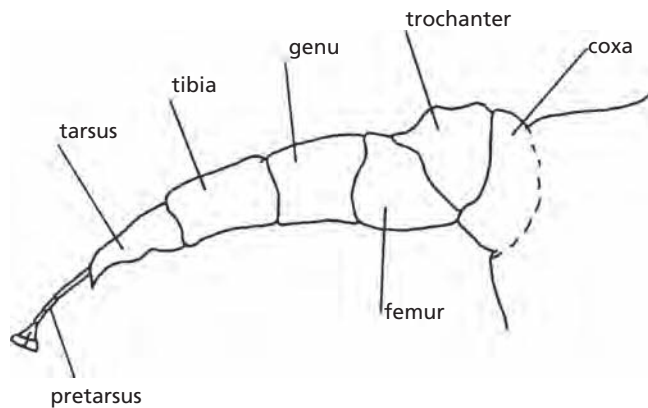

Fig. 3.84 Divisions of the leg of a generalised mite.

their host, so that transmission from host to host is primarily by physical contact. Infestation by mites is called **acariasis** and can result in severe dermatitis, known as **mange**, which may cause significant welfare problems and economic losses. Some mites may be intermediate hosts of anoplocephalid cestodes, including *Anoplocephala*, *Moniezia* and *Stilesia*.

Parasitic mites are small, most being less than 0.5 mm long, though a few blood-sucking species may attain several millimetres when fully engorged. The body is unsegmented but can show various sutures and grooves. The body is divided into two sections, the gnathosoma and idiosoma. The idiosoma may be soft, wrinkled and unsclerotised. However, many mites may have two or more sclerotised dorsal shields and two or three ventral shields: the **sternal**, **genitoventral** and **anal** shields (Fig. 3.85). These may be important features for mite identification. The genitoventral shield, located between the last two (posterior) pairs of legs, bears the genital orifice.

The gnathosoma is a highly specialised feeding apparatus bearing a pair of sensory palps and a pair of chelicerae, the latter sometimes bearing claw-like, or stylet-like **chelae** at their tips (Fig. 3.86). Between the chelicerae is the **buccal cone**, both of which fit within a socket-like chamber formed by enlarged coxae of the palps, ventrally and laterally and by a dorsal projection of the body wall called the **rostrum**.

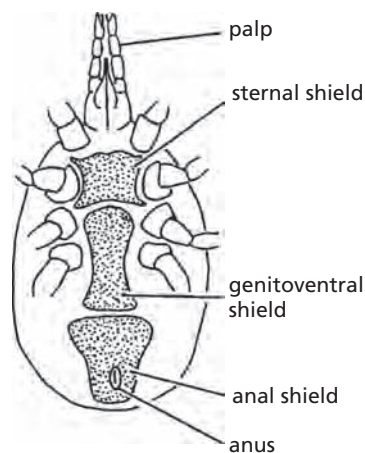

Fig. 3.85 Ventral shields of a generalised mesostigmatid mite.

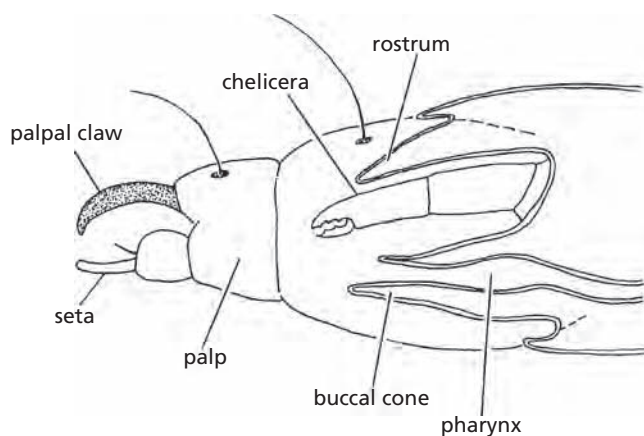

Fig. 3.86 Longitudinal section through the gnathosoma of a generalised mite.

In the mesostigmatic mites, the fused expanded coxal segments of the palps at the base of the gnathosoma are known as the **basal capituli**, from which protrudes the hypostome (but which is not toothed as in the ticks). The palps are one- or two-segmented in most astigmatic and prostigmatic mites, and five- or six-segmented in the Mesostigmata. The last segment of the palps usually carries a **palpal claw** or **apotele**.

Nymphal and adult mites have four pairs of legs arranged in two sets of anterior and posterior legs. Larval mites have three pairs of legs. The first pairs of legs are often modified to form sensory structures and are frequently longer and slender. At the end of the tarsus may be a pretarsus that may bear an **ambulacrum**, usually composed of paired claws, and an **empodium**, which is variable in form and may resemble a pad, sucker, claw or filamentous hair. In some parasitic astigmatic mites, the claws may be absent and replaced by stalked **pretarsi**, which may be expanded terminally into bell or sucker-like **pulvilli** (Figs 3.84 and 3.87).

In many mites, particularly astigmatic mites, gas exchange takes place through the integument. In other mites, gas exchange takes place through one to four pairs of stigmata, found on the idiosoma. The presence or absence of stigmata is used for taxonomic purposes. The stigmata in mesostigmatic mites can be associated with elongated processes called **peritremes**.

Eyes are usually absent and hence most mites are blind. Where they are present, however, in groups such as the trombidiformes, the eyes are simple. Hairs, or setae, many of which are sensory in function, cover the idiosoma of many species of mite. The number, position and size of the setae are extremely important in the identification of mite species.

Life cycles

There are four basic life cycle stages: the egg, a six-legged larva, eight-legged nymph and eight-legged adult (Fig. 3.88). These may be further divided into pre-larva, larva, protonymph, deutonymph, tritonymph and adult. There may also be more than one moult in each of these instars. In many Acari, pre-larval and larval instars take place within the egg or have been lost. In others, one or more of the nymphal instars may be omitted.

Although mites, like the ticks, are obligate parasites, they differ in the important respect that most species spend their entire life cycle, from egg to adult, on the host so that transmission is mainly by contact. The life cycle of many parasitic species may be completed in less than 4 weeks and in some species as little as 8 days. Unlike the ticks, once infection is established, pathogenic populations can build up rapidly on an animal without further acquisitions. Female mites produce relatively large eggs from which a small six-legged larva hatches. The larva moults to become an eight-legged nymph. There may be between one and three nymphal stages, known respectively as the protonymph, deutonymph and tritonymph. In many groups of mites, particularly the Astigmata, one of these nymphal instars, usually the deutonymph, is usually a facultative inactive, dispersal or protective stage, and may be omitted from the life cycle altogether. The tritonymph then moults to become an eight-legged adult.

ORDER ASTIGMATA (SARCOPTIFORMES)

The Astigmata (Sarcoptiformes) are a large group of relatively similar mites. They are all weakly sclerotised; stigmata and tracheae are absent and respiration occurs directly through the cuticle. The

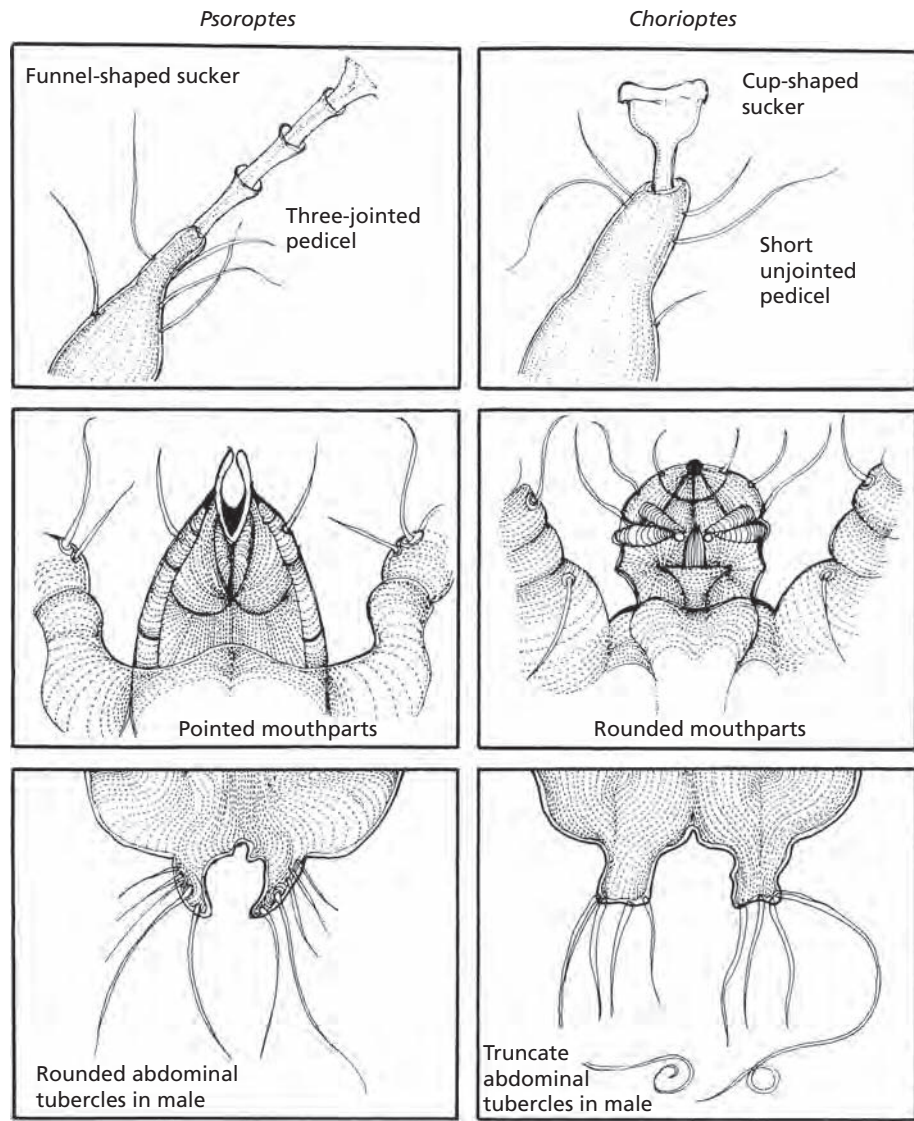

Fig. 3.87 Differential features of *Psoroptes* and *Chorioptes*.

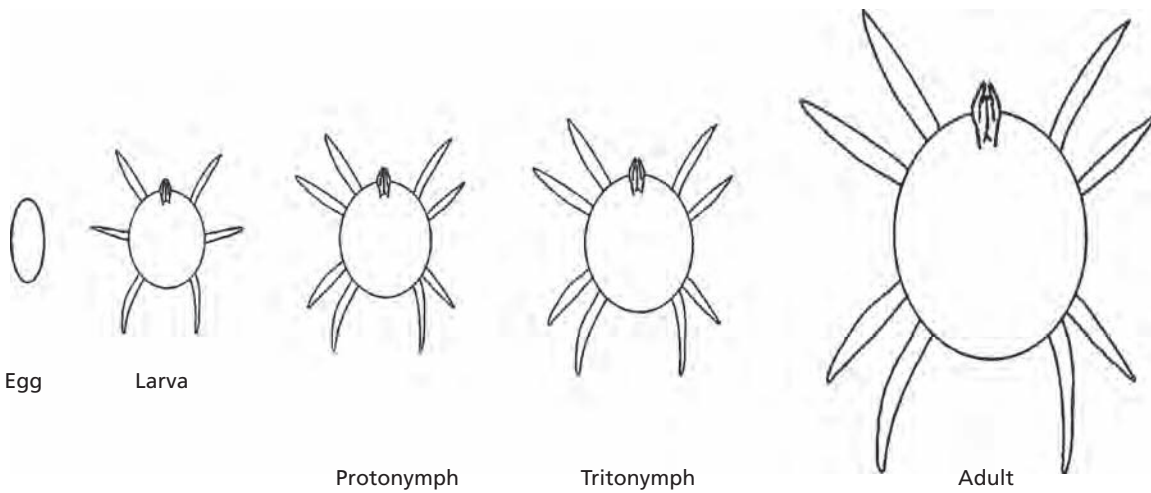

Fig. 3.88 Generalised life cycle of a psoroptid mite.

order includes the families **Sarcoptidae**, **Psoroptidae** and **Knemidocoptidae**, which are of major veterinary importance because they contain the most common mite species causing mange and scab. Species of several other families may be important ectoparasites and species of the **Cytoditidae** and **Laminosioptidae** live in the respiratory tracts and muscles of birds and mammals.

FAMILY SARCOPTIDAE

These are burrowing astigmatic mites with circular bodies flattened ventrally and a cuticle covered with fine striations. The coxae are sunk into the body, creating a 'short-leg' appearance with the third and fourth pairs of legs not usually visible when viewed dorsally. The legs have a claw-like empodium with the pulvillus borne on a stalk-like pretarsus. Paired claws on the tarsus are absent. The three genera of veterinary importance are *Sarcoptes*, *Notoedres* and *Trixacarus*.

Sarcoptes

Previously, over 30 species of *Sarcoptes* were described, but today it is generally accepted that there is only one species, *Sarcoptes scabiei*, with a variety of host-adapted strains. Sarcoptid mites are globose mites with a flat ventral surface, the cuticle finely striated and the chelicerae adapted for cutting and paring. Characteristically, the anus is posterior in *Sarcoptes* mites.

Sarcoptes species of veterinary importance

| Species | Hosts | Site |
|--------------------------|---------------------------------|------|
| <i>Sarcoptes scabiei</i> | All domestic mammals and humans | Skin |

Sarcoptes scabiei (sarcoptic mange mite, itch mite)

Description: The adult of this species has a round, ventrally flattened, dorsally convex body (Fig. 3.89). Adult females are 0.3–0.6 mm long and 0.25–0.4 mm wide, while males are smaller, typically up to 0.3 mm long and 0.1–0.2 mm wide. The posterior two pairs of limbs do not extend beyond the body margin. In both sexes, the pretarsi of the first two pairs of legs bear empodial claws and a sucker-like pulvillus, borne on a long stalk-like pretarsus. The sucker-like pulvilli help the mite grip the substrate as it moves. The third and fourth pairs of legs in the female and the third pair of legs in the male end in long setae and lack stalked pulvilli. The mouthparts have a rounded appearance. These mites have no eyes or stigmata. The dorsal surface of the body of *S. scabiei* is covered with transverse ridges, but also bears a central patch of triangular scales. The dorsal setae are strong and spine-like. The anus is terminal and only slightly dorsal. There are a number of host-adapted varieties of *S. scabiei* that differ subtly in their morphology.

Life cycle: The entire life cycle takes place on the host. Mating probably takes place at the skin surface, following which the female creates a permanent winding burrow, parallel to the skin surface, using her chelicerae and the claw-like empodium on the front two pairs of legs. This burrow may be up to 1 cm in length and burrowing may proceed at up to 5 mm/day. Each tunnel contains only one female, her eggs and faeces. Maturation of the eggs takes 3 or 4 days, following which the female starts to oviposit one to three eggs per

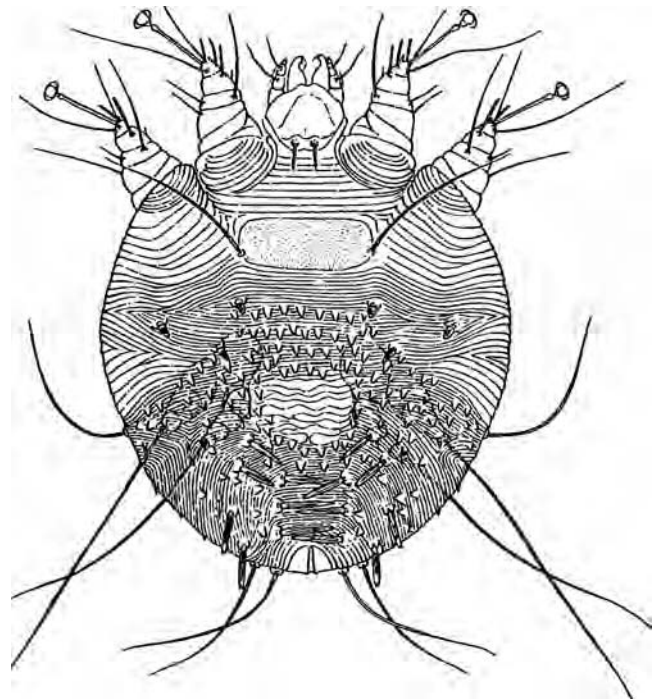

Fig. 3.89 Adult female of *Sarcoptes scabiei*. (From Baker *et al.*, 1956.)

day, over a reproductive life of about 2 months. The eggs, which are oval and about half the length of the adult, are laid singly at the ends of outpockets, which branch off along the length of these tunnels. Three to four days after oviposition, the six-legged larva hatches from the egg. Most larvae will crawl from the burrow towards the skin surface, while some remain in the tunnels where they continue their development. Two to three days later the larva moults to become a protonymph. During this time the larva and nymph find shelter and food in the hair follicles. The protonymph moults to become a tritonymph and again a few days later to become an adult.

Both adult sexes then start to feed and burrow at the skin surface, creating small pockets of up to 1 mm in length in the skin. Mating occurs on the skin. The male dies shortly after copulation. After fertilisation, female mites wander over the pelage to seek a suitable site for a permanent burrow. Despite their short legs, adults are highly mobile, capable of moving at up to 2.5 cm/min. Within an hour of mating the female begins to excavate her burrow. Females burrow without direction, eating the skin and tissue fluids that result from their excavations. Egg-laying begins 4 or 5 days after completion of the initial permanent winding burrow. Female mites rarely leave their burrows and if removed by scratching they will attempt to burrow again. The total egg-to-adult life cycle takes between 17 and 21 days, but may be as short as 14 days. During this period, the mortality rate is high, with just 10% of mites that hatch completing their development. During an infection mite numbers increase rapidly, then decline, leaving a relatively stable mite population.

Notoedres

Mange mites of this genus are found on the ears of mammals. More than 20 species of *Notoedres* have been described, most of them being parasites of tropical bats. Three species are of interest to the

veterinary entomologist, and one, *N. cati*, is important. *Notoedres muris* occurs on rats throughout the world, including laboratory colonies, and *N. musculi* infests the house mouse in Europe. The anus in this genus is dorsal.

Notoedres species of veterinary importance

| Species | Hosts | Site |
|--|--|------------------------------------|
| <i>Notoedres cati</i> (syn. <i>Notoedres cuniculi</i>) | Cat, rabbit, but may infest dogs, wild cats, foxes, canids and civets, human | Ears |
| <i>Notoedres muris</i> | Rat, wild rodents | Ears, nose, tail, genitalia, limbs |
| <i>Notoedres musculi</i> | House mouse | Ears, nose, tail, genitalia, limbs |

Notoedres cati (notoedric mange mite)

Description: *Notoedres* closely resembles *Sarcoptes*, with a circular outline and short legs with long unjointed pedicels, but it is distinguished by its concentric 'thumbprint' striations and absence of spines (Fig. 3.90). The dorsal scales are rounded and arranged transversely. This species is also smaller than *S. scabiei*; females are about 225 µm in length and males about 150 µm, with a short square rostrum. The anal opening is distinctly dorsal and not posterior. Females have suckers on legs 1 and 2.

Life cycle: Similar to that of *Sarcoptes*, except that the females in the dermis are usually found in aggregations. The fertilised female creates a winding burrow or tunnel in the upper layers of the epidermis, feeding on liquid oozing from the damaged tissues. The eggs are laid in these tunnels, hatch in 3–5 days, and the six-legged larvae crawl on to the skin surface. These larvae, in turn, burrow into the superficial layers of the skin to create small 'moulted pockets', in which the moults to nymph and adult are completed. Development from egg to adult takes 6–10 days. The adult male then emerges and seeks a female either on the skin surface or in a moulted pocket.

Fig. 3.90 Adult female *Notoedres cati* in dorsal view.

After fertilisation the females either produce new tunnels or extend the moulted pocket. New hosts are infected by contact, presumably from transferral of larvae, which are present more superficially than the other stages.

Notoedres muris (rat ear mange mite)

Description: Female mites are larger than *N. cati* (330–440 µm) and lack dorsal idiosomal denticles.

Trixacarus

The single species, *Trixacarus caviae*, is commonly found on guinea pigs.

Trixacarus species of veterinary importance

| Species | Hosts | Site |
|---|------------|------------|
| <i>Trixacarus caviae</i> (syn. <i>Caviacoptes caviae</i>) | Guinea pig | Skin, body |

Trixacarus caviae (guinea pig mite)

Synonym: *Caviacoptes caviae*

Description: *Trixacarus caviae* superficially resembles *S. scabiei*. The dorsal striations of the idiosoma of *T. caviae* are similar to those of *S. scabiei*. However, the dorsal scales, which break the striations, are more sharply pointed and the dorsal setae are simple and not spine-like. Like *N. cati*, the anus is located on the dorsal surface. *Trixacarus caviae* is also smaller than *S. scabiei* and similar in size to *N. cati*; females are about 240 µm in length and 230 µm in breadth (Fig. 3.91).

Life cycle: The life cycle is believed to be similar to that of *S. scabiei*.

Fig. 3.91 Adult female of *Trixacarus caviae* (dorsal view).

Fig. 3.92 Adult *Psoroptes ovis*, ventral views: (a) female; (b) male. (From Baker *et al.*, 1956.)

FAMILY PSOROPTIDAE

These are oval-bodied, non-burrowing, astigmatic mites. The legs are longer than those of the burrowing mites and the third and fourth pairs of legs are usually visible from above. Males have a pair of copulatory suckers, which engage the copulatory tubicles of the female tritonymph. The three genera of veterinary importance are *Psoroptes*, *Chorioptes* and *Otodectes*.

Psoroptes

Mites of the genus *Psoroptes* are non-burrowing mites, with adult females up to 0.75 mm in length and adult males 0.55 mm in length. The body is oval in shape and all legs project beyond the body margin. The most important recognition features are the pointed mouthparts and the three-jointed pretarsi (pedicels) bearing funnel-shaped suckers (pulvilli). The taxonomy of the mites in this genus is confused, with mites located in different parts of the body or on different hosts traditionally given different species names; however, little good evidence exists to support this nomenclature. While *P. cuniculi* is described separately here, it appears very likely that this species is simply a host-adapted population of the species *Psoroptes ovis*.

Psoroptes species of veterinary importance

| Species | Hosts | Site |
|---|--|---|
| <i>Psoroptes ovis</i> (syn. <i>Psoroptes aucheniae</i> , <i>Psoroptes bovis</i> , <i>Psoroptes cervinus</i> , <i>Psoroptes communis</i> var. <i>ovis</i> , <i>Psoroptes equi</i>) | Sheep, cattle, goat, horse, rabbit, camelids | Skin, body, neck, shoulders, flanks, axillae, groin, ears, intraorbital fossae |
| <i>Psoroptes cuniculi</i> | Rabbit, sheep, horses | Ears, ear canal |
| <i>Psoroptes natalensis</i> | Cattle, buffalo | Skin, shoulders, back, tail head |

Psoroptes ovis (scab mite)

Synonyms: *Psoroptes aucheniae*, *Psoroptes bovis*, *Psoroptes cervinus*, *Psoroptes communis* var. *ovis*, *Psoroptes equi*

Description: Mites of the genus *Psoroptes* are non-burrowing mites, up to 0.75 mm in length and oval in shape (Fig. 3.92). All the legs project beyond the body margin. Its most important recognition features are the pointed mouthparts and the three-jointed pretarsi (pedicels) bearing funnel-shaped suckers (pulvilli) (Fig. 3.87). Adult females have jointed pretarsi and pulvilli on the first, second and fourth pairs of legs and long whip-like setae on the third pair. In contrast, the smaller adult males, which are recognisable by their copulatory suckers and paired posterior lobes, have pulvilli on the first three pairs of legs and setae on the fourth pair. The legs of adult females are approximately the same length, whereas in males the fourth pair is extremely short.

Life cycle: The eggs of *P. ovis* are relatively large, about 250 µm in length, and oval. The hexapod larva which hatches from the egg is about 330 µm long. The larva moults into a protonymph, the protonymph moults into a tritonymph and the tritonymph moults to become an adult. Egg, larval, protonymph and tritonymph stages and the adult pre-oviposition period each require a minimum of 2 days to be completed, giving a mean egg-to-adult time of about 10 days.

Adult males attach to female tritonymphs, and occasionally protonymphs, and remain attached until the females moult for the final time, at which point insemination occurs.

Adult females produce eggs at a rate of about two to three per day on average. The median life expectancy for an adult female *P. ovis* is about 16 days, during which it will have laid about 40–50 eggs. Populations of *P. ovis* on a host may therefore grow quickly, doubling every 6 days or so.

Psoroptes cuniculi (ear mite)

Description: The species status of *P. cuniculi* remains in question and it has been argued that it should be synonymised with *P. ovis*. In adults of mites described as *P. cuniculi*, the outer opisthosomal setae are, on average, slightly shorter than those seen in *P. ovis*.

Nevertheless, the usefulness of this character is questionable, since there is considerable variation and overlap in the lengths of the setae between the two groups, and the mean length of the setae of mites is known to decrease with the age of a body lesion. Mites described as *P. cuniculi* are found only in the ear of their host.

Life cycle: The eggs of *P. cuniculi* are relatively large (about 250 µm in length) and oval. The hexapod larva, which hatches from the egg, is about 330 µm long. The larva moults into a protonymph, the protonymph moults into a tritonymph and the tritonymph moults to become an adult. Egg, larval, protonymph and tritonymph stages and the adult pre-oviposition period each require a minimum of 2 days to be completed, giving a mean egg-to-adult time of about 10 days.

Psoroptes natalensis

Description: Very similar to *P. ovis* but it is believed that *P. natalensis* can be distinguished morphologically by the length and spatulate shape of the fourth outer opisthosomal seta of the male. However, the precise species status of *P. natalensis* has yet to be confirmed.

Chorioptes

Chorioptic mange is the commonest form of mange in horses and cattle; it may also be common in goats, llamas and alpacas. Detailed studies of *Chorioptes* have suggested that two distinct species exist, *Chorioptes bovis* and *Chorioptes texanus*, separated by differences in the lengths of the posterior setae of adult males. Both are found infesting the body of their host, but no clear host preference appears to exist in the two species. No behavioural differences in their parasitic behaviour have been recorded. A third species, found within the ear canal of reindeer and moose, may also exist but has not yet been named. The names *Chorioptes ovis*, *Chorioptes equi*, *Chorioptes caprae* and *Chorioptes cuniculi* used to describe the chorioptic mites found on sheep, horses, goats and rabbits, respectively, are now all thought to be synonyms of *C. bovis* or *C. texanus*. Adult female *Chorioptes* are about 300 µm in length, considerably smaller than *Psoroptes ovis*. *Chorioptes* do not have jointed pretarsi; their pretarsi are shorter than in *Psoroptes* and the sucker-like pulvillus is more cup-shaped (Fig. 3.87), as opposed to trumpet-shaped in *Psoroptes*.

Chorioptes species of veterinary importance

| Species | Hosts | Site |
|---|--|---------------------------------------|
| <i>Chorioptes bovis</i> (syn. <i>Chorioptes caprae</i> , <i>Chorioptes cuniculi</i> , <i>Chorioptes equi</i> , <i>Chorioptes ovis</i> , <i>Chorioptes japonensis</i>) | Cattle, sheep, horse, goat, rabbit, camel, llama, alpaca | Skin, legs, feet, base of tail, udder |
| <i>Chorioptes texanus</i> | Cattle | Skin, legs, feet, base of tail, udder |

Chorioptes bovis (chorioptic mange mite, barn itch mite)

Synonyms: *Chorioptes caprae*, *Chorioptes cuniculi*, *Chorioptes equi*, *Chorioptes ovis*, *Chorioptes japonensis*

Description: In the adult female, tarsi I, II and IV have short-stalked pretarsi and tarsi III have a pair of long, terminal, whip-like setae.

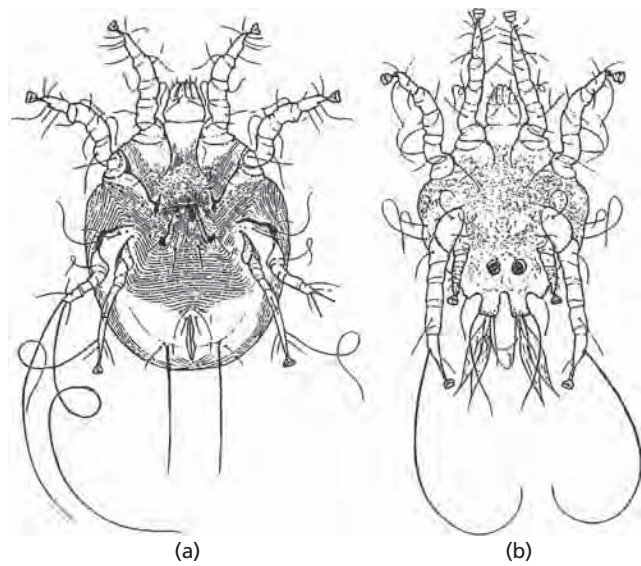

Fig. 3.93 Adult *Chorioptes bovis*, ventral views: (a) female; (b) male. (From Baker *et al.*, 1956.)

The first and second pairs of legs are stronger than the others and the fourth pair has long slender tarsi. In the male, all legs possess short-stalked pretarsi and pulvilli. However, the fourth pair is extremely short, not extending beyond the body margin. Male *C. bovis* are characterised by a very long opisthosomal seta 1 (ae) and short spatulate setae 2 (l4 and d5), on well-developed posterior lobes (Fig. 3.93). The mouthparts are distinctly rounder, and the abdominal tubercles of the male are noticeably more truncate than those of *Psoroptes*.

Life cycle: The life cycle is typical: egg, hexapod larva, followed by octopod protonymph, tritonymph and adult. All developmental stages occur on the host. The complete egg-to-adult life cycle takes about 3 weeks. Eggs are deposited at a rate of one per day and are attached to the host skin. Adult females produce 15–20 eggs and live for 2–3 weeks. *Chorioptes bovis* has mouthparts which are adapted for chewing skin debris. Mites may survive for up to 3 weeks off the host, allowing transmission from housing and bedding as well as by direct contact.

Chorioptes texanus (chorioptic mange mite)

Description: Identical to *C. bovis*, except for differing lengths of opisthosomal setae; in *C. texanus*, setae 2 (l4 and d5) are longer and narrower than in *C. bovis*, but most of the other setae are shorter and this is particularly the case for seta 1 (ae).

Life cycle: Believed to be identical to that of *C. bovis*.

Otodectes

Contains the single species, *Otodectes cynotis*, which is an ear mite of dogs, cats and other animals.

Life cycle: The life cycle is typical: egg, hexapod larva, followed by octopod protonymph, tritonymph and adult. All developmental stages occur on the host. The complete egg-to-adult life cycle takes about 3 weeks. Eggs are deposited at a rate of one per day and are attached

to the host skin. Adult females produce 15–20 eggs and live for 2–3 weeks. Like *Chorioptes*, this mite feeds superficially on skin debris.

Otodectes species of veterinary importance

| Species | Hosts | Site |
|--------------------------|--------------------------------------|---|
| <i>Otodectes cynotis</i> | Cat, dog, ferret, fox, small mammals | External ear canal, occasionally head, back, tip of tail and feet |

Otodectes cynotis (ear mite)

Description: *Otodectes* resembles *Psoroptes* and *Chorioptes* in general conformation, having an ovoid body and projecting legs (Fig. 3.94). Like *Chorioptes*, however, it is smaller than *Psoroptes* and does not have jointed pretarsi. The sucker-like pulvillus is cup-shaped, as opposed to trumpet-shaped in *Psoroptes*. In the adult female, the first two pairs of legs carry short, stalked pretarsi, while the third and fourth pairs of legs have a pair of terminal whip-like setae. The fourth pair is much reduced. The genital opening is transverse. In males all four pairs of legs carry short, stalked pretarsi and pulvilli, but the posterior processes are small.

FAMILY KNEMIDOCOPTIDAE

Twelve species of the genus *Knemidocoptes* (*Neocnemidocoptes*) have been described, of which five are of veterinary importance on poultry and domestic birds.

Knemidocoptes

This is the only burrowing genus parasitising domestic birds, and resembles *Sarcoptes* in many respects.

Life cycle: The fertilised female creates a winding burrow or tunnel in the upper layers of the epidermis, feeding on liquid oozing from the damaged tissues. Females are ovoviviparous, giving birth to live hexapod larvae, which crawl onto the skin surface. These larvae, in turn,

burrow into the superficial layers of the skin to create small ‘moulting pockets’, in which the moults to protonymph, tritonymph and adult are completed. The adult male then emerges and seeks a female either on the skin surface or in a moulting pocket. After fertilisation the females either produce new tunnels or extend the moulting pocket. The entire life cycle is spent on the host and is completed in 17–21 days.

Knemidocoptes species of veterinary importance

| Species | Hosts | Site |
|---|----------------------------------|---|
| <i>Knemidocoptes gallinae</i> (syn. <i>Cnemidocoptes gallinae</i>) | Chicken, turkey, pheasant, goose | Feathers |
| <i>Neocnemidocoptes laevis gallinae</i> (syn. <i>Knemidocoptes laevis gallinae</i>) | Chicken, pheasant, partridge | Feathers |
| <i>Knemidocoptes mutans</i> (syn. <i>Cnemidocoptes mutans</i>) | Chicken, turkey | Skin, scales of feet and legs |
| <i>Knemidocoptes pilae</i> (syn. <i>Cnemidocoptes pilae</i>) | Psittacines (budgerigar) | Skin, feather follicles on face, legs, hock |
| <i>Knemidocoptes jamaicensis</i> | Canary | Legs |

Knemidocoptes gallinae (depluming itch mite)

Synonym: *Cnemidocoptes gallinae*

Description: The circular body and short stubby legs and the avian host are usually sufficient for generic diagnosis (Fig. 3.95). Although similar in appearance to *Knemidocoptes mutans*, individuals are typically smaller, and the pattern of dorsal striations is unbroken.

Neocnemidocoptes laevis gallinae (depluming itch mite)

Synonym: *Knemidocoptes laevis gallinae*

Description: Distinguished from *Knemidocoptes* by having serrated striations on the dorsal surface of the idiostoma, and legs III and IV of the female have a terminal seta which is longer than the leg. The male

Fig. 3.94 Adult *Otodectes cynotis*: (a) male, dorsal view; (b) female, ventral view. (From Baker *et al.*, 1956.)

Fig. 3.95 Adult female of *Knemidocoptes gallinae*, dorsal view. (From Hirst, 1922.)

has a pair of suckers flanking the anus, the posterior limits of apodemes I and II are divergent, and apodemes III and IV are not connected.

***Knemidocoptes mutans* (scaly leg mite)**

Synonym: *Cnemidocoptes mutans*

Description: The general morphology and location on the host are usually sufficient for diagnosis.

***Knemidocoptes pilae* (scaly face mite)**

Synonym: *Cnemidocoptes pilae*

Description: The general morphology and location on the host are usually sufficient for diagnosis. The female mites of *K. pilae* have dorsolateral shields and fused or continuous bases of the setae lateral to the anterior dorsal shield. Male *K. pilae* are characterised by their bilobed pulvillus.

FAMILY LISTROPHORIDAE

These are parasites of fur-bearing mammals with a distinct dorsal shield, and mouthparts and legs modified for grasping hairs. The genus of veterinary interest is *Leporacarus* (*Listrophorus*).

Leporacarus

***Leporacarus* species of veterinary importance**

| Species | Hosts | Site |
|---|--------------|------|
| <i>Leporacarus gibbus</i> (syn. <i>Listrophorus gibbus</i> , <i>Listracarus gibbus</i>) | Rabbit, hare | Fur |

***Leporacarus gibbus* (rabbit fur mite)**

Synonyms: *Listrophorus gibbus*, *Listracarus gibbus*

Description: Mites of this species are laterally compressed, brown mites with short legs and a prescapular shield, with a straight anterior margin, that extends over the gnathostoma. The palp coxae are expanded into two overlapping, weakly striated flaps. The legs do not have clasping adaptations, so instead attach to the hair via membranous flaps that arise from the first pair of coxae. Female mites are large and oval with a thumbprint pattern over the body. Males are slightly smaller and have two long adanal processes plus distinct anal suckers.

Life cycle: An obligate parasite, completing all stages of the life cycle (egg, larva, nymph, adult) on the host.

FAMILY MYOLOPTIDAE

Mites of this family were originally a subfamily of the Listrophoridae but are now considered as a separate family. The genus of veterinary interest is *Myocoptes*.

Myocoptes

***Myocoptes* species of veterinary importance**

| Species | Hosts | Site |
|---------------------------|-------------------|------|
| <i>Myocoptes musculus</i> | Mouse, guinea pig | Fur |

***Myocoptes musculus* (myocoptic mange mite)**

Description: These mites are soft-bodied, strongly striated with a distinct dorsal shield, and have mouthparts and legs modified for grasping hairs (Fig. 3.96). Adult female *Myocoptes musculus* are elongated ventrally, about 300 µm in length, and the propodosomal body striations have spine-like projections. The genital opening is a transverse slit. The anal opening is posterior and ventral. Legs I and II are normal, possessing short-stalked, flap-like pretarsi. Legs III and IV are highly modified for clasping hair. The tibia and tarsus of legs III and IV (female) or III only (male) fold back over enlarged femur and genu. Males are smaller than females, about 190 µm in length, with less-pronounced striations and a greatly enlarged fourth pair of legs for grasping the female during copulation. The posterior of the male is bilobed.

Life cycle: *Myocoptes musculus* spends its entire life on the hair of the host rather than on the skin, feeding at the base of the hair and gluing its eggs to the hairs. The life cycle is typical: egg, hexapod larva, followed by octopod protonymph, tritonymph and adult. All developmental stages occur on the host. The entire life cycle requires around 14 days.

FAMILY CYTODITIDAE

Members of the genus *Cytodites* are found in the respiratory system, lungs and air sacs of chickens, turkeys, canaries and a range of wild birds, and in rodents and bats.

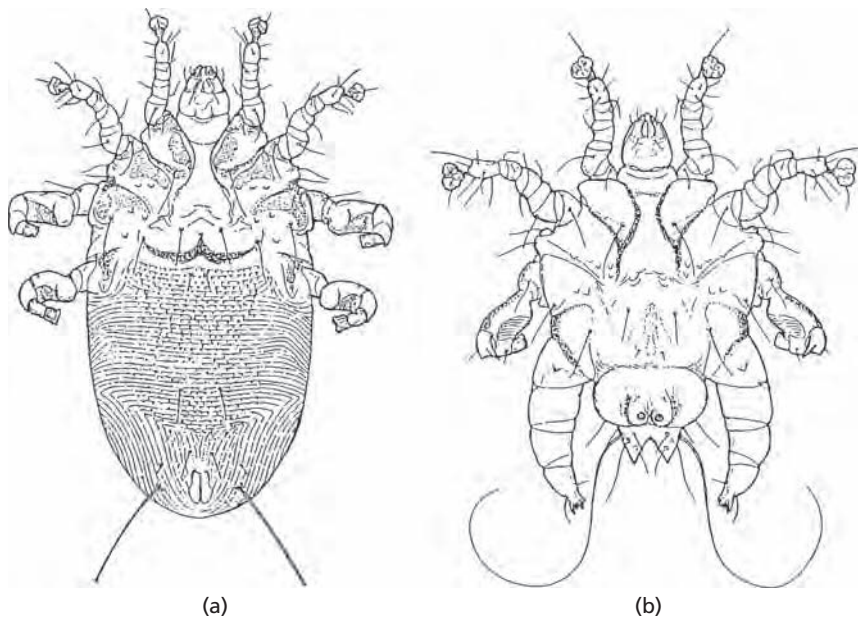

Fig. 3.96 Adults of *Myocoptes musculus*: (a) female, ventral view; (b) male, ventral view. (From Baker *et al.*, 1956.)

Cytodites

Species belonging to this genus are endoparasites, mainly in the respiratory tract, of birds.

Cytodites species of veterinary importance

| Species | Hosts | Site |
|------------------------|-------------------------------------|---------------|
| <i>Cytodites nudus</i> | Chicken, turkey, canary, wild birds | Lung, air sac |

Cytodites nudus (air sac mite)

Description: The mite is oval and about 500 µm long, with a broadly oval idiosoma and smooth cuticle (Fig. 3.97). The chelicerae are absent and the palps are fused to form a soft, sucking organ. Legs are stout and unmodified, ending in a pair of stalked suckers and a pair of small claws.

Life cycle: Larval, nymphal and adult stages take place on the surface of the respiratory tract of the host, with the complete life cycle of the mite requiring 14–21 days.

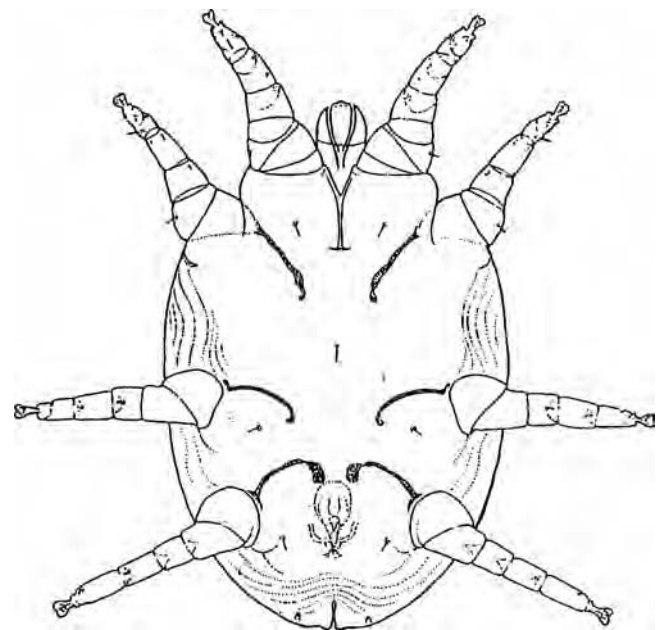

Fig. 3.97 Adult *Cytodites nudus*, ventral view. (From Baker *et al.*, 1956.)

FAMILY LAMINOSIPTIDAE

Laminosiptes

Laminosiptes are relatively small mites with a smooth elongated body and a few setae, and are subcutaneous parasites of birds.

Laminosiptes species of veterinary importance

| Species | Hosts | Site |
|-------------------------------|--|--|
| <i>Laminosiptes cysticola</i> | Chicken, turkey, goose, pigeon, wild birds | Subcutaneous tissues, lung, peritoneum |

Laminosiptes cysticola (fowl cyst mite)

Description: This mite is small, approximately 250 µm in length, with a smooth elongated body and few setae. The gnathosoma is small and not visible when viewed from above. The posterior two pairs of legs end in claws and suckerless pedicels, while the anterior two pairs of legs end in claws (Fig. 3.98). The apodemes of coxae II meet in the midline of the idiostoma, then diverge posteriorly.

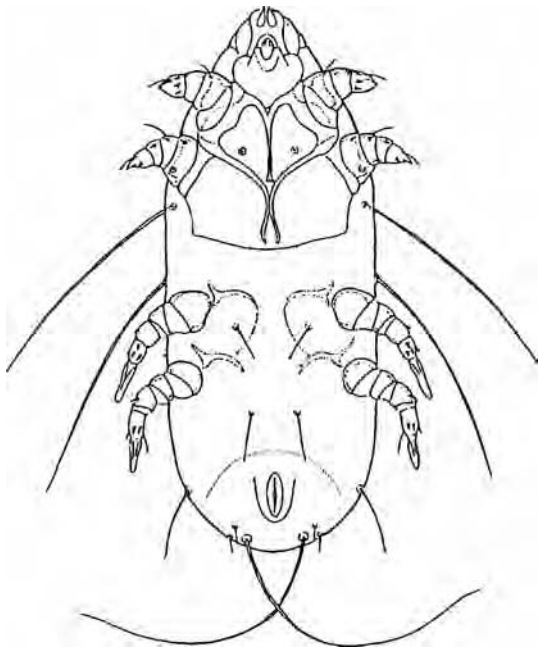

Fig. 3.98 Adult female *Laminosioptes cysticola*, ventral view. (From Baker et al., 1956.)

Life cycle: The life cycle is typical: egg, hexapod larva, followed by octopod protonymph, tritonymph and adult. All developmental stages occur in the host, although complete life-cycle details are lacking.

FAMILY ANALGIDAE

Feather mites of the genus *Megninia* are found on down and contour feathers of the chicken and other captive Galliformes.

Megninia

Megninia species of veterinary importance

| Species | Hosts | Site |
|----------------------------|--|----------------------------|
| <i>Megninia gingylmura</i> | Chicken, galliform birds, pigeon, wild birds | Feathers on body and wings |
| <i>Megninia cubitalis</i> | Chicken, wild birds | Feathers on body and wings |
| <i>Megninia ortari</i> | Chicken, wild birds | Feathers on body and wings |

Megninia gingylmura (feather mite)

Description: The anterior dorsal shield is narrow with two broad longitudinal bars converging anteriorly. The male has greatly enlarged third legs and large posterior lobes with copulatory suckers. The legs of the female are all of a similar size. Legs I and II have a long anterior spine on the tibia.

Megninia cubitalis (feather mite)

Description: Similar to *M. gingylmura* except in the female there is a crescent-shaped pregenital sclerite located between apodemes II.

Also, the posterior lateral and median pairs of setae near the genital opening are of equal length. In the male, apodemes I are fused into a Y-shape and the anal suckers are flanked by a pair of sclerites.

Megninia ortari (feather mite)

Description: In the female mites, the pregenital sclerite occupies an anterior position between the posterior part of apodeme I. In the male, apodemes I are fused into a Y-shape but there are no sclerites flanking the anal suckers.

FAMILY ATOPOMELIDAE

One species of *Chirodiscoides* has been reported on guinea pigs. Mites of the genus *Listrocarpus* spp. have been reported from primates.

Chirodiscoides

Members of this genus are mainly confined to tropical regions. They were originally a subfamily of the Listrophoridae but are now considered as a separate family. *Chirodiscoides caviae* is found on the fur of guinea pigs.

Chirodiscoides species of veterinary importance

| Species | Hosts | Site |
|---|------------|------|
| <i>Chirodiscoides caviae</i> (syn. <i>Campylochirus caviae</i>) | Guinea pig | Fur |

Chirodiscoides caviae (guinea pig fur mite)

Description: Females of *Chirodiscoides caviae* are about 500 µm and males about 400 µm in length (Fig. 3.99). The gnathosoma is

Fig. 3.99 Adults of *Chirodiscoides caviae*: (a) male, ventral view; (b) female, ventral view.

distinctly triangular. The propodosomal sternal shield is strongly striated and used to clasp hairs. The body is flattened dorsoventrally. All legs are slender and well developed, with legs I and II strongly modified for clasping to hair.

Life cycle: *Chirodiscoides caviae* spends its entire life on the hair of the host rather than on the skin, feeding at the base of the hair and gluing its eggs to the hairs. The life cycle is typical: egg, hexapod larva, followed by octopod protonymph, tritonymph and adult. All developmental stages occur on the host. The entire life cycle requires approximately 14 days.

FAMILY DERMOGLYPHIDAE

Members of the genus *Dermoglyphus* are found on the quills of chickens and cage birds.

Dermoglyphus

Dermoglyphus species of veterinary importance

| Species | Hosts | Site |
|--------------------------------|-------------------------------------|----------------|
| <i>Dermoglyphus elongatus</i> | Chicken | Feather quills |
| <i>Dermoglyphus passerinus</i> | Cage birds, canary, wild passerines | Feather quills |

Dermoglyphus elongatus (quill mite)

Description: Small elongate mites, the male of which has no posterior lobes or anal suckers on the idiosoma. The apodemes of I and II are fused and the apex of leg IV does not extend beyond the posterior idiosomal margin. *Dermoglyphus elongatus* possesses a dorsal shield that is twice as long in length than in width, has two slender sclerotised bars that curve slightly outwards posteriorly, and has internal setae with separate bases.

Dermoglyphus passerinus (quill mite)

Description: Similar to *D. elongatus* except the dorsal shield is roughly rectangular (length about 1.7 times the width), the sclerotised bars curve slightly inwards and the internal setae have contiguous bases.

FAMILY FREYANITIDAE

Members of the genus *Freyana* are found on the quills of chickens and cage birds, particularly the feathers of turkeys.

Freyana

Freyana species of veterinary importance

| Species | Hosts | Site |
|---------------------------|--------|----------------|
| <i>Freyana largifolia</i> | Duck | Skin |
| <i>Freyana anatina</i> | Duck | Skin |
| <i>Freyana chanayi</i> | Turkey | Skin, feathers |

FAMILY EPIDERMOPTIDAE

Bird ked mites cause depluming mange. The genera of interest are *Epidermoptes* and *Rivoltasia*, found on chickens; *Microlichus* found on quail; and *Promyialges* found on passeriform cage and aviary birds. Ked mites also affect hippoboscids affecting the bird host.

Epidermoptes

Epidermoptes species of veterinary importance

| Species | Hosts | Site |
|-------------------------------|---------------|------|
| <i>Epidermoptes bilobatus</i> | Chicken, duck | Skin |

Epidermoptes bilobatus (ked mite)

Description: These are small mites, approximately 0.4 mm long, with a circular soft body. The idiosoma has a triangular anterior dorsal shield and a posterior dorsal shield, which in the female is roughly square with a concave posterior margin. The idiosoma in the female is rounded posteriorly with one pair of adanal, long setae. Males have a triangular posterior dorsal shield and a pair of adanal suckers.

Rivoltasia

Rivoltasia species of veterinary importance

| Species | Hosts | Site |
|-----------------------------|---------|------|
| <i>Rivoltasia bifurcata</i> | Chicken | Skin |

Rivoltasia bifurcata

Description: Males have long membraneous posterior lobes and female mites have fused pregenital sclerites and apodemes I forming a U-shape. Both sexes have backwardly directed processes on femora III and IV.

Microlichus

Microlichus species of veterinary importance

| Species | Hosts | Site |
|-------------------------------|-------|------|
| <i>Microlichus americanus</i> | Quail | Skin |

Microlichus americanus (ked mite)

Description: Small rounded mites with a triangular anterior dorsal shield and short legs ending in a terminal, recurved, claw-like process on legs I and II. The trochanter of legs III and IV have a ventral flange. In the female mites, the posterior margin of the idiosoma is widely rounded with two pairs of long setae. The posterior shield in the male is triangular and strongly indented, the posterior margin of the idiosoma has two well-formed separated lobes and there are two adanal suckers.

Promyialges

Promyialges species of veterinary importance

| Species | Hosts | Site |
|---|-----------------------------|------|
| <i>Promyialges macdonaldi</i> (syn. <i>Myialges macdonaldi</i>) | Cage birds, wild passerines | Skin |

Promyialges macdonaldi (ked mite)

Synonym: *Myialges macdonaldi*

Description: Similar to *Microlichus* but the male is without posterior lobes and anal suckers. In the female, there is a large claw-like process on leg I and the idiosoma narrows to straight posterior margin with four pairs of thick, spine-like, long setae. The tarsi on legs II–IV in the female and I–IV in the male have a small terminal pointed process.

FAMILY PTEROLICHIDAE

The two genera of veterinary significance are *Pterolichus*, found on the tail and flight feathers of chickens, and *Sideroferus*, found on the budgerigar.

Pterolichus

Pterolichus species of veterinary importance

| Species | Hosts | Site |
|----------------------------|---------|------|
| <i>Pterolichus obtusus</i> | Chicken | Skin |

Pterolichus obtusus (feather mite)

Description: Similar to *Sideroferus* but the apodemes I are free; the female pregenital sclerite is an inverted U-shape and the male has a weakly divided opisthosoma posteriorly, and the legs are all of similar size.

Sideroferus

Sideroferus species of veterinary importance

| Species | Hosts | Site |
|---|---------------------------|---------------------------------|
| <i>Sideroferus lunula</i> (syn. <i>Pterolichus lunula</i> , <i>Protolichus lunula</i> , <i>Megninia lunula</i>) | Cage birds, budgerigar | Skin, tail and wing feathers |

Sideroferus lunula (feather mite)

Synonyms: *Pterolichus lunula*, *Protolichus lunula*, *Megninia lunula*

Description: Mites are elongate and both sexes are strongly sclerotised. The males have bifurcated tarsi on the first pair of legs and two long paragenital apodemes extending from the genital region to the posterolateral margins of the body.

FAMILY GABUCINIIDAE

There are several species in this genus, which infest a range of wild birds. Two species of *Gabucinia* are quill mites of ostriches. These are pale elongated mites, about 0.5 µm in length. The dorsal idiosoma appears patterned or sculpted. The first two pairs of legs protrude anteriorly.

Life cycle: Typical: egg, nymphal stages and reproductive adult. Knowledge of the biology of these quill mites is very limited. Under intensive conditions this parasite is able to multiply rapidly on ostriches, reaching high densities.

Gabucinia species of veterinary importance

| Species | Hosts | Site |
|--|---------|----------|
| <i>Gabucinia sculpturata</i> | Ostrich | Feathers |
| <i>Gabucinia bicaudatus</i> (syn. <i>Pterolichus bicaudatus</i>) | Ostrich | Feathers |

FAMILY HYPODERIDAE

The genus *Hypodectes* is of importance in pigeons, doves and other wild and captive birds. Their life cycle is unusual in that the adults are free-living and non-feeding, and the deutonymph is the main parasitic form present in subcutaneous cysts.

Hypodectes

Hypodectes species of veterinary importance

| Species | Hosts | Site |
|--------------------------|--------------|--------------------|
| <i>Hypodectes propus</i> | Pigeon, dove | Subcutaneous cysts |

Hypodectes propus

Description: The deutonymph (hypopus) present in subcutaneous cysts are elongate (~1.5 mm long) with parallel sides and very short legs. The adults present in the nest have reduced palps and gnathosoma and in the female reduced chelicerae.

Life cycle: Free-living, nest-inhabiting mite which develops into a 'hypopus' that transiently invades the skin of birds. After leaving the host, the hypopus moults directly into an adult mite.

ORDER PROSTIGMATA (TROMBIDIFORMES)

The Prostigmata (Trombidiformes) is a large and diverse group of mites existing in a wide range of forms, and occupying various ecological habitats. These prostigmatic mites usually have stigmata, which open on the gnathosoma or the anterior part of the idiosoma, known as the propodosoma. There are over 50 families, of which four contain species of veterinary importance: Demodicidae, Cheyletiellidae, Trombiculidae and Psorergatidae. Other families may be of lesser importance, not as parasites but because of the allergic responses they induce.

FAMILY DEMODICIDAE

The Demodicidae is a family of prostigmatid mites, containing a single genus of veterinary interest, *Demodex*, species of which are found in a wide range of animals including humans.

Species of the genus *Demodex* are highly specialised mites that live in the hair follicles and sebaceous glands of a wide range of wild and domestic animals, including humans. They are believed to form a group of closely related sibling species which are highly specific to particular hosts: *Demodex phylloides* (pig), *Demodex canis* (dog), *Demodex bovis* (cattle), *Demodex equi* (horse), *Demodex musculi* (mouse), *Demodex ratticola* (rat), *Demodex caviae* (guinea pig), *Demodex cati* (cat) and *Demodex folliculorum* and *Demodex brevis* on humans.

Demodex

These are small mites with an elongated cigar-shaped body, up to 0.1–0.4 mm in length, with four pairs of stumpy legs ending in small blunt claws in the adult (Fig. 3.100). Setae are absent from the legs and body. The legs are located at the front of the body, and as such the striated opisthosoma forms at least half the body length.

Life cycle: *Demodex* spp. usually live as commensals in the skin, and are highly site-specific, occupying the hair follicles and sebaceous glands. Females lay 20–24 spindle-shaped eggs in the hair follicle that give rise to hexapod larvae, in which each short leg ends in a single three-pronged claw. Unusually, a second hexapod larval stage follows, in which each leg ends in a pair of three-pronged claws. Octopod protonymph, tritonymph and adult stages then follow. These migrate more deeply into the dermis. One follicle may harbour all life-cycle stages concurrently. The life cycle is completed in 18–24 days. In each follicle or gland the mites may occur in large numbers in a characteristic head-downward posture.

Fig. 3.100 Adult *Demodex* spp., ventral view. (From Baker *et al.*, 1956.)

In the newborn and very young these sites are simple in structure, but later they become compound by outgrowths. The presence of *Demodex* mites much deeper in the dermis than sarcoptids means that they are much less accessible to surface-acting acaricides. Species of *Demodex* are unable to survive off their host.

Demodex species of veterinary importance

| Species | Hosts | Site |
|---|------------|------|
| <i>Demodex bovis</i> | Cattle | Skin |
| <i>Demodex ovis</i> (syn. <i>Demodex aries</i>) | Sheep | Skin |
| <i>Demodex caprae</i> | Goat | Skin |
| <i>Demodex equi</i> (syn. <i>Demodex caballi</i>) | Horse | Skin |
| <i>Demodex phylloides</i> | Pig | Skin |
| <i>Demodex canis</i> | Dog | Skin |
| <i>Demodex cati</i> | Cat | Skin |
| <i>Demodex gatoi</i> | Cat | Skin |
| <i>Demodex musculi</i> | Mouse | Skin |
| <i>Demodex ratticola</i> | Rat | Skin |
| <i>Demodex caviae</i> | Guinea pig | Skin |
| <i>Demodex folliculorum</i> | Human | Skin |
| <i>Demodex brevis</i> | Human | Skin |

FAMILY CHEYLETIDAE

The majority of mites in this family are predatory, but several species of mites of the genus *Cheyletiella* are of veterinary and medical importance as ectoparasites of dogs, cats or rabbits that may transfer to humans. The body of the mite, up to 0.4 mm long, has a 'waist' and the palps are greatly enlarged, giving the appearance of an extra pair of legs. The legs terminate in 'combs' instead of claws or suckers.

Cheyletiella

Three very similar species of *Cheyletiella* are of veterinary importance and are common: *Cheyletiella yasguri* on dogs, *C. blakei* on cats and *C. parasitivorax* on rabbits. All three species are morphologically very similar; the solenidion, on the genu of the first pair of legs, is described as globose in *C. parasitivorax*, conical in *C. blakei* and heart-shaped in *C. yasguri* (Fig. 3.101). Nevertheless, this feature can vary in individuals and between life-cycle stages, making precise identification difficult. Identification to genus and knowledge of the host is usually sufficient for diagnosis, but it is important to be aware of the potential for cross-transmission of the various species of *Cheyletiella* from other in-contact hosts.

Life cycle: All developmental stages occur on the host animal. Eggs are glued to hairs 2–3 mm above the skin. A pre-larva and then a larva develop within the egg, with fully developed octopod nymphs eventually emerging from the egg. The mites then moult through two nymphal stages before the adult stage is reached. The life cycle is completed in approximately 2 weeks. The mites live in the hair and fur, only visiting the skin to feed on lymph and other tissue fluids. They feed on these fluids by piercing the epidermis with their stylet-like chelicerae. Adults can survive for at least 10 days off the host without feeding, or longer in cool environments.

Fig. 3.101 (a) Adult female *Cheyletiella parasitivorax*, dorsal view (from Baker *et al.*, 1956). (b–d) Genu of the first pair of legs of adult females of (b) *Cheyletiella parasitivorax*, (c) *Cheyletiella blakei* and (d) *Cheyletiella yasguri*.

Cheyletiella species of veterinary importance

| Species | Hosts | Site |
|-----------------------------------|---------------|------|
| <i>Cheyletiella parasitivorax</i> | Rabbit, human | Fur |
| <i>Cheyletiella yasguri</i> | Dog, human | Fur |
| <i>Cheyletiella blakei</i> | Cat, human | Fur |

Cheyletiella parasitivorax (rabbit fur mite)

Description: Adults are about 400 µm in length and ovoid and have blade-like chelicerae that are used for piercing their host, and short, strong, opposable palps with curved palpal claws. The palpal femur possesses a long serrated dorsal seta. The body tends to be slightly elongated with a 'waist'. The legs are short; tarsal claws are lacking and the empodium is a narrow pad with comb-like pulvilli at the ends of the legs. Adults are highly mobile and are able to move about rapidly. The solenidion, on the genu of the first pair of legs, is described as globose in *C. parasitivorax*.

Cheyletiella yasguri

Description: This species is most easily differentiated from other species by a heart-shaped dorsal solenidion on genu I. Female mites have two small shields behind the anterior dorsal shield. The solenidion, on the genu of the first pair of legs, is heart-shaped.

Cheyletiella blakei

Description: The solenidion, on the genu of the first pair of legs, is conical in *C. blakei*. However, this feature can vary in individuals and between life-cycle stages, making identification difficult.

FAMILY TROMBICULIDAE

Species of the family Trombiculidae are commonly known as chiggers, red bugs, harvest mites and scrub itch mites. Mites of this family are parasitic only at the larval stage, the nymphs and adults being free-living. More than 1500 species have been described. The principal species of veterinary interest are in the genus *Trombicula*. Other lesser genera include *Leptotrombidium*, a vector of scrub typhus (tsutsugamushi fever) in the Far East, and *Neoschongastia*, which can affect chickens, quail and turkeys in North and Central America.

Trombicula

The genus *Trombicula* is divided into several subgenera, of which *Neotrombicula* (harvest mites), which has a wide distribution in the Old World, and *Eutrombicula*, which occurs in North and South America and whose larvae are known as chiggers, are of veterinary importance. Larvae of both these genera will parasitise any animal, including humans.

Trombicula species of veterinary importance

| Species | Hosts | Site |
|---|--|--|
| <i>Trombicula</i> (<i>Neotrombicula</i>) <i>autumnalis</i> | Dog, cat, cattle, horse, rabbit and birds, human | Skin, foot, legs, head |
| <i>Trombicula</i> (<i>Eutrombicula</i>) <i>alfreddugesi</i> | Dog, cat, cattle, horse, rabbit, birds | Skin, commonly face, muzzle, thigh and belly |
| <i>Trombicula</i> (<i>Eutrombicula</i>) <i>splendens</i> | Wild mammals, birds, reptiles, poultry, human | Skin, face, feet, legs |
| <i>Trombicula</i> (<i>Eutrombicula</i>) <i>sarcina</i> | Kangaroo, sheep | Skin, face, feet, legs |

Fig. 3.102 Parasitic larval stage of the harvest mite *Trombicula* (*Neotrombicula*) *autumnalis*. (From Savory, 1935.)

Trombicula (*Neotrombicula*) *autumnalis* (harvest mites)

Description: The hexapod larvae are rounded, red to orange in colour and about 0.2 mm in length (Fig. 3.102). The scutum bears a pair of sensillae and five setae. In *N. autumnalis* the scutum is roughly pentangular and has numerous small punctations. There are two simple eyes on each side of the scutum. The body is covered dorsally with 25–50 relatively long, ciliated, feather-like setae. The chelicerae are flanked by stout five-segmented palps. The palpal femur and genu each bear a single seta. The palpal tibia has three setae and a thumb-like terminal claw, which opposes the palpal tarsus. The palpal claw is three-pronged (trifurcate). Adults and nymphs have a pronounced figure-of-eight shape. They have stigmata, which open at the base of the chelicerae and their bodies are covered with setae. Adults are about 1 mm in length.

Life cycle: They are parasitic only in the larval stage. Female adults lay their spherical eggs in damp but well-drained soil. After about 1 week the hexapod larva hatches from the egg and begins to crawl about the soil, eventually climbing an object such as a grass stem. Here it awaits a passing host. Larvae of the species of veterinary interest are not highly host-specific and may attach to a variety of domestic animals. The larva attaches itself by its blade-like chelicerae and feeds on the host's serous tissues for several days before falling from the host. After feeding, the larva enters a quiescent stage for a few days as a nymphochrysalis, before moulting to become the active octopod nymph. After a further inactive imagochrysalis nymphal stage, the adult emerges. The nymphal and adult stages are free-living, mobile and predatory. The life cycle typically requires 50–70 days. *Neotrombicula autumnalis* passes through only one generation per year and its abundance is usually strongly seasonal.

Trombicula (*Eutrombicula*) *alfreddugesi* (chigger mites)

Description: The larvae of *Eutrombicula alfreddugesi*, known as chiggers, are similar in appearance to those of *N. autumnalis*. They are reddish-orange and vary in length between 0.15 mm when not engorged to 0.6 mm when fully fed. However, for the larvae of *E. alfreddugesi* the palpal claws are two-pronged (bifurcate), the scutum is approximately rectangular and 22 dorsal setae are present.

Life cycle: The life cycle is similar to that described for *N. autumnalis*. Adult chiggers are free-living while the immature stages are parasitic. Infestation is most common around the face, muzzle, thigh and belly. The resulting pruritus may persist for several days and is generally a hypersensitivity reaction to the mite saliva, occurring after the individual has detached.

Trombicula (*Eutrombicula*) *splendens* (chigger mites)

Description: *Eutrombicula splendens* is morphologically similar and frequently sympatric with *E. alfreddugesi*.

Trombicula (*Eutrombicula*) *sarcina* (scrub itch mites, black soil itch mites)

Description: The parasitic larvae are small (0.2 mm long) round mites with numerous setae.

Leptotrombidium

The larvae (chiggers) feed on rodents, but also occasionally humans and other large mammals. The mites are both vector and reservoir for scrub typhus (*Orientia tsutsugamushi*) infection.

Leptotrombidium species of veterinary importance

| Species | Geographic range |
|-----------------------------------|--|
| <i>Leptotrombidium akamushi</i> | Japan |
| <i>Leptotrombidium deliense</i> | China; Thailand; Northern Territory, Australia |
| <i>Leptotrombidium pallidum</i> | Japan |
| <i>Leptotrombidium scutellare</i> | Japan |

Neoschongastia

Larvae of these small mites normally feed on wild animals, birds and reptiles but also attack poultry causing dermatitis particularly under the wings.

Neoschongastia species of veterinary importance

| Species | Hosts | Site |
|---------------------------------|------------------------|-----------------------------|
| <i>Neoschongastia americana</i> | Turkey, chicken, quail | Skin, feathers, under wings |

***Neoschongastia americana* (turkey chigger)**

Description: Differentiated from other chigger mites by the presence of a single dorsal tooth on each chelicera, a sunken posterior dorsal shield covered in striations and the shape of the sensilli which are bulbous.

FAMILY PSORERGATIDAE

Two species of the genus *Psorobia* are found on cattle and sheep; the species found on sheep is a major ectoparasite in southern hemisphere countries. The body is almost circular with the legs arranged equidistant around the body circumference, with two pairs of elongate posterior setae in the female adult mite and single pairs in the male. The femur of each leg bears a large, inwardly directed, curved spine.

Life cycle: The life cycle is typical: egg, hexapod larva, followed by octopod protonymph, tritonymph and adult. All developmental stages occur on the host. The egg-to-adult life cycle requires approximately 35 days.

Psorobia

***Psorobia* species of veterinary importance**

| Species | Hosts | Site |
|---|--------|------|
| <i>Psorobia ovis</i> (syn. <i>Psorergates ovis</i>) | Sheep | Skin |
| <i>Psorobia bovis</i> (syn. <i>Psorergates bos</i>) | Cattle | Skin |

***Psorobia ovis* (sheep itch mite)**

Synonym: *Psorergates ovis*

Description: *Psorobia ovis* is a small mite, roughly circular in form and less than 0.2 mm in diameter (Fig. 3.103). The legs are arranged more or less equidistantly around the body circumference, giving the mite a crude star shape. Larvae of *P. ovis* have short stubby legs. The legs become progressively longer during the nymphal stages until, in the adult, the legs are well developed and the mites become mobile. Adults are about 190 µm long and 160 µm wide. The tarsal claws are simple and the empodium is pad-like. The femur of each leg bears a large, inwardly directed, curved spine. In the adult female, two pairs of long whip-like setae are present posteriorly; in the male there is only a single pair.

***Psorobia bovis* (cattle itch mite)**

Synonym: *Psorergates bos*

Description: Morphologically similar to *Psorobia ovis* but smaller in size (female, 135–145 µm; male, 160 µm).

FAMILY PYEMOTIDAE

These are 'forage' mites found on hay and grain that pre-date largely on insect larvae, but they can cause dermatitis on

Fig. 3.103 Adult female *Psorobia*. (From Baker *et al.*, 1956.)

animals and humans. Mites of the genus *Pyemotes* are small mites with elongated bodies, the female mites giving birth to fully formed adults.

Pyemotes

***Pyemotes* species of veterinary importance**

| Species | Hosts | Site |
|-------------------------|--------------|------|
| <i>Pyemotes tritici</i> | Horse, human | Skin |

***Pyemotes tritici* (straw itch mite)**

Description: Elongate to oval, grey or yellowish mites; females are 220–250 µm but may reach up to 2 mm in diameter when gravid. Legs are long with II and III widely separated. Tarsus I ends in a hooked claw.

FAMILY MYOBIDAE

These are small blood-feeding mites found on rodents, bats and insectivores. Species of the genera *Myobia* and *Radfordia* may cause a mild dermatitis of laboratory mice and rats, respectively.

Myobia

***Myobia* species of veterinary importance**

| Species | Hosts | Site |
|-----------------------|-------|------|
| <i>Myobia musculi</i> | Mouse | Fur |

Myobia musculi (mouse fur mite)

Description: The mouse fur mite, *Myobia musculi*, is a small translucent mite, typically around 300 µm in length and 190 µm wide. The body is broadly rounded at the rear with transverse striations on the integument (Fig. 3.104). The gnathosoma is small and simple with stylet-like chelicerae. Between the second, third and fourth pairs of legs there are lateral bulges and each tarsus bears an empodial claw. The anus is dorsal and flanked by a long pair of setae.

Life cycle: The female oviposits in the fur, cementing the eggs to the base of the hairs. Eggs hatch within 8 days, and the larvae moult 4 days later. The egg-to-adult life cycle requires a minimum period of 12 days. All stages feed on extracellular fluids.

Radfordia

Mites of this genus are morphologically similar to *M. musculi*, but can be distinguished by the presence of two tarsal claws as opposed to just one (Fig. 3.105).

Radfordia species of veterinary importance

| Species | Hosts | Site |
|---------------------------|-------|----------------------------|
| <i>Radfordia affinis</i> | Mouse | Fur, shoulders, neck, face |
| <i>Radfordia ensifera</i> | Rat | Fur |

Radfordia affinis

Description: Found on rats and identified by the claws on tarsus II, which are equal in size.

Fig. 3.104 Adult female *Myobia musculi* (dorsal view). (From Baker et al., 1956.)

Fig. 3.105 Adult female *Radfordia ensifera* (dorsal view). (From Baker et al., 1956.)

Radfordia ensifera

Description: Found on mice and has claws of unequal size on tarsus II.

FAMILY SYRINGOPHILIDAE

Poultry quill mites, *Syringophilus*, feed on tissue fluids of feather follicles causing feather loss.

Syringophilus

Syringophilus species of veterinary importance

| Species | Hosts | Site |
|-----------------------------------|---------------------------|-----------------------------------|
| <i>Syringophilus bipectinatus</i> | Chicken, other galliforms | Quill of flight and body feathers |

Syringophilus bipectinatus (quill mite)

Description: Elongate mites, females are approximately 600 µm in length and males 500 µm in length; the chelicerae are fused to form a stylophore with pointed posterior margin.

FAMILY OPHIOPTIDAE

These mites are found beneath the scales of snakes.

FAMILY CLOACARIDAE

These are mites found in the cloacal mucosa of reptiles. *Cloacarus* are found in aquatic terrapins.

FAMILY PTERYGOSOMATIDAE

These are parasites of lizards and include the genera *Geckobiella*, *Hirstiella*, *Ixodiderma*, *Pimeliaphilus*, *Scapothrix* and *Zonurobia*.

ORDER MESOSTIGMATA

The Mesostigmata (gamesid mites) are a large group of mites, the majority of which are predatory, but a small number of species are important as ectoparasites of birds and mammals. Mesostigmatid mites have stigmata located above the coxae of the second, third or fourth pairs of legs. They are generally large with usually one large sclerotised shield on the dorsal surface, and a series of smaller shields in the midline of the ventral surface. The legs are long and positioned anteriorly. Some species are host-specific but the majority parasitise a range of hosts. There are two main families of veterinary interest, the Dermanyssidae and Macronyssidae, and four families of minor interest: Laelapidae, Halarachinidae, Entonyssidae and Rhinonyssidae.

FAMILY MACRONYSSIDAE

These are relatively large blood-sucking ectoparasites of birds and mammals of which *Ornithonyssus*, in birds, and *Ophionyssus*, in reptiles, are of veterinary importance. Only the protonymph and adult stages blood-feed. The mites have relatively long legs and can be seen with the naked eye. The female genital shield and the male holovenral shield taper posteriorly to coxae IV.

Ornithonyssus

Includes the northern fowl mite, *Ornithonyssus sylviarum*, which is capable of transmitting a number of important viral diseases, and *bacoti* (the tropical rat mite).

Ornithonyssus species of veterinary importance

| Species | Hosts | Site |
|---|---|--|
| <i>Ornithonyssus sylviarum</i> (syn. <i>Liponyssus sylviarum</i> , <i>Macronyssus sylviarum</i>) | Chicken, poultry, pigeon, wild birds, occasionally mammals, human | Base of feathers, particularly vent |
| <i>Ornithonyssus bursa</i> (syn. <i>Macronyssus bursa</i> , <i>Leiognathus bursa</i>) | Poultry, wild birds | Skin, feathers |
| <i>Ornithonyssus bacoti</i> (syn. <i>Liponyssus bacoti</i> , <i>Macronyssus bacoti</i>) | Rodents, cat, human, chicken, wild birds | Skin |

Ornithonyssus sylviarum (northern fowl mite)

Synonyms: *Liponyssus sylviarum*, *Macronyssus sylviarum*

Description: The adults are relatively large, oval-shaped and 0.75–1 mm in length with long legs that allow it to move rapidly (Fig. 3.106). The body is usually greyish-white, becoming red to black when engorged. A single dorsal shield is wide for two-thirds of its length, then tapers posteriorly to become about half as wide, and is truncated at its posterior margin. The female typically has only two pairs of setae on the sternal shield. The anal shield is relatively large and at least as wide as the genitoventral plate. Three anal setae are present. The chelicerae are elongate and stylet-like. The body carries many long setae and is much more hairy than *Dermanyssus*.

Life cycle: Unlike *Dermanyssus*, *Ornithonyssus* spends its entire life on the bird and can only survive for about 10 days away from a host. The female lays one to five sticky whitish-coloured eggs on the host at the base of the feathers, primarily in the vent area, after a blood meal. The eggs hatch within approximately a day to produce hexapod larvae. The larvae do not feed, and moult to become protonymphs. The protonymphs feed on blood from the host, before moulting to become tritonymphs. The tritonymphs do not feed, and moult to the adult stage. The entire life cycle can be completed in 5–12 days under optimal conditions, but usually takes

Fig. 3.106 Adult female *Ornithonyssus sylviarum* (northern fowl mite): (left) dorsal view; (right) ventral view. (From Baker *et al.*, 1956.)

longer. Because of the short generation times, large populations can develop rapidly on the birds.

***Ornithonyssus bursa* (tropical fowl mite)**

Synonyms: *Macronyssus bursa*, *Leiognathus bursa*

Description: Similar to *O. sylviarum*. However, the ventral plate bears three pairs of setae, while in *O. sylviarum* and *Dermanyssus gallinae* only two pairs of setae are present.

Life cycle: Similar to that of *O. sylviarum*.

***Ornithonyssus bacoti* (tropical rat mite)**

Synonyms: *Liponyssus bacoti*, *Macronyssus bacoti*

Description: This rapidly moving, long-legged mite has an oval body, about 1 mm in length. Both sexes feed on blood. The colour varies from white to reddish-black depending on the amount of blood ingested. It is similar in appearance and life cycle to the fowl mite, *Ornithonyssus sylviarum*. However, the female mites bear three pairs of setae on the sternal shield, and the setae on the dorsal shield are as long, or longer, than those on the surrounding cuticle. In the male, the holoventral shield has parallel sides, posterior to coxae IV. The body carries many long setae and is much more hairy than the red mite of poultry, *Dermanyssus gallinae*. The adult female survives for around 70 days, during which it feeds every 2 or 3 days and lays about 100 eggs.

Life cycle: *Ornithonyssus bacoti* spends its entire life on the host and can only survive for about 10 days away from a host.

Ophionyssus

Parasites of reptiles, the most important species of which, *Ophionyssus natricis* (the reptile mite), is commonly found on snakes and other captive lizards, turtles, crocodiles and other reptiles.

***Ophionyssus* species of veterinary importance**

| Species | Hosts | Site |
|--|-----------------|--------------|
| <i>Ophionyssus natricis</i> (syn. <i>Ophionyssus serpentium</i> , <i>Serpenticola serpentium</i>) | Snakes, lizards | Skin, scales |

***Ophionyssus natricis* (reptile mite)**

Synonyms: *Ophionyssus serpentium*, *Serpenticola serpentium*

Description: Adults are 0.6–1.3 mm long. Unfed females are yellow-brown; engorged females are dark red, brown or black. The cuticle bears only a few short bristle-like hairs (Fig. 3.107).

Life cycle: The engorged female leaves the host and deposits eggs in cracks and crevices. The eggs hatch in 1–4 days, developing through larva, protonymph and deutonymph stages to the adult. Larvae do not feed but nymphs must feed before moulting to the next stage. The life cycle takes 13–19 days.

Fig. 3.107 *Ophionyssus natricis*. (Redrawn from Reichenhack-Klinke & Elkan, 1965. Reproduced with permission from Elsevier.)

FAMILY DERMANYSIIDAE

Species of the genus *Dermanyssus* are blood-feeding ectoparasites of birds and mammals. They are large mites with long legs, greyish white, becoming red when engorged. *Liponyssoides*, which affect rodents, are of minor veterinary significance but can act as disease vectors of Q-fever and rickettsial pox to humans.

Dermanyssus

The red mite or chicken mite, *Dermanyssus gallinae*, is one of the most common mites of poultry. It feeds on the blood of fowl, pigeons, cage birds and many other wild birds. It also occasionally bites mammals, including humans, if the usual hosts are unavailable.

***Dermanyssus* species of veterinary importance**

| Species | Hosts | Site |
|-----------------------------|--|------|
| <i>Dermanyssus gallinae</i> | Chicken, turkey, duck, pigeon, canary, wild birds; occasionally mammals, human | Skin |

***Dermanyssus gallinae* (poultry red mite)**

Description: Adult mites are relatively large at 0.75–1 mm in length, with long legs (Fig. 3.108). The body is usually greyish-white, becoming red to black when engorged. The chelicerae are elongate and stylet-like, and the middle segment in female mites is very slender. A single dorsal shield is present, which tapers posteriorly but is truncated at its posterior margin. The anal shield is relatively large and is at least as wide as the genitoventral plate. Three anal setae are present. In the male, there are small sucker-like projections subterminally on tarsi III and IV.

Fig. 3.108 Adult female of the red mite, *Dermonyssus gallinae*: (left) dorsal view; (right) ventral view. (From Baker *et al.*, 1956.)

Life cycle: This mite spends much of its life cycle away from its host, the adult and nymph only visiting birds to feed, mainly at night. The favoured habitats are poultry houses, usually of timber construction, in the crevices of which the eggs are laid. The life cycle can be completed in a minimum of a week, allowing large populations to develop rapidly, although during cold weather the cycle is slower. Approximately 1 day after feeding, batches of eggs are laid in hiding places, detritus or near nests and roosts. Within 2–3 days the eggs hatch into six-legged larvae. The larvae do not feed before moulting, and become an octopod protonymph 1–2 days later. Within another couple of days they moult again, and soon afterward they complete their final moult to become an adult. Both nymphal stages feed, as do the adult mites. The adult can survive for several months without feeding, so a reservoir population can persist in unoccupied poultry houses and aviaries.

FAMILY HALARACHNIDAE

Mites of the subfamily Halarachinae are obligate parasites found in the respiratory tract of mammals. *Pneumonyssoides* is found in the nasal sinuses and nasal passages of dogs. *Pneumonyssus* and *Rhinophaga* are found in the respiratory tract of monkeys. Members of the subfamily Raillietiinae are obligate parasites in the external ears of mammals.

Pneumonyssoides

Pneumonyssoides species of veterinary importance

| Species | Hosts | Site |
|---|-------|-----------------------|
| <i>Pneumonyssoides caninum</i> (syn. <i>Pneumonyssus caninum</i>) | Dog | Nasal cavity, sinuses |

Pneumonyssoides caninum (nasal mite)

Synonym: *Pneumonyssus caninum*

Description: The mites are oval and pale yellow, adults measuring approximately 1–1.5 by 0.6–0.9 mm in length. They have a smooth cuticle with relatively few setae. The mites have a single irregularly shaped dorsal plate and a small sternal plate. Genital plates are absent in this species and the genital opening is a transverse slit between the coxae of the fourth pair of legs. They have long legs, relative to their body size, which terminate in claws and small chelicerae.

Life cycle: The details of the life history of these mites are not fully known. There appear to be two main life stages, the adult and a six-legged larval stage. There is no nymphal stage in the life cycle of this parasite. The female is ovoviparous and mature females often contain eggs and it is probable that they give birth to larvae.

Raillietia

Raillietia species are found in the ears of domesticated cattle and small ruminants.

Raillietia species of veterinary importance

| Species | Hosts | Site |
|--------------------------|-------------|-----------|
| <i>Raillietia caprae</i> | Goat, sheep | Ear canal |
| <i>Raillietia auris</i> | Cattle | Ear canal |

Raillietia caprae

Description: Similar to *Pneumonyssoides*, with a heavily patterned holodorsal shield but with a well-developed tritosternum, longer

peritremes and the presence of both a genital and sternal shield in the female. This species has a short dorsal shield (500–600 µm) with 17 pairs of setae.

Life cycle: Details of the life history of these mites are not fully known. There appear to be two main life stages, the adult and a six-legged larval stage. There is no nymphal stage in the life cycle of this parasite. The female is ovoviviparous and mature females often contain eggs and it is probable that they give birth to larvae.

Raillietia auris

Description: As for *R. caprae* but with a longer dorsal shield (700–800 µm) with 12 pairs of setae.

FAMILY ENTONYSSIDAE

Mites of the family Entonyssidae are found in the respiratory tract of reptiles. *Entonyssus*, *Entophionyssus* and *Mabuyonyssus* are found in the trachea and lungs of snakes.

FAMILY RHINONYSSIDAE

Most species are parasites of the nasopharynx of birds. *Sternostoma* occurs worldwide and is found in a range of domestic and wild birds, including canaries and budgerigars.

Sternostoma

The canary lung mite, *Sternostoma tracheacolum*, causes pneumonia and inflammation of the respiratory system in caged and wild birds.

Sternostoma species of veterinary importance

| Species | Hosts | Site |
|---------------------------------|--|---|
| <i>Sternostoma tracheacolum</i> | Cage birds, budgerigar, canary, wild birds | Trachea, air sacs, lungs, liver, nasal cavities |

Sternostoma tracheacolum (air sac mite)

Description: Mites are elongate up to 1 mm in size, with a small gnathosoma and thick legs with claws on II to IV.

FAMILY LAELAPIDAE

Species of the genera *Haemogamasus*, *Laelaps*, *Androlaelaps*, *Haemolaelaps*, *Echinolaelaps* and *Hirstionyssus* are blood-feeding parasites of rodents and are found worldwide.

Haemogamasus

Haemogamasus species of veterinary importance

| Species | Hosts | Site |
|--|---------|------------------|
| <i>Haemogamasus pontiger</i> (syn. <i>Eupaelaps pontiger</i>) | Rodents | Fur, free-living |

Haemogamasus pontiger

Description: Mites are brown in colour, over 1 mm long, covered in many short setae and with long slender legs. Both sexes have a large dorsal shield and in the female there is a sternal shield with a deeply concave posterior margin. The anal shield in female mites is an inverted pear-shape with two small median papillae on the anterior margin.

Laelaps

Laelaps species of veterinary importance

| Species | Hosts | Site |
|--------------------------|----------------|------|
| <i>Laelaps echidnina</i> | Rodents, human | Skin |

Laelaps echidnina (spiny rat mite)

Description: Similar to *Haemogamasus* but with a more circular idiosoma and thicker setae and legs. In the female, there is an opisthogenital shield with a posterior concavity.

Androlaelaps

Androlaelaps casalis, the poultry litter mite or nest mite, can occur in large numbers in chicken house litter.

Androlaelaps species of veterinary importance

| Species | Hosts | Site |
|---|---------|-------------------|
| <i>Androlaelaps casalis</i> (syn. <i>Haemolaelaps casalis</i>) | Poultry | Skin, free-living |

Androlaelaps casalis (poultry litter mite)

Description: Similar to *Haemogamasus* but has fewer and mostly paired setae on the dorsal shield and a more tongue-shaped genital shield bearing only one pair of setae. The male holoventral shield has 15 setae, all paired except for the most posterior.

ORDER IXODIDA (METASTIGMATA)

The ticks are obligate blood-feeding ectoparasites of vertebrates, particularly mammals and birds. They are relatively large and long-lived, feeding periodically on large blood meals, often with long intervals between meals. Tick bites may be directly damaging to animals, causing irritation, inflammation or hypersensitivity and, when present in large numbers, anaemia and production losses. The salivary secretions of some ticks may cause toxicosis and paralysis; however, more importantly, when they attach and feed they are capable of transmitting a number of pathogenic viral, bacterial, rickettsial and protozoal diseases.

Ticks belong to two main families, the *Ixodidae* and *Argasidae*. The most important is the *Ixodidae*, often called the **hard ticks**, because of the presence of a rigid chitinous scutum, which covers the entire dorsal surface of the adult male. In the adult female and in the larva and nymph it extends for only a small area, which permits

the abdomen to swell after feeding. The other family is the Argasidae or **soft ticks**, so-called because they lack a scutum; included in this family are the bird ticks and the tampan.

FAMILY IXODIDAE

The Ixodidae are relatively large ticks, between 2 and 20 mm in length, and flattened dorsoventrally. The enlarged fused **coxae** of the palps are known as the **basis capituli**, which vary in shape in the different genera. Its ventromedial wall is extended anteriorly to form the **hypostome**, which lies below the chelicerae (Fig. 3.109). The hypostome is armed with rows of backward barbs or teeth, and is used as an anchoring device when the tick feeds. The structure of the hypostome and chelicerae permit the outward flow of saliva and inward flow of host blood. The four-segmented sensory **palps** and heavily sclerotised **chelicerae** are anterior and visible from the dorsal surface. On the dorsal surface of the basis capituli ixodid females have a pair of depressions filled with tiny pores, known as the **porose area**. Projecting from the posterior corners of the basis capituli may be a pair of projections, called **cornua** on the dorsal surface and **auriculae** on the ventral surface. The presence and shape of these projections may be important in the identification of tick species.

Ixodid ticks have a chitinous dorsal plate or **scutum** (Fig. 3.110), which extends over the whole dorsal surface of the male, but covers only a small area behind the gnathosoma in the larva, nymph or female. Other distinguishing features are a series of grooves on the scutum and body and, in some species, a row of notches, called **festoons**, on the posterior border of the body. Chitinous plates are sometimes present on the ventral surface of the males. Some ticks have coloured enamel-like areas on the body and these are called '**ornate**' ticks.

The coxa of the leg may be armed with internal and external **ventral spurs**; their number and size may be important in species

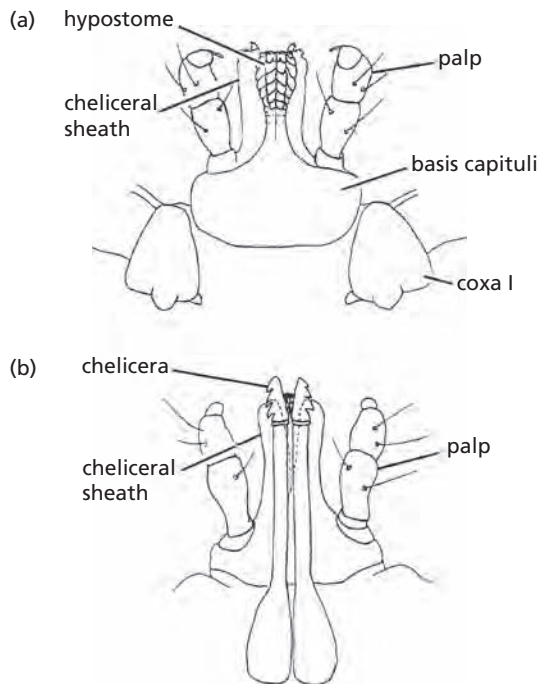

Fig. 3.109 Tick mouthparts: (a) ventral view showing toothed hypostome; (b) dorsal view showing the chelicerae behind the cheliceral sheaths.

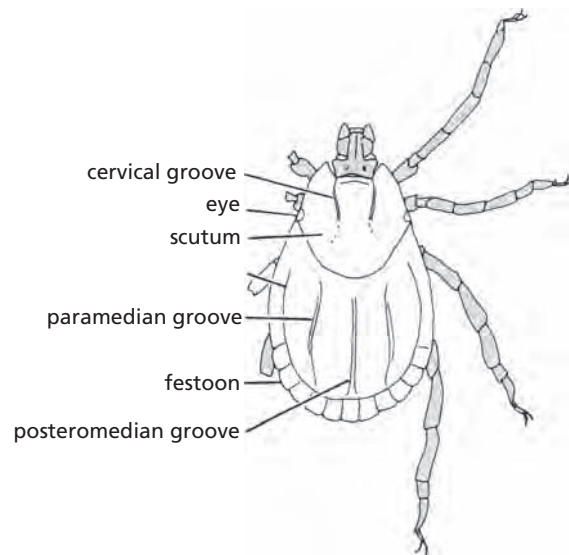

Fig. 3.110 Dorsal view of a generalised female ixodid tick.

identification (Fig. 3.111). Located on the tarsi of the first pair of legs is Haller's organ, which is packed with chemoreceptors used for locating potential hosts. Eyes, when present, are situated on the outside margin of the scutum. Adult and nymphal ticks have a pair of respiratory openings, the **stigmata**, which lead to the tracheae. The stigmata are large and positioned posterior to the coxae of the fourth pair of legs. In adults, the genital opening, the **gonopore**, is situated ventrally behind the gnathosoma, usually at the level of the second pair of legs, and is surrounded by the **genital apron**. A pair of **genital grooves** extends backwards from the gonopore to the **anal groove**, located ventrally and usually posterior to the fourth pair of legs (Fig. 3.112).

The hard ticks are temporary parasites and most species spend relatively short periods on the host. There is a single hexapod larval stage, and a single octopod nymphal stage leading to the reproductive, eight-legged adult stage (Fig. 3.113).

During the passage through these stages ixodid ticks take a number of large blood meals, interspersed by lengthy free-living

Fig. 3.111 (a) Ventral view of the coxae showing internal and external spurs and (b) segments of the leg of a generalised ixodid tick.

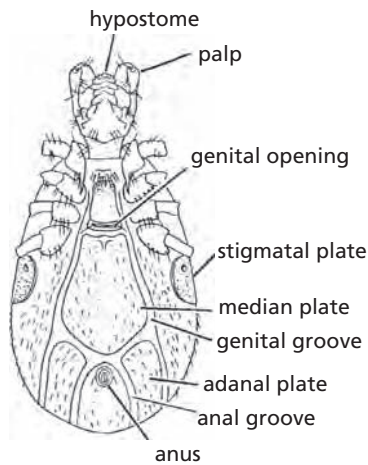

Fig. 3.112 Ventral view of a generalised male ixodid tick.

Fig. 3.113 Life cycle of an ixodid tick.

periods. They are relatively long-lived and each female may produce several thousand eggs. Most hard ticks are relatively immobile and, rather than actively hunting for their hosts, the majority adopt a strategy known as questing, in which they wait at the tips of vegetation for an appropriate host to brush past. Once contact is made the ticks transfer to the host, and then move over the surface to find their preferred attachment sites, such as the ears. Preferred sites for attachment may be highly specific to the particular species of tick.

Ticks have developed a variety of complex life cycles and feeding strategies, which reflect the nature of the habitat that the various species of tick inhabit and the probability of contact with an

appropriate host. The number of hosts to which they attach during their parasitic life cycle varies from one to three. Based on this, they are classified as follows.

- **One-host ticks**, where the entire parasitic development from larva to adult takes place on the one host.
- **Two-host ticks**, where larva and nymph occur on one host and the adult on another.
- **Three-host ticks**, where each stage of development takes place on different hosts.

For most, a three-host life cycle has been adopted. Larvae, nymphs and adults all feed on different hosts. Blood-feeding typically takes

between 4 and 6 days after which they drop to the ground and either moult to the next life-cycle stage or lay eggs. Ticks must then relocate a suitable host to feed and moult again or lay eggs. For a relatively small number of ixodid ticks, about 50 species, which inhabit areas where hosts are scarce and in which lengthy seasonal periods of unfavourable climate occur, two- and one-host feeding strategies have evolved.

In temperate habitats, feeding and generation cycles of hard ticks are closely synchronised with periods of suitable temperature and humidity conditions. Ticks, particularly in the immature stages, are very susceptible to desiccation, particularly when ticks are active. To minimise drying out they start questing when saturated with water and return to the humid ground level when dehydrated. Water may also be imbibed by drinking.

Ixodid ticks are important vectors of protozoal, bacterial, viral and rickettsial diseases. The Ixodidae contains about 650 species of ticks. The phylogeny of tick families and genera is undergoing revision and is still not fully resolved, and some genera have been more recently synonymised. *Ixodes* is the largest genus, containing 217 species. Other genera of veterinary importance include *Dermacentor*, *Haemaphysalis*, *Rhipicephalus* (which now subsumes the synonymised genus *Boophilus*), *Hyalomma* and *Amblyomma* (synonymised genus *Aponomma*).

Ixodes

Ixodes is the largest genus in the family Ixodidae, with about 250 species. They are small inornate ticks that do not have eyes or festoons. The mouthparts are long and are longer in the female than male. The fourth segment of the palps is greatly reduced and bears chemoreceptor sensilla. The second segment of the palps may be restricted at the base, creating a gap between the palp and chelicerae (Fig. 3.114a). Males have several ventral plates, which almost cover

the ventral surface. *Ixodes* can be distinguished from other ixodid ticks by the anterior position of the anal groove. In other genera of the Ixodidae the anal groove is either absent or is posterior to the anus.

***Ixodes* species of veterinary importance**

| Species | Hosts | Site |
|--|--|------|
| <i>Ixodes ricinus</i> | Sheep, cattle, goat, but can feed on all mammals and birds; juvenile stages may also feed on lizards | Skin |
| <i>Ixodes canisuga</i> | Dog, fox, sheep, horse and mule | Skin |
| <i>Ixodes hexagonus</i> | Hedgehog; dog, cat, fox, sheep, horse, mole | Skin |
| <i>Ixodes holocyclus</i> | Cattle, sheep, goat, dog, cat; all mammals and birds | Skin |
| <i>Ixodes persulcatus</i> | Sheep, cattle, goat, horse, dog, other mammals, birds and human | Skin |
| <i>Ixodes rubicundus</i> | Sheep, goat, cattle and wild ungulates | Skin |
| <i>Ixodes scapularis</i> (syn. <i>Ixodes dammini</i>) | Mammals and birds | Skin |
| <i>Ixodes pacificus</i> | Rodents, lizards and large mammals such as horses, deer and dogs | Skin |
| <i>Ixodes pilosus</i> | Cattle, sheep, goat, horse, dog, cat and wild ungulates | Skin |
| <i>Ixodes angustus</i> | Wild mammals, dog | Skin |
| <i>Ixodes cookei</i> | Wild mammals, dog | Skin |
| <i>Ixodes kingi</i> | Wild mammals, dog | Skin |
| <i>Ixodes rugosus</i> | Wild mammals, dog | Skin |
| <i>Ixodes sculptus</i> | Wild mammals, dog | Skin |
| <i>Ixodes muris</i> | Wild mammals, dog | Skin |
| <i>Ixodes texanus</i> | Wild mammals, dog | Skin |

Ixodes ricinus (sheep tick, castor bean tick)

Description: The engorged adult female is light grey, up to 1 cm in length and bean shaped (Fig. 3.115). However, when engorged the legs are not visible when viewed from above. Adult male *Ixodes ricinus* are only 2–3 mm in length, and because they take smaller blood meals than females, the four pairs of legs are readily visible from above. Nymphs resemble the adults but are less than 2 mm in length. The larvae, often described as ‘seed ticks’ or ‘pepper ticks’, are less than 1 mm in length and usually yellowish in colour. The tarsi are tapered (Fig. 3.116a) and the posterior internal angle of the first coxa bears a spur, which overlaps the second coxa (Fig. 3.117a).

Life cycle: *Ixodes ricinus* is a three-host tick and the life cycle requires 3 years. The tick feeds for only a few days each year, as a larva in the first year, a nymph in the second and an adult in the third. Mating takes place on the host. After attachment the female is

inseminated once and subsequently completes a single large blood meal; in contrast, the males feed intermittently and mate repeatedly. During mating, the male crawls under the female and, after manipulating the female genital opening with its mouthparts, transfers the spermatophore, a sac containing the spermatozoa, into the opening with the aid of his front legs and gnathosoma. Once fertilised, the female subsequently feeds for about 14 days and then drops to the ground to lay several thousand eggs in the soil in sheltered spots, over a period of about 30 days, after which she dies.

The eggs hatch to produce larvae. Larvae begin to quest several days to several weeks after hatching, the precise time depending on temperature and humidity. The larvae climb up the stems of vegetation ready to attach to a passing host. Once a host is located, larvae feed for 3–5 days, increasing their body weight by 10–20 times, then drop back on to the vegetation where they digest their blood meal and moult to become nymphs. The following year the nymphs begin to seek a new host, again feeding for 3–5 days, before dropping off the host and moulting into the adult stage.

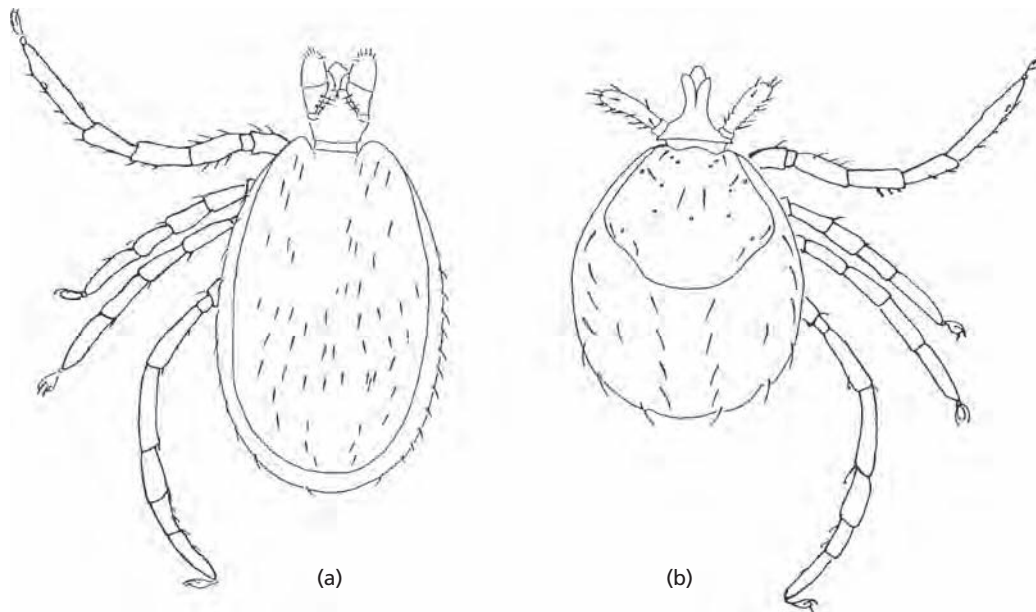

Fig. 3.115 Adult *Ixodes ricinus* in dorsal view: (a) male; (b) female. (From Arthur, 1962.)

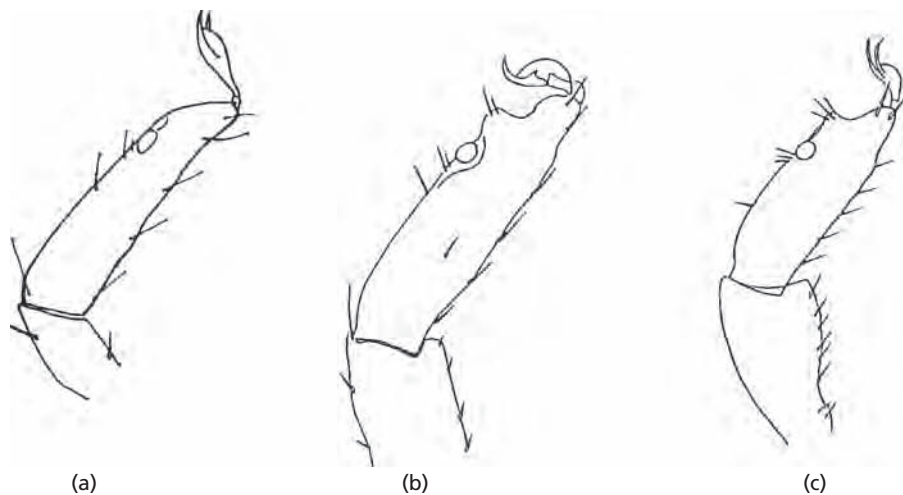

Fig. 3.116 The tarsi of adult male (a) *Ixodes ricinus*, (b) *Ixodes hexagonus* and (c) *Ixodes canisuga*. (From Arthur, 1962.)

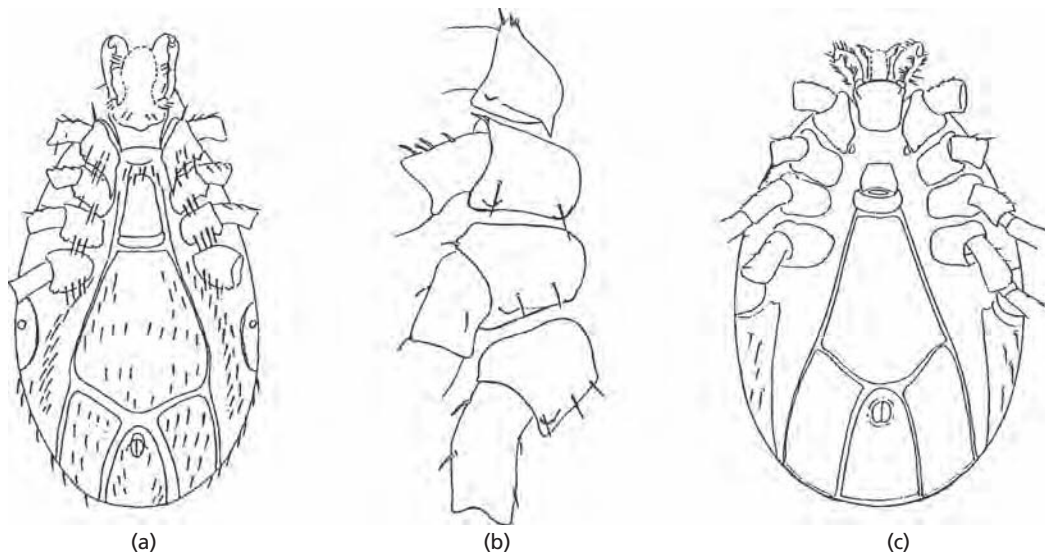

Fig. 3.117 Ventral view of the coxae of adult male (a) *Ixodes ricinus*, (b) *Ixodes hexagonus* and (c) *Ixodes canisuga*. (From Arthur, 1962.)

The host on which nymphs feed is usually larger than that of the larvae, typically a bird, rabbit or squirrel. Twelve months later adults begin to quest for a host, on which they feed and mate. Adults feed for 8–10 days on larger mammals, such as sheep, cattle or deer, and achieve this selection by climbing to different levels in the vegetation while questing.

Although the life cycle takes 3 years to complete, the larvae, nymphs and adults feed for a total of only 15–20 days and *I. ricinus* is therefore a temporary parasite. Unfed larvae, nymph and adults can survive for many months, entering a state of diapause to assist survival over winter, but the precise period over which they can survive between blood meals depends on temperature and humidity.

***Ixodes hexagonus* (hedgehog tick)**

Description: Adult ticks are red–brown, with legs that may appear somewhat banded in colour. The scutum is broadly hexagonal (hence the name *hexagonus*) and, like *I. ricinus*, the coxae of the first pair of legs bear a spur. However, the spur is smaller than in *I. ricinus* and does not overlap the coxa of the second pair of legs (Fig. 3.117b). When engorged the female may be up to 8 mm in length. Males are about 3.5–4 mm in length. The tarsi are long (0.8 mm in the female and 0.5 mm in the male) and sharply humped apically (Fig. 3.116b).

Life cycle: *Ixodes hexagonus* is a three-host tick adapted to live with hosts which use burrows or nests. It is primarily a parasite of hedgehogs but may also be found on dogs and other small mammals. The life cycle is similar to that of *I. ricinus*: egg, hexapod larva, octopod nymph and adult, occurring over 3 years. All life-cycle stages feed on the same host for periods of about 8 days. After dropping to the ground adult females produce 1000–1500 eggs over a period of 19–25 days, before they die. The ticks may be active from early spring to late autumn, but are probably most active during April and May. This species inhabits sheltered habitats such as burrows and kennels and may infest pets in large numbers when they are exposed.

***Ixodes canisuga* (dog tick)**

Description: *Ixodes canisuga* is an inornate tick, without festoons or eyes. The palps are long and the ventral surface of the male is almost entirely covered with a series of plates. An anal groove is present anterior to the anus. The engorged adult female is light grey, up to 10 mm in length and bean-shaped, with four pairs of legs. The adult males are only 2–3 mm long, and the four pairs of legs are readily visible. *Ixodes canisuga* can be differentiated from *I. ricinus* by the presence of humped tarsi (Fig. 3.116c) and the absence of a spur on the posterior internal angle of the first coxa (Fig. 3.117c). Nymphs resemble the adults and also have four pairs of legs, but are less than 2 mm in size. The larvae ('pepper ticks') are less than 1 mm, usually yellowish in colour and have only three pairs of legs.

Life cycle: *Ixodes canisuga* is a three-host tick and the life cycle requires approximately 3 years to complete. The tick feeds for only a few days each year, as a larva in the first year, a nymph in the second and an adult in the third. The life cycle is adapted to life in a lair or den. Mating takes place in the den and adult males are only rarely found on the host. Adult females lay relatively small numbers of eggs, probably about 400.

***Ixodes holocyclus* (paralysis tick)**

Description: The Australian paralysis tick is found along the eastern coastline of Australia. Unfed adult females are oval, flat and yellowish in colour and 2–4 mm in length. The palps are long and slender. The anal groove forms a complete oval around the anus; this feature gives the tick its species name *holocyclus* or 'complete circle'. The marginal groove is well developed and continuous; hairs on the body are small, scattered and most numerous in the region of the marginal fold. Fully engorged adult females may be up to 14 mm in length. The first and last pairs of legs are distinctly darker than the two middle pairs of legs.

Life cycle: This species is a three-host tick. The tick feeds for only a few days each year, as a larva in the first year, a nymph in the second and an adult in the third. Mating takes place on the host. After

attachment the female is inseminated once and subsequently completes her single large blood meal; in contrast, the males feed intermittently and mate repeatedly. Once fertilised, the female subsequently feeds for about 14 days and then drops to the ground to lay several thousand eggs in sheltered spots, after which she dies. The larvae, which hatch from the eggs, will feed for about 6 days in the following year, then drop to the ground and moult to the nymphal stage. In the third year this stage feeds, drops off and becomes adult. Although the life cycle takes 3 years to complete, the larvae, nymphs and adults feed for a total of only 26–28 days.

***Ixodes persulcatus* (taiga tick)**

Description: The taiga tick is morphologically very similar to *I. ricinus*; it is an inornate, red–brown tick, without festoons or eyes. The palps are long and the ventral surface of the male is almost entirely covered with a series of plates. The engorged adult female is light grey and up to 10 mm in length. The major difference is that the female adult *I. persulcatus* has a straight or wavy genital opening rather than arched as in *I. ricinus*.

Life cycle: The taiga tick has a similar life cycle to *I. ricinus*, although adults are rarely active during autumn.

***Ixodes rubicundus* (Karoo paralysis tick)**

Description: Adult ticks have a small internal spine on coxa I and a posterior flap of weakly sclerotised cuticle on coxae I–III. In the male, the ventral ridge on the basis capituli has a central and two smaller lateral lobes and there are two large basal hypostomal teeth. The female scutum has a narrowly rounded posterior margin and flattened oval porose areas.

Life cycle: This is a three-host tick species. The tick feeds for only a few days as a larva, a nymph and an adult. The life cycle of this species takes about 2 years. Mating takes place on the host. After attachment the female is inseminated once and subsequently completes her single large blood meal; in contrast, the males feed intermittently and mate repeatedly. Once fertilised, the female subsequently feeds for about 14 days and then drops to the ground to lay several thousand eggs in sheltered spots, after which she dies.

***Ixodes scapularis* (deer tick, black-legged tick)**

Synonym: *Ixodes dammini*

Description: The identifying characteristics are the black legs, black scutum and long black capitulum.

Life cycle: This is a three-host tick species. It feeds for only a few days each year, as a larva in the first year, a nymph in the second and an adult in the third. Mating usually takes place on the host. After attachment the female is inseminated and subsequently completes her single large blood meal. In contrast, the adult males feed intermittently and mate repeatedly. Once fertilised, the female subsequently feeds for about 14 days and then drops to the ground to lay several thousand eggs in sheltered spots, after which she dies. The following year, peak larval activity occurs in August, when larvae attach and

feed on a wide variety of mammals and birds, particularly white-footed mice (*Peromyscus leucopus*). After feeding for 3–5 days, engorged larvae drop from the host to the ground where they overwinter before moulting to become a nymph. In May of the following year, larvae moult to become nymphs, which feed on a variety of hosts for 3–4 days. Engorged nymphs then detach and drop to the forest floor where they moult into the adult stage, which becomes active in October. Adult ticks remain active through the winter on days when the ground and ambient temperatures are above freezing. The adult ticks feed on large mammals, primarily white-tailed deer, *Odocoileus virginianus*. Although the life cycle takes 3 years to complete, the larvae, nymphs and adults feed for a total of only 26–28 days.

***Ixodes pacificus* (western black-legged tick)**

Description: A very similar species to *Ixodes scapularis*. Adult ticks are red–brown in colour and about 3 mm in size. Larvae and nymphs are smaller and paler in colour.

Dermacentor

Ticks of the genus *Dermacentor* are medium-sized to large ticks, usually with ornate patterning. The palps and mouthparts are short and the basis capituli is rectangular (Fig. 3.114c). Festoons and eyes are present. The coxa of the first pair of legs is divided into two sections in both sexes. Coxae progressively increase in size from I to IV. The males lack ventral plates and, in the adult male, the coxa of the fourth pair of legs is greatly enlarged. Most species of *Dermacentor* are three-host ticks, but a few are one-host ticks. The genus is small with about 30 species, most of which are found in the New World.

***Dermacentor* species of veterinary importance**

| Species | Hosts | Site |
|---|--|------|
| <i>Dermacentor andersoni</i> (syn. <i>Dermacentor venustus</i>) | Rodents, wild and domestic ruminants | Skin |
| <i>Dermacentor variabilis</i> | Rodents, dog, horse, cattle, human, wild animals | Skin |
| <i>Dermacentor albipictus</i> | Moose, deer, wild mammals, cattle, horse, human | Skin |
| <i>Dermacentor reticulatus</i> | Sheep, cattle, dog, horse, pig, human; nymphs and larvae feed on rodents, insectivores, and occasionally birds | Skin |
| <i>Dermacentor marginatus</i> | Sheep, cattle, deer, dog, human, hare and hedgehog; nymphs and larvae feed on rodents, insectivores, birds | Skin |
| <i>Dermacentor nitens</i> | Horse, cattle, human, many domestic and wild mammals | Skin |
| <i>Dermacentor silvarum</i> | Cattle, sheep, horse, dog, human | Skin |
| <i>Dermacentor nuttalli</i> | Rodents, human | Skin |
| <i>Dermacentor occidentalis</i> | Cattle, horse, wild mammals | Skin |

***Dermacentor andersoni* (Rocky Mountain wood tick)**

Synonym: *Dermacentor venustus*

Description: *Dermacentor andersoni* is an ornate tick, with a base colour of brown and a grey pattern (Fig. 3.118). Males are about

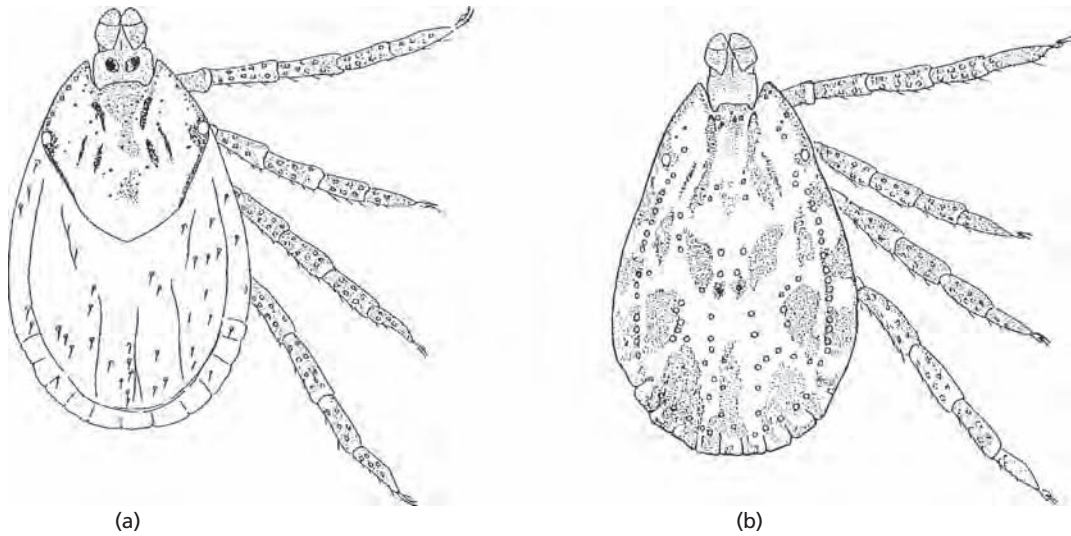

Fig. 3.118 Adult *Dermacentor andersoni*: (a) dorsal view of female; (b) dorsal view of male. (From Arthur, 1962.)

2–6 mm in length and females around 3–5 mm in length when unfed and 10–11 mm in length when engorged. The mouthparts are short. The basis capituli is short and broad (Fig. 3.114c). The legs are patterned in the same manner as the body. The coxae of the first pair of legs have well-developed external and internal spurs.

Life cycle: *Dermacentor andersoni* is a three-host tick. Immature stages primarily feed on small rodents, while adults feed largely on wild and domestic herbivores. Mating takes place on the host, following which females lay up to 6500 eggs over about 3 weeks. The eggs hatch in about 1 month, and the larvae begin to quest. Larvae feed for about 5 days, before dropping to the ground and moulting to the octopod nymphal stage. One- and two-year population cycles may occur. Eggs hatch in early spring and individuals that are successful in finding hosts pass through their larval stages in spring, their nymphal stages in late summer and then overwinter as adults in a 1-year cycle. Nymphs that fail to feed have to overwinter,

and form a spring-feeding generation of nymphs the following year. Unfed nymphs may survive for up to a year. *Dermacentor andersoni* is most common in areas of scrubby vegetation, since these attract both the small mammals required by the immature stages and the large herbivorous mammals required by the adults.

***Dermacentor variabilis* (American dog tick, wood tick)**

Description: These are ornate, pale brown and grey ticks with eyes and festoons (Fig. 3.119). The basis capituli is rectangular and the palps short. Adult males are about 3–4 mm in length and adult females about 4 mm in length when unfed and 15 mm in length when engorged. *Dermacentor variabilis* can be distinguished by the absence of a posterodorsal spur on palp segment II.

Fig. 3.119 Adult *Dermacentor variabilis*: (a) dorsal view of female; (b) dorsal view of male. (From Arthur, 1962.)

Life cycle: *Dermacentor variabilis* is a three-host tick, feeding once in each of the larval, nymphal and adult life-cycle stages. After each feed it drops from the host. Mating takes place on the host. Once fertilised, the adult female feeds for 5–27 days before dropping to the ground to lay 4000–6000 eggs in sheltered spots, after which she dies. Oviposition may last 14–32 days, depending on temperature and humidity. The larvae hatch from the eggs after 20–57 days and feed for between 2 and 13 days on the host, then drop to the ground and moult to the nymphal stage. This stage feeds over a period of several days, drops off and moults to become an adult. Unfed larvae, nymphs and adults can survive for very long periods of time under appropriate environmental conditions. The larval and nymphal stages feed on wild rodents, particularly the short-tailed meadow mouse (*Microtus* spp.), while the preferred hosts of adults are larger mammals, particularly wild and domestic carnivores.

***Dermacentor albipictus* (winter tick, moose tick)**

Description: The adults are ornately patterned ticks with eyes and festoons present. The basis capituli is rectangular and the palps short. The males lack ventral plates and the coxae of the fourth pair of legs are enlarged. In the adults of both sexes the coxa of the first pair of legs has an enlarged spur (bidentate), and in the male the coxae increase in size from I to IV.

Life cycle: This is a one-host species of tick. The larva, nymph and adult all attach to, and develop on, a single host. This species feeds only in winter, usually between October and March/April, on horses, deer and related large mammals. The engorged female drops off the host in the spring and lays between 1500 and 4400 eggs over a period of 19–42 days. The eggs hatch within 33–71 days. The larvae remain inactive until autumn when they then attach to a host, feed and moult to the nymph stage in 10–76 days. The nymphs engorge and moult to the adult stage in 10–76 days. Mating takes place on the host. The total period spent on the host is between 28 and 60 days, although unfed larvae can survive for up to 12 months before attachment to the host. Under normal conditions this tick species produces one generation per year.

***Dermacentor reticulatus* (ornate dog tick, marsh tick, meadow tick)**

Synonym: *Dermacentor pictus*

Description: This species is an ornate tick with eyes and festoons present (Fig. 3.120; see also Fig. 17.20). In both sexes the scutum is usually pale with variegated brown splashes (but coloration may be highly variable). The basis capituli is rectangular and the palps short. The adult female is 3.8–4.2 mm when unfed and 10 mm in length when engorged. The adult male is approximately 4.2–4.8 mm in length. The males lack ventral plates, and the coxae of the fourth pair of legs are enlarged with a narrow tapering external spur. In the adults of both sexes the coxa of the first pair of legs has an enlarged spur (bidentate). The other coxae have short internal spurs that become progressively smaller in legs II to IV.

Life cycle: *Dermacentor reticulatus* is a three-host tick, and the life cycle can be completed in only 1–2 years, depending on environmental conditions. The species feeds once in each of the larval, nymphal and adult life cycle stages, dropping from a host, moulting and then reacquiring a new host between feeds. Mating

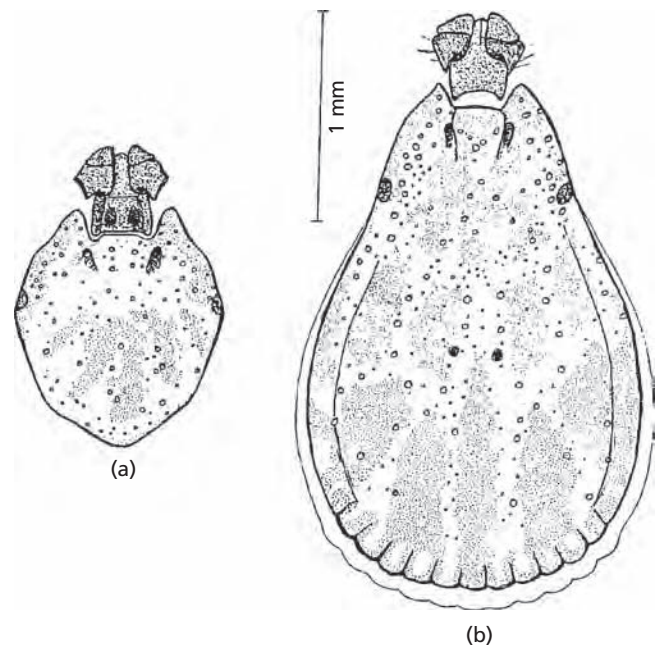

Fig. 3.120 Dorsal view of the gnathosoma and scutum of adult (a) female and (b) male *Dermacentor reticulatus*. (From Arthur, 1962.)

takes place on the host and once fertilised the adult female feeds for 9–15 days, before dropping to the ground to lay approximately 4000 eggs in sheltered spots, after which she dies. Oviposition may last for 6–40 days, depending on temperature and humidity, with oviposition rate peaking on about the fifth day. The larvae hatch from the eggs after 2–3 weeks and feed for approximately 2 days on the host, then drop to the ground and moult to the nymphal stage. This stage feeds over a period of several days, drops off and moults to become an adult.

***Dermacentor marginatus* (ornate sheep tick)**

Description: *Dermacentor marginatus* is distinguished from other species of *Dermacentor* by the sclerotised thickening at the base of the dorsal prolongation of the spiracular plate. In the adult, an external and internal spur is present on coxae I, the external spur being slightly shorter than the internal spur. In females the genital aperture forms a narrow V-shape. The engorged adult female may be up to 15 mm in length.

Life cycle: This is a three-host tick.

***Dermacentor nitens* (tropical horse tick)**

Description: Male ticks are 2–4 mm long, inornate and appear yellowish-brown in colour. Females are 2–5 mm long. The scutum of female ticks is brownish-yellow in colour, somewhat longer than wide with no discernible pattern, but appears glossy.

Life cycle: This is a one-host tick species; the larva, nymph and adult all attach to, and develop on, a single host. The engorged female drops

off the host, and lays up to 3500 eggs over a period of 15–37 days. The eggs hatch within 19–39 days. The larvae then attach to the host, feed and moult to the nymph stage in 8–16 days. The nymphs engorge and moult to the adult stage in 7–29 days. Mating takes place on the host. The total period spent on the host is between 26 and 41 days, although unfed larvae can survive for up to 117 days before attachment to the host. Under favourable tropical conditions this tick species can produce several generations per year.

Dermacentor nuttalli

Description: The basis capituli in the male is broader than long and the ventral spur on palpal segment 3 is lacking. In the female the basis capituli is almost twice as broad as long. The first pair of coxae is small with a relatively broad and bluntly rounded spur. The external spurs on coxae II–IV are approximately equal in length and those of coxae IV do not extend beyond the posterior margin.

Dermacentor occidentalis (Pacific coast tick)

Description: The basis capituli is longer than wide, with the cornua as long as or longer than wide. Sizes of scutal punctations are not greatly disparate and the pearl-grey coloration of the scutum is more extensive than brown.

Life cycle: *Dermacentor occidentalis* is a three-host tick. The tick feeds for only a few days as a larva, a nymph and an adult, each on a different host. Mating takes place on the host. After attachment the female is inseminated once, subsequently completes her single large blood meal, drops to the ground and lays her eggs.

Haemaphysalis

Ticks of the genus *Haemaphysalis* inhabit humid well-vegetated habitats in Eurasia and tropical Africa. They are three-host ticks, with the larvae and nymphs feeding on small mammals and birds and adults

infesting larger mammals and, importantly, livestock. There are about 150 species, found largely in the Old World, with only two species found in the New World. Most species of the genus are small, with short mouthparts and a rectangular basis capituli (Fig. 3.114g). The palps are short and broad, and usually with lateral projections at the base. Ventral plates are not present in the male. Spiracular plates are rounded or oval in females and rounded or comma-shaped in males. Like *Ixodes* spp., these ticks lack eyes, but they differ in having festoons and a posterior anal groove. The identification of more than the major species is beyond the scope of this text and interested readers will need to consult a relevant taxonomic specialist.

Haemaphysalis species of veterinary importance

| Species | Hosts | Site |
|---------------------------------------|--|------|
| <i>Haemaphysalis punctata</i> | Cattle, sheep, goat, horse, deer, wolf, bear, bat, birds, rabbit Larvae: on birds, hedgehogs, rodents and reptiles such as lizards and snakes | Skin |
| <i>Haemaphysalis leachi</i> | Dog, domestic and wild carnivores, small rodents and occasionally cattle | Skin |
| <i>Haemaphysalis longicornis</i> | Cattle. All mammals and birds | Skin |
| <i>Haemaphysalis spinigera</i> | Monkeys, birds and cattle Larvae and nymphs: small mammals, human | Skin |
| <i>Haemaphysalis bispinosa</i> | Wide variety of mammals, sheep and cattle | Skin |
| <i>Haemaphysalis concinna</i> | Variety of mammals, sheep | Skin |
| <i>Haemaphysalis cinnabarina</i> | Variety of ruminants | Skin |
| <i>Haemaphysalis leporispalustris</i> | Rabbit, snowshoe hare, birds, rarely feeds on humans | Skin |

Haemaphysalis punctata

Description: Small inornate ticks with festoons; eyes absent (Fig. 3.121; see also Fig. 17.21). The palps and hypostome are short. The adults of both sexes are about 3 mm in length, the female reaching about 12 mm in length when engorged. However, sexual

Fig. 3.121 Dorsal view of the gnathosoma and scutum of adult (a) female and (b) male *Haemaphysalis punctata*. (c) Ventral view of the coxae of an adult male. (From Arthur, 1962.)

dimorphism is not pronounced. The basis capituli is rectangular, about twice as broad as long. The sensory palps are short and broad, with the second segment extending beyond the basis capituli. The anal groove is posterior to the anus. The coxae of the first pair of legs have a short blunt internal spur, which is also present on the coxae of the second and third pair of legs and which is enlarged and tapering on the coxae of the fourth pair of legs. In the male the spur may be as long as the coxa.

Life cycle: *Haemaphysalis punctata* is a three-host tick, feeding once in each of the larval, nymphal and adult life-cycle stages. After each blood meal it drops from the host. Engorgement on the host may take 6–30 days to complete. Once fed, each adult female lays 3000–5000 eggs on the ground, over a period of 10 days to 7 months. Unfed larvae can survive for up to 10 months, unfed nymphs and adults for 8.5 months.

***Haemaphysalis leachi* (yellow dog tick)**

Description: Inornate elongate ticks with 11 festoons; eyes absent. The palps are widely triangular with a basal spur on segment II.

Life cycle: *Haemaphysalis punctata* is a three-host tick, feeding once in each of the larval, nymphal and adult life-cycle stages. After each blood meal it drops from the host. Engorgement on the host may take 6–30 days to complete. Once fed, each adult female lays 3000–5000 eggs on the ground, over a period of 10 days to 7 months. Unfed larvae can survive for up to 10 months, unfed nymphs and adults for 8.5 months.

***Haemaphysalis longicornis* (scrub tick, New Zealand cattle tick)**

Description: Males ticks have a small internal spur on coxa IV and both sexes have a long internal spur on coxa I.

Life cycle: A three-host tick species. The larvae and nymphs primarily feed on small mammals and birds while adults infest larger mammals.

***Haemaphysalis concinna* (bush tick)**

Description: Similar to *H. punctata* but the female lacks cornua and the male has a long pointed spur on coxa IV.

***Haemaphysalis bispinosa* (bush tick)**

Description: Similar to *H. punctata* but has a prominent dorsal spur on the posterior edge of palp segment II.

Life cycle: A three-host tick species. Of interest is the suggestion that this tick may reproduce parthenogenetically.

Rhipicephalus

The genus is composed of about 60 species, all of which were originally endemic to the Old World and, for the most part, distributed

throughout sub-Saharan Africa. However, many species have now been introduced into a range of new habitats worldwide. They act as important vectors of a number of disease pathogens. They infest a variety of mammals but seldom birds or reptiles. Most species are three-host ticks but some species of the genus are two-host ticks.

The basis capituli is hexagonal (Fig. 3.114f) and, in the male, paired plates are found on each side of the anus. They are not ornate. Palps are short and eyes and festoons are usually present. Spiracular plates are comma-shaped. The identification of more than the major species is beyond the scope of this text and interested readers will need to consult a relevant taxonomic specialist.

***Rhipicephalus* species of veterinary importance**

| Species | Hosts | Site |
|-------------------------------------|--|---------------------------|
| <i>Rhipicephalus appendiculatus</i> | Cattle, horse, sheep, goat, deer, antelope, dog, rodents and wide range of mammals and birds | Skin, ears |
| <i>Rhipicephalus bursa</i> | Cattle, sheep, horse, dog and wide range of mammals and birds | Skin |
| <i>Rhipicephalus capensis</i> | Cattle, horse, sheep, goat, deer, antelope, dog and wide range of mammals and birds | Skin |
| <i>Rhipicephalus evertsi</i> | Cattle, sheep, goat, horse, dog and wide range of mammals and birds | Skin |
| <i>Rhipicephalus sanguineus</i> | Dog, other mammals and birds | Skin, ears, toes |
| <i>Rhipicephalus pulchellus</i> | Zebra, also infests livestock and game animals | Skin, ears, lower abdomen |
| <i>Rhipicephalus simus</i> | Dog, wild carnivores, livestock, game animals and humans Larvae and nymphs: burrowing rodents | Skin, ears, lower abdomen |

***Rhipicephalus appendiculatus* (brown ear tick)**

Description: Adult male *R. appendiculatus* are brownish, reddish-brown or very dark, with reddish-brown legs. They vary from 1.8 to 4.4 mm in length. The scutal punctations are scattered and of moderate size; they are evenly dispersed in the centre, but few or none may be found beyond the lateral grooves and in the lateral fields. The cervical grooves are moderately reticulate or non-reticulate. The posteromedian and paramedian grooves are narrow and distinct. The adanal shields are long and have slightly rounded angles, but can be somewhat variable. Adult female ticks are also brown, reddish-brown or very dark. The punctations are small to moderate-sized and are similar to those found in the male. The scutum is approximately equal in length and width; its posterior margin is slightly tapering or abruptly rounded. The lateral grooves are short, poorly defined or absent. The cervical grooves are long and shallow and almost reach the posterolateral margins.

Life cycle: This is a three-host tick.

Rhipicephalus bursa

Description: A highly distinctive species. The male has a combination of an anterior spur on coxa I which is visible dorsally, distinct

lateral and posterior grooves, and densely punctate scutum and broad adanal plates. The scutum of the female is similar to the conscutum of the male in being densely punctate and without apparent cervical fields. Both sexes have large numbers of setae around the spiracles.

Life cycle: This is a three-host species of tick, feeding once in each of the larval, nymphal and adult life-cycle stages. After engorging as a larva and nymph it drops from the host and then moults, before locating a further host. After engorging, adult females drop to the ground, lay their eggs and then die.

***Rhipicephalus capensis* (Cape brown tick)**

Description: Ticks are red-brown in colour, with relatively long, wide and expanding cervical grooves and distinct median and paramedian grooves.

Life cycle: This is a three-host species of tick. After locating a host, the adult female engorges in 4–21 days. It then drops to the ground where it lays 3000–7000 eggs before dying. The eggs hatch in 28 days to 3 months, depending on the temperature and climatic conditions. Subsequently the hexapod larvae locate a suitable host and engorge over a period of 3–6 days. They then drop to the ground before moulting 5–49 days later to become nymphs. The nymphs locate a further host where they engorge over a period of 3–9 days. Nymphs then drop to the ground and moult 10–61 days later to become adults.

***Rhipicephalus evertsi* (red-legged tick)**

Description: This species can be distinguished from other members of the genus by its red legs. It has a black scutum, which is

densely pitted, and in the male leaves a red margin of the opisthosoma uncovered.

Life cycle: This is a two-host species of tick. The larval and nymphal stages engorge on the same host. The female lays approximately 5000–7000 eggs over a period of 6–24 days. These hatch in 4–10 weeks depending on the temperature and climatic conditions. Larvae and nymphs remain on the host for between 10 and 15 days before dropping to the ground. Nymphs then moult after 42–56 days. Subsequently, adults locate a second host, when the adult female engorges in 6–10 days. The larvae and nymphs are commonly found in the ears or the inguinal region, while the adults are mainly found under the tail. Unfed larvae can survive for 7 months, while unfed adults can survive for 14 months.

***Rhipicephalus sanguineus* (brown dog tick, kennel tick)**

Description: This species is yellow, reddish or blackish-brown in colour and unfed adults may be 3–4.5 mm in length, although size is highly variable and engorged females may reach a length of 12 mm (Fig. 3.122). The palps and hypostome are short and the basis capituli hexagonal dorsally. The coxa of the first pair of legs has two spurs. The legs may become successively larger from the anterior to the posterior pair. The tarsi of the fourth pair of legs possess a marked ventral tarsal hook. The anal groove encircles only the posterior half of the anus and then extends into a median groove. The males have adanal plates and accessory shields. The six-legged larvae are small and light brown in colour, while the eight-legged nymphs are reddish-brown in colour. Recent taxonomic studies suggest that *Rhipicephalus sanguineus sensu lato* may be a species complex, with morphologically similar but genetically distinct types.

Life cycle: This species has a three-host life cycle. Mating takes place on the host. Once fertilised, the female feeds for about 14 days

Fig. 3.122 Dorsal view of the gnathosoma and scutum of adult (a) female and (b) male *Rhipicephalus sanguineus*. (c) Ventral view of the coxae and trochanters of an adult male. (d, e) Tarsi and metatarsi of the fourth pair of legs of an adult (d) male and (e) female. (From Arthur, 1962.)

and then drops to the ground to lay approximately 4000 eggs in sheltered spots, after which she dies. Egg masses are likely to be found in above-ground cracks and crevices (e.g. kennel roofs) due to the females' behavioural tendency to crawl upward. The eggs hatch after 17–30 days. The larvae, which hatch from the eggs, will feed for about 6 days the following year, then drop to the ground and moult to the nymphal stage over a period of 5–23 days. In the third year this stage feeds for 4–9 days, drops off the host and moults to the adult stage. Under favourable conditions the life cycle may require as little as 63 days, hence several generations may occur each year. However, under adverse conditions unfed larvae can survive for as long as 9 months, unfed nymphs for 6 months and unfed adults for 19 months.

***Rhipicephalus pulchellus* (ivory-ornamented tick, zebra tick)**

Description: Male ticks have a pattern of stripes of white enamel on a dark brown background over their entire conscutum.

Life cycle: Adults and immatures generally infest the same host; however, immatures also feed on small mammals

***Rhipicephalus simus* (glossy tick)**

Description: Characterised by a shiny black, largely smooth scutum, which in the male has a row of large punctations in the deep marginal groove.

***Rhipicephalus* (*Boophilus*)**

Ticks of the genus *Boophilus* ('blue ticks') are now considered a subgenus of *Rhipicephalus*, and the name *Rhipicephalus* (*Boophilus*) is used for the five species in the subgenus for which there is a large amount of literature. *Rhipicephalus* (*Boophilus*) species are important as vectors of *Babesia* spp. and *Anaplasma marginale* in cattle in subtropical and tropical countries. The males have adanal or accessory ventral shields. The basis capituli is hexagonal dorsally. The mouthparts are short and compressed and the palps are ridged dorsally and laterally (Fig. 3.114e). Unfed adults may be only 2 or 3 mm long, reaching lengths of up to 12 mm when engorged. The identification of more than the major species is beyond the scope of this text and interested readers will need to consult a relevant taxonomic specialist.

***Rhipicephalus* (*Boophilus*) species of veterinary importance**

| Species | Hosts | Site |
|--|--|------|
| <i>Rhipicephalus</i> (<i>Boophilus</i>) <i>annulatus</i> | Cattle, horse, goat, sheep, camel, dog and wide range of mammals and birds | Skin |
| <i>Rhipicephalus</i> (<i>Boophilus</i>) <i>microplus</i> | Cattle, sheep, goat, wild ungulates | Skin |
| <i>Rhipicephalus</i> (<i>Boophilus</i>) <i>calcaratus</i> | Cattle, sheep, goat, wild ungulates | Skin |
| <i>Rhipicephalus</i> (<i>Boophilus</i>) <i>decoloratus</i> | Cattle, horse, donkey, sheep, goat, dog, wild ungulates | Skin |

***Rhipicephalus* (*Boophilus*) *annulatus* (blue cattle tick, Texas cattle fever tick)**

Description: The internal margin of the first palp article is long and slightly concave, and the spurs and cleft between the spurs on the first coxa of females are less distinct than those of *Rhipicephalus* (*Boophilus*) *microplus* females. The second coxa in females lacks a spur and the males lack a caudal appendage.

Life cycle: This is a one-host tick species. The larva, nymph and adult all attach to, and develop on, a single host. The engorged female drops off the host and lays between 2000 and 3000 eggs over a period of 14–59 days. The larvae hatch after 23–159 days depending on climatic conditions. The larvae then attach to the host, feed and moult to the nymph and then adult stage. Mating takes place on the host. The total period spent on the host is between 15 and 55 days, although unfed larvae can survive for up to 8 months before attachment to the host. Two to four generations may occur per year, depending on climatic conditions; the entire life cycle of this species can be completed in 6 weeks.

***Rhipicephalus* (*Boophilus*) *microplus* (tropical cattle tick, southern cattle tick)**

Description: Adult ticks have a short straight gnathosoma. The legs are pale cream. The body is oval to rectangular and the scutum is oval and wider at the front. The anal groove is obsolete in the female and is faint in the male and surrounds the anus posteriorly. Coxa I is bifid. The spiracles are circular or oval. The nymphs of this species have an orange–brown scutum. The body is oval and wider at the front. The body colour is brown to blue–grey, with white at the front and sides.

Life cycle: This species is a one-host tick. The larva, nymph and adult all attach to, and develop on, a single host. The engorged female drops off the host and lays between 2000 and 4500 eggs over a period of 4–44 days. The larvae hatch after 14–146 days depending on climatic conditions. The larvae then attach to the host, feed and moult to the nymph and then adult stages. From the attachment of larvae to engorgement of the adult female requires 3 weeks. After engorging, females can weigh up to 250 times more than when unfed. Mating takes place on the host. The total period spent on the host is between 17 and 52 days, and the entire life cycle can be completed within 2 months, although unfed larvae can survive for up to 20 weeks before attachment to the host. Although present all year round, populations reach their peak in summer.

***Rhipicephalus* (*Boophilus*) *decoloratus* (blue tick)**

Description: The engorged females have slate-blue coloured bodies with pale yellow legs.

Life cycle: This is a one-host tick species. The larva, nymph and adult all attach to, and develop on, a single host. The engorged female drops off the host, then lays and incubates approximately 2500 eggs over a period of 3–6 weeks. The larvae then attach to the

host, feed and moult to the nymph and then adult stage. Mating takes place on the host. The total period spent on the host ranges between 21 and 25 days, although unfed larvae can survive for up to 7 months before attachment to the host.

Hyalomma

It has been suggested that ticks in the family Hyalomminae should be synonymised with the Rhipicephalinae but as this is still not universally accepted, ticks in the genus *Hyalomma* will be considered separately within this text. *Hyalomma* spp. are usually two-host ticks, though some species may use three hosts. They are most commonly found on the legs, udder and tail, or perianal region. There are about 20 species, found usually in semi-desert lowlands of central Asia, southern Europe and North Africa. They can survive exceptionally cold and dry conditions. Species of *Hyalomma* are medium-sized or large ticks, usually inornate, but with banded legs (giving them the common name of the 'bont-legged' ticks). The palps and hypostome are long (Fig. 3.114b), eyes are present and festoons sometimes present. The males have ventral plates on each side of the anus.

Hyalomma species of veterinary importance

| Species | Hosts | Site |
|--|--|---|
| <i>Hyalomma anatolicum</i> <i>H. anatolicum anatolicum</i> <i>H. anatolicum excavatum</i> (brown ear tick) | Cattle, horse, wide range of mammals and birds Rodents; adults on ruminants, horses | Skin, axilla, inguinal region, face, ears |
| <i>Hyalomma aegyptium</i> | Tortoises (<i>Testudo</i> spp.), lizards, dog, horse | Skin |
| <i>Hyalomma detritum</i> <i>H. detritum detritum</i> <i>H. detritum scupense</i> <i>H. detritum mauretanicum</i> | Cattle, sheep, goat, horse, wide range of mammals and birds | Skin, axilla, inguinal region, face, ears |
| <i>Hyalomma dromedarii</i> | Camels, ruminants, horses | Skin, axilla, inguinal region, face, ears |
| <i>Hyalomma marginatum</i> <i>H. marginatum marginatum</i> <i>H. marginatum rufipes</i> <i>H. marginatum turanicum</i> <i>H. marginatum isaaci</i> | Wild herbivores, ruminants, horses Larvae and nymphs: small mammals, birds, lizards | Skin, axilla, inguinal region, face, ears |
| <i>Hyalomma truncatum</i> | Cattle, sheep, goat, pig, horse, wide range of mammals and birds | Skin, axilla, inguinal region, face, ears |
| <i>Hyalomma impressum</i> | Cattle, sheep, large African mammals | Skin, axilla, inguinal region, face, ears |

Hyalomma anatolicum (bont-legged tick)

Subspecies: *Hyalomma anatolicum anatolicum*, *Hyalomma anatolicum excavatum*

Description: Usually with banded legs; eyes are present and festoons sometimes present. The palps and hypostome are long. The gnathosoma and coxae are dark, reddish or black-brown. The males have adanal shields. The second segment of the palps is less

than twice as long as the third segment, and the scutum has no pattern.

Life cycle: This species is a two- or three-host tick. Larvae acquire a host, feed and moult. Nymphs reattach to the same host soon after moulting. Following engorgement nymphs drop off the host, moult to the adult stage and then acquire a new second host where they feed. After attachment, mating occurs and the female completes her single large blood meal. Males feed intermittently and mate repeatedly. Once fertilised the female feeds for about 14 days and then drops to the ground to lay several thousand eggs in sheltered spots, after which she dies. The larvae and nymphs feed on birds and small mammals, and the adults on ruminants and equines. When larvae and nymphs infest smaller mammals, birds or reptiles, the life cycle may become a three-host model.

Hyalomma aegyptium (tortoise tick)

Description: These are large brown ticks with eyes and long mouthparts. Females 5.5–20 mm; males 3–6 mm. Coxa I has a large divergent spur in females and a prominent, sharply pointed spur in males.

Life cycle: This species is a two-host tick. The larval and nymphal stages engorge on the same host.

Hyalomma detritum (bont-legged tick)

Subspecies: *Hyalomma detritum detritum*, *Hyalomma detritum scupense*, *Hyalomma detritum mauretanicum*

Synonyms: *Hyalomma volgense*, *Hyalomma uralense*

Description: *Hyalomma detritum detritum* is similar to the subspecies *Hyalomma detritum scupense* and both are relatively small and lacking in punctations compared to other *Hyalomma* species. Both these subspecies do not have pale rings on the legs. The legs are yellow to orange coloured in *H. d. detritum* and relatively long, but brown and short in *H. d. scupense*. The relative thicknesses of the ends of the spiracle plates are distinctive in both sexes; narrow in *H. d. detritum*, broad in *H. d. scupense*.

Life cycle: This species is a two-host tick. The larval and nymphal stages engorge on the same host. The female lays 5000–7000 eggs over a period of 37–59 days. These hatch in 34–66 days depending on the temperature and climatic conditions. Larvae and nymphs remain on the first host for between 13 and 45 days. Nymphs drop off the host and then moult to become adults. Subsequently the adult finds a second host where the adult female engorges in 5–6 days. Unfed larvae can survive for 12 months, unfed nymphs for 3 months and unfed adults for 14 months.

Hyalomma dromedarii (camel tick)

Description: *Hyalomma dromedarii* is usually inornate but with banded legs; eyes are present and festoons are sometimes present. The second segment of the palps is usually less than twice as long as the third segment, and the scutum has no pattern.

Life cycle: This is predominantly a two-host species of tick. Larvae acquire a host, feed and moult. Nymphs reattach to the same host soon after moulting. Following engorgement nymphs drop off the host, moult to the adult stage and then acquire a new second host where they feed. After attachment, mating occurs and the female completes her single large blood meal. Males feed intermittently and mate repeatedly. Once fertilised the female feeds for about 14 days and then drops to the ground to lay several thousand eggs in sheltered spots, after which she dies. In some circumstances, a variable life cycle has been reported for *H. dromedarii* with a three-host life cycle observed on sheep or cattle. It appears that the type of host, rearing conditions, density and age of the larvae may influence the life cycle adopted by this species.

***Hyalomma marginatum* (Mediterranean tick)**

Subspecies: *Hyalomma marginatum marginatum*, *Hyalomma marginatum rufipes*, *Hyalomma marginatum turanicum*, *Hyalomma marginatum isaaci*

Description: Dark-brown or reddish ticks with pale banded legs (see Fig. 17.23). Eyes are present and festoons sometimes present. The palps and hypostome are long. The males have adanal shields. The second segment of the palps is less than twice as long as the third segment, and the scutum has no pattern. Female ticks have a large porose area and punctations on the scutum are small and sparse. In both sexes, coxa I has a long slender external spur.

Life cycle: The members of this species complex have a two-host life cycle, larvae and nymphs remaining and feeding on the same host. The engorged nymphs drop to the ground and moult to become an adult. Subsequently the adult feeds and engorges on a second host. The life cycle takes a minimum of 14 weeks from egg to adult.

***Hyalomma truncatum* (bont-legged tick)**

Description: Reddish-brown to nearly black ticks. The posteromedian and posterolateral spurs on coxa I are long and subequal in length in both sexes. In the female, the genital aperture is wide and deeply rounded.

Life cycle: This species is a two-host tick.

Amblyomma

Members of this genus are large, often highly ornate ticks with long legs, which are often banded. Unfed females are up to 8 mm in length, but when engorged may reach 20 mm in length. Eyes and festoons are present. Males lack ventral plates. They have long mouthparts (Fig. 3.114d) with which they can inflict a deep painful bite that may become secondarily infected. There are about 100 species of *Amblyomma*, largely distributed in tropical and subtropical areas of Africa. However, one important species is found in temperate North America. The identification of more than the major species is beyond the scope of this book and interested readers will need to consult a relevant taxonomic specialist.

***Amblyomma* species of veterinary importance**

| Species | Hosts | Site |
|-----------------------------|--|---|
| <i>Amblyomma americanum</i> | Wild and domestic animals, particularly cattle; birds Larvae: small mammals | Skin, ears, flanks, head and ventral abdomen |
| <i>Amblyomma variegatum</i> | Wide range of mammals, particularly cattle | Skin |
| <i>Amblyomma cajennense</i> | Wide range of mammals, particularly horses | Skin, lower surface of body, axilla and groin |
| <i>Amblyomma hebraeum</i> | Wide range of mammals and birds | Skin |
| <i>Amblyomma gemma</i> | Wide range of mammals, particularly cattle, camels, large herbivores | Skin |
| <i>Amblyomma maculatum</i> | Wide range of mammals and birds | Skin, ears |
| <i>Amblyomma pomposum</i> | Mammals, particularly cattle, sheep and goats | Skin |
| <i>Amblyomma lepidum</i> | Sheep, goats, cattle | Skin |
| <i>Amblyomma astrion</i> | Buffalo, cattle | Skin |
| <i>Amblyomma sparsum</i> | Reptiles, tortoise | Skin |
| <i>Amblyomma marmorium</i> | Tortoise tick | Skin |

***Amblyomma americanum* (lone star tick)**

Description: The lone star tick, *Amblyomma americanum*, is so called because of a single white spot on the scutum of the female (Fig. 3.123). These are large, usually ornate, ticks the legs of which have bands of colour. Eyes and festoons are present. The palps and hypostome are long, and ventral plates are absent in the males. The engorged female is up to 10 mm in length, bean-shaped and has four pairs of legs. The female is reddish-brown in colour, becoming light grey when engorged. On the scutum are two deep parallel cervical grooves and a large pale spot at its posterior margin. The male is small with two pale symmetrical spots near the hind margin of the body, a pale stripe at each side, and a short oblique pale stripe behind each eye. The males are only 2–3 mm in length, and because of the small idiosoma the four pairs of legs are readily visible. In

Fig. 3.123 Dorsal view of the gnathosoma and scutum of adult (a) female and (b) male *Amblyomma americanum*. (From Arthur, 1963.)

both sexes, coxa I has a long external spur and a short internal spur, and the mouthparts are much longer than the basis capituli.

Nymphs resemble the adults and also have four pairs of legs but are less than 2 mm in size, while the larvae ('pepper ticks') are less than 1 mm in length, usually yellowish in colour and have only three pairs of legs.

Life cycle: The life cycle is typical of a three-host tick. Adult females attach to a host and take a single large blood meal over a period of 3–4 weeks, taking 0.5–2.0 mL of blood, during the course of which they mate once. In contrast, the males feed intermittently and mate repeatedly. Once fertilised, the female drops to the ground to lay several thousand eggs in sheltered spots, after which she dies. The larvae which hatch from the eggs will feed for about 6 days in the following year, then drop to the ground and moult to the nymphal stage. In the third year this stage feeds, drops off and becomes adult. Although the life cycle takes 3 years to complete, the larvae, nymphs and adults feed for a total of only 26–28 days. Larvae and nymphs feed on rodents, rabbits and ground-inhabiting birds. Adults feed on larger mammals such as deer, cattle, horses and sheep.

***Amblyomma variegatum* (variegated tick, tropical bont tick)**

Description: Female *A. variegatum* are brown with a large pale patch on the posterior scutum, while males are brightly ornamented with orange coloration and a dark-brown border to the idiosoma (see Fig. 17.24). Both sexes of *A. variegatum* have hemispherical eyes. *Amblyomma variegatum* (and *A. hebraeum*) can be distinguished from *A. americanum* and *A. cajennense* by the shorter external spur on coxa I, which is closely associated with the internal spur. The scutum sides are straight and the scutum posterior angle is broad. The genital aperture is broadly U-shaped.

***Amblyomma cajennense* (cayenne tick)**

Description: In adults the scutum is usually very ornate, lattice-patterned often with bright multicoloured iridescent patterns. There may be pale central patches on the festoons.

***Amblyomma hebraeum* (bont tick)**

Description: *Amblyomma hebraeum* is an ornate tick with pink to orange ornamentation and pale rings on the legs. The eyes are slightly convex and close to the margin of the scutum. The scutum sides are convex and the scutum posterior angle is broad. The species has a short external spur on coxa I, which is closely associated with the internal spur.

Amblyomma gemma

Description: An ornate tick with large amounts of striking pink to orange ornamentation on the dorsal surface. The scutum has straight sides and broad posterior angle. The legs have pale-coloured rings. The eyes are flat and close to the margin of the scutum. In the female tick, the primary punctation on the scutum is localised and small to medium in size. In both male and female ticks, the external spurs on coxae I are medium in length and the internal spurs are short. In the male there is a broad posteromedian stripe.

***Amblyomma maculatum* (Gulf coast tick)**

Description: Similar to *A. americanum* but it has spurs on the second, third and fourth pairs of legs and more diffuse pale markings on the female ticks.

Aponomma

The genus *Aponomma* has been synonymised with the genus *Amblyomma*. Almost all the *Amblyomma* (*Aponomma*) tick species parasitise reptiles, such as snakes, lizards and tuatara. Four species are adapted to feed on primitive Australian mammals, the monotremes and marsupials.

Fig. 3.124 An argasid tick, *Argas vespertilonis*: (a) dorsal view of female; (b) ventral view of female. (From Arthur, 1963.)

FAMILY ARGASIDAE

Soft ticks have a leathery and unsclerotised body with a textured surface (Fig. 3.124), which in unfed ticks may be characteristically marked with folds or grooves. The integument is **inornate**. The palps appear somewhat leg-like, with the third and fourth segments equal in size. The gnathosoma is located ventrally and is not visible from the dorsal view in nymphs and adults. When present, the eyes are found in lateral folds above the legs. The stigmata are small and anterior to the coxae of the fourth pair of legs. The legs are similar to those of hard ticks; the pulvilli are usually absent or rudimentary in nymphs and adults, but may be well developed in larvae.

The soft ticks have a multi-host life cycle. The larval stage feeds once before moulting to become a first-stage nymph. There are between two and seven nymphal stages, each of which feed then leave the host before moulting to the next stage. The adult females lay small batches of eggs after each short feed, lasting only a few minutes.

These ticks, unlike the Ixodidae, are drought resistant and capable of living for several years, and are found predominantly in deserts or dry conditions, but living in close proximity to their hosts. There are three genera of veterinary importance, *Argas*, *Otobius* and *Ornithodoros*.

Argas

Species of the genus *Argas* are usually dorsoventrally flattened, with definite margins, which can be seen even when the tick is engorged. The cuticle is wrinkled and leathery. Most species are nocturnal. Sixty-one species have been described in the genus *Argas*, and they are allocated to seven subgenera. Two subgenera, *Argas* and *Persicargas*, parasitise birds; other subgenera are associated with bats and a small number of other mammals, while *Argas (Microargas) transversus* is a permanent ectoparasite of the Galapagos giant tortoise (*Geochelone elephantopus*). Most species seldom attack humans. Species of this genus are usually found in dry arid habitats. Descriptions of only the major species of veterinary importance are presented.

Argas species of veterinary importance

| Species | Hosts | Site |
|--|--------------------------------|----------------------------|
| <i>Argas persicus</i> | Chicken, turkey and wild birds | Skin |
| <i>Argas reflexus</i> | Pigeon | Skin |
| <i>Argas walkerae</i> (syn. <i>Persicargas walkerae</i>) | Chicken | Skin, common beneath wings |
| <i>Argas miniatus</i> | Wild birds | Skin |
| <i>Argas radiatus</i> | Wild birds | Skin |
| <i>Argas robertsi</i> | Wild birds | Skin |
| <i>Argas snachezi</i> | Wild birds | Skin |

Argas persicus (fowl tick, chicken tick, adobe tick, blue bug)

Argas persicus is of considerable veterinary importance as the most widespread argasid tick feeding on poultry.

Description: The unfed adult is pale yellow to reddish-brown, turning slate blue when fed. The female is about 8 mm in length and the male about 5 mm. The margin of the body appears to be composed of irregular quadrangular plates or cells, and no scutum is present. Unlike hard ticks, the four segments of the pedipalps are equal in length. The stigmata are situated on the sides of the body above the third and fourth pairs of legs. The integument is granulated, leathery and wrinkled. The hypostome is notched at the tip (Fig. 3.125f), and the mouthparts are not visible when the tick is viewed from above.

Life cycle: *Argas persicus* is nocturnal and breeds and shelters in cracks and crevices in the structure of poultry houses. Females deposit batches of 25–100 eggs in these cracks and crevices. Up to 700 eggs may be produced by a single female at intervals, each oviposition preceded by a blood meal. After hatching, larvae locate a host and remain attached and feed for several days. After feeding they detach, leave the host and shelter in the poultry house structure. Several days later they moult to become first-stage nymphs. They then proceed through two or three nymphal stages, interspersed with frequent nightly feeds, before moulting to the adult stage. Adult males and females feed about once a month, but can survive for long periods without a blood meal. Females can become completely engorged within 30–45 minutes. Under favourable conditions the life cycle can be completed in about 30 days. All stages of these ticks remain around the roosting area of poultry, quiescent in the day and actively feeding at night. *Argas persicus* can survive in empty poultry housing for years, and may travel long distances to find their hosts. This tick can undergo rapid increases in abundance, passing through one to ten generations per year, particularly in areas where birds are present all year round.

Argas reflexus (pigeon tick)

Description: The adult *Argas reflexus* is between 6 and 11 mm in length and may be distinguished from the fowl tick, *Argas persicus*, by its body margin, which is composed of irregular grooves, and the hypostome, which is not notched apically (Fig. 3.125e). It is reddish-brown in colour with paler legs.

Life cycle: The life cycle is similar to that of *A. persicus*. *Argas reflexus* is nocturnal and breeds and shelters in cracks and crevices in the roost structure. Females deposit batches of 50–100 eggs in these cracks and crevices. After hatching, larvae locate and attach to a host, where they remain and feed for several days. After feeding they detach, leave the host and shelter in the pigeon lofts or roosts. Several days later they moult to become first-stage nymphs. They then proceed through two to four nymphal stadia (with the fewest occurring in cooler temperatures), interspersed with frequent feeds, before moulting to the adult stage. Adult males and females feed about once a month. Females can become completely engorged within 30–45 minutes. All stages of these ticks remain around the roosting area, quiescent in the day and actively feeding at night. *Argas reflexus* can survive in empty roosts for more than a year. The egg-to-adult life cycle can take up to 11 years to complete. Engorged female ticks diapause during the summer months. If oviposition has already commenced, egg-laying stops and resumes the following year without the need for another blood meal.

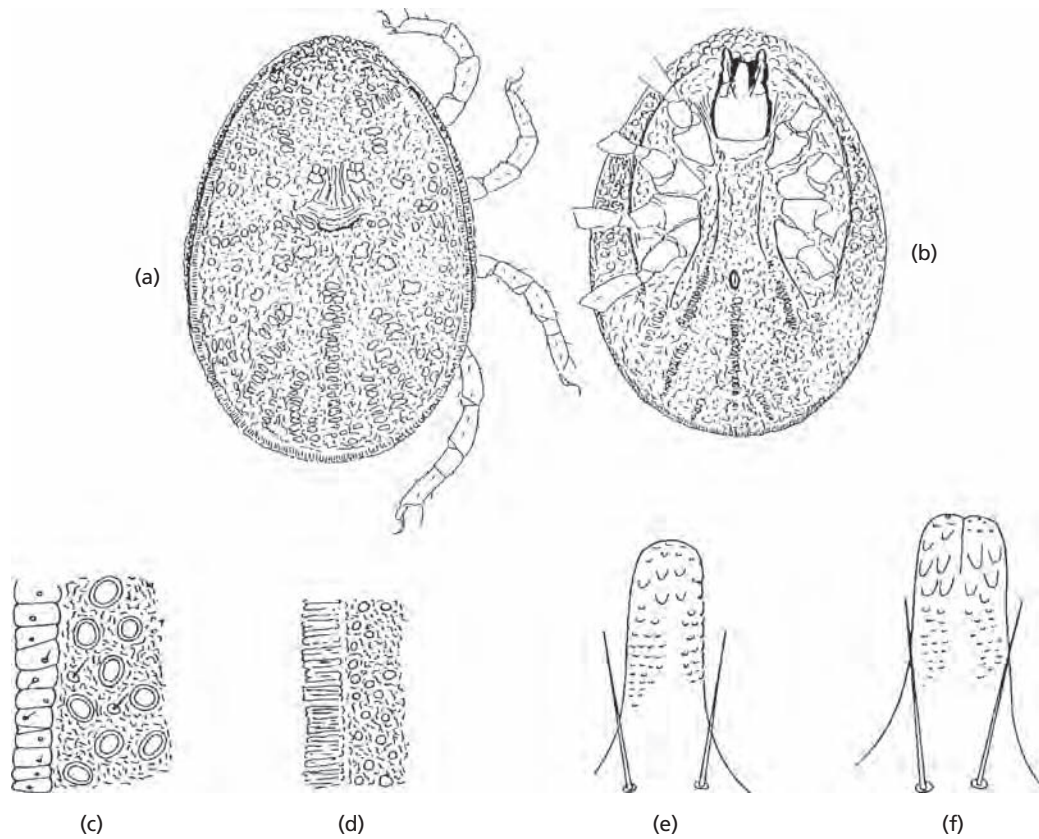

Fig. 3.125 Female *Argas reflexus*: (a) dorsal and (b) ventral view. Margin of (c) *Argas reflexus* and (d) *Argas persicus*. Hypostome of female (e) *Argas reflexus* and (f) *Argas persicus*. (From Arthur, 1962.)

***Argas walkerae* (chicken tick, southern fowl tample)**

Description: In the adults, the dorsal idiosomal discs are arranged more randomly than in *A. persicus*, the cells of the lateral structure vary in shape, and the apex of the hypostome is rounded.

Life cycle: Like most species of this genus: egg, larva, three nymphal stages and adult. It lives in crevices in the poultry house or nest material, moving on to the host to feed.

Ornithodoros

This genus includes 113 species, almost all of which are found in tropical and subtropical habitats in both the Old and New World. Most *Ornithodoros* species are found in Africa, commonly in the burrows of warthogs and bush pigs, though other species may be found in Central and South America and the Rocky Mountain states of the USA. They are nocturnal and the mouthparts are well developed. The integument has a wrinkled pattern, which runs continuously over the dorsal and ventral surfaces (see Fig. 17.25). There is no distinct lateral margin to the body, which appears sac-like. Species of this genus are found largely in habitats such as dens, caves, nests and burrows, and so are not normally problems for most domestic animals. Only the nymphs and adults are parasitic and may be responsible for considerable irritation; heavy infestations can cause mortality of stock from blood loss. Several species of *Ornithodoros* inflict painful bites and may be major vectors of the pathogens responsible for relapsing fever. Descriptions of the major species of veterinary importance are presented.

***Ornithodoros* species of veterinary importance**

| Species | Hosts | Site |
|--|--|------|
| <i>Ornithodoros savignyi</i> | Most mammals, particularly camels, also cattle, poultry, human | Skin |
| <i>Ornithodoros moubata</i> (subsp. <i>O. moubata porcinus</i>) | Wide range of mammals: warthog, bushpig, porcupine, pig | Skin |
| <i>Ornithodoros erraticus</i> (syn. <i>Ornithodoros maroccanus</i>) | Small mammals, domestic livestock, pig, human | Skin |
| <i>Ornithodoros hermsi</i> | Wide range of mammals, particularly rodents | Skin |
| <i>Ornithodoros parkeri</i> | Wide range of mammals, particularly rodents | Skin |
| <i>Ornithodoros tholozani</i> | Most mammals, birds and some reptiles | Skin |
| <i>Ornithodoros turicata</i> | Wide range of mammals, particularly rodents | Skin |
| <i>Ornithodoros rudis</i> | Wide range of mammals, particularly rodents, human | Skin |
| <i>Ornithodoros lahorensis</i> | Wild sheep, domestic sheep and goat | Skin |
| <i>Ornithodoros coriaceus</i> | Cattle, deer, human | Skin |

***Ornithodoros savignyi* (sand tample, eyed tample)**

Description: Female ticks are 10–13 mm and males 8–12 mm in length, and rounded when engorged. The cuticle is covered in mammillae of equal size and the dorsal and ventral surfaces are separated by a groove. The sand tample has two pairs of hemispherical dark

eyes located dorsal to coxa I and to coxae III and IV. The leg tarsi and tibiae have distinct dorsal humps and the leg coxae decrease in size posteriorly.

***Ornithodoros moubata* (eyeless tampan, hut tampan)**

Subspecies: *Ornithodoros moubata porcinus*, *Ornithodoros moubata moubata*

Description: Members of the *O. moubata* complex are slightly smaller than *O. savignyi*; females are 8–11 mm long, but are most easily differentiated by the absence of eyes. The taxonomic position of the two or more known strains of *O. moubata* is not satisfactorily resolved. *Ornithodoros moubata moubata* is a hut-dwelling strain that feeds on people and chickens, and *O. moubata porcinus* lives in burrows and feeds on the occupants (warthogs, antbears and porcupines).

Ornithodoros hermsi

Description: *Ornithodoros hermsi* is a pale, sandy coloured soft tick, which appears greyish-blue when engorged. The adult female *O. hermsi* is typically 5–6 mm in length and 3–4 mm wide. The male is morphologically similar, though slightly smaller.

Life cycle: Females lay batches of approximately 100 eggs in the sand of the host den, cave, nest or burrow and remain with them until they hatch to produce larvae several days later. The larvae remain quiescent until they have moulted to the nymphal stage. There are several nymphal stadia. Both nymphs and adults only feed on their hosts for short periods of time, typically 15–30 minutes. This species is able to survive for long periods without feeding; juvenile stages may live as long as 95 days unfed, and the adults more than 7 months.

Otobius

This small genus contains only two species, *Otobius megnini* and *Otobius lagophilus*, which infest the ear canals of mammals.

***Otobius* species of veterinary importance**

| Species | Hosts | Site |
|---------------------------|---|-----------|
| <i>Otobius megnini</i> | Cattle, horses, sheep, goats, dogs, deer, human, wild ruminants | Ear canal |
| <i>Otobius lagophilus</i> | Rabbits, hares | Ear canal |

***Otobius megnini* (spinose ear tick)**

Description: The adult body is rounded posteriorly and slightly attenuated anteriorly (Fig. 3.126). Adult females range in size from 5 to 8 mm in length; males are slightly smaller. They have no lateral sutural line, and no distinct margin to the body. Nymphs have spines. In adults the hypostome is much reduced and the integument is granular. The body has a blue–grey coloration with pale yellow legs and mouthparts. Larvae measure 2–3 mm in length, and fully grown engorged nymphs measure 7–10 mm.

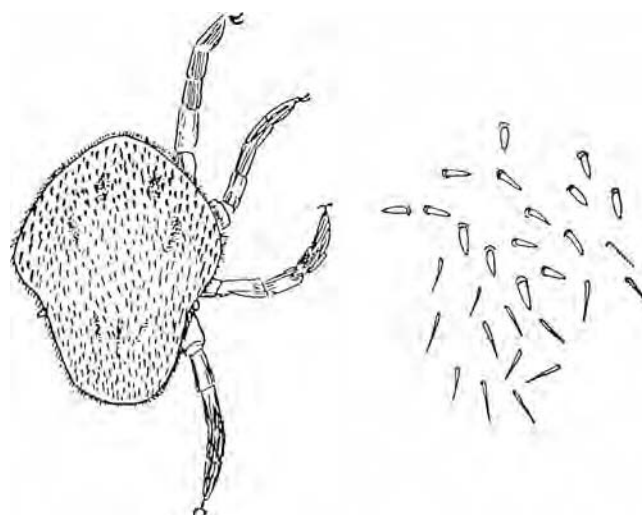

Fig. 3.126 Dorsal view of nymphal *Otobius megnini* and part of the integument showing hairs and spines. (From Arthur, 1962.)

Life cycle: This species is a one-host tick. The larval and nymphal stages are parasites of a wide range of mammals, but the adults are not parasitic. Mating takes place off the host, and batches of eggs are laid in sheltered sites such as in cracks and crevices in the walls of animal shelters or under stones or the bark of trees. The larvae hatch within 3–8 weeks and attach to a host animal. They may survive without food for 2–4 months. The preferred predilection site for larvae is deep within the ear. The larvae moult in the ears and nymphs remain there for 1–7 months. When fully grown and engorged, the nymphs drop off the host and seek dry sheltered sites, where they moult after a few days to become adults. The adults do not feed, and unmated females can survive in empty shelters and stables for over a year. Females lay 500–600 eggs over a period of up to 6 months.

***Otobius lagophilus* (rabbit ear tick)**

Description: The body is rounded both ends and constricted slightly behind legs IV. The integument is granular with numerous circular pits both dorsally and ventrally, which are more densely arranged than with *O. megnini*. Anterodorsal spines on the nymphs are thick and peg-like in structure.

Life cycle: This species is a one-host tick. Only larvae and nymphs are parasitic.

CLASS PENTASTOMIDA

The adults of this strange class of aberrant arthropods are found in the respiratory passages and viscera of vertebrates and resemble annelid worms rather than arthropods. The genus *Linguatula* is of some veterinary significance, with adult parasites occurring in the nasal passages and sinuses of dogs, cats, foxes and primates. *Armilifer* is found in the lungs of large snakes but has also been reported in the viscera of primates and humans. Pentastomids are up to 2 cm long, transversely striated, and shaped like an elongated tongue

Fig. 3.127 Pentastomid: female *Linguatula serrata*. (Redrawn from Soulsby, 1971. Reproduced with permission from Lord Soulsby of Swaffham Prior.)

(Fig. 3.127) with a small mouth and tiny claws at the extremity of the thick anterior end.

Linguatula species of veterinary importance

| Species | Final hosts | Intermediate hosts | Site |
|---------------------------|---------------|--|---|
| <i>Linguatula serrata</i> | Dog, cat, fox | Sheep, cattle, horse, rabbit, primates | Nasal cavity, sinuses, mesenteric lymph nodes |

Linguatula serrata (tongue worm)

Description: Males measure up to 20 mm in length while females are 30–130 mm in length. Both sexes are transversely striated, expanded anteriorly and shaped like an elongated tongue. Anteriorly there are five small protruberances, one bearing a small mouth at its extremity, the others bearing tiny claws.

Life cycle: With most pentastomids the life cycle requires an intermediate host. In the case of *Linguatula serrata*, eggs are expelled from the respiratory passage of the host by coughing or sneezing. Eggs are ingested by the herbivorous intermediate host, commonly sheep or cattle or rabbits, and pass into the gut where they hatch. The larva bores through the intestinal wall to the mesenteric glands, liver and lungs. Here, larval development involving a number of moults takes place. The larvae then encyst to develop into the infective nymphal stage. The cysts, about 1 mm in diameter, may be visible in cut surfaces of mesenteric glands. The final host is infected by eating uncooked viscera. Following ingestion, the nymph migrates to the nasal passages where the final moult, mating and egg production occur.

Laboratory diagnosis of parasitism

HELMINTH INFECTIONS

FAECAL EXAMINATION

Although there is much current interest in the use of serology and molecular methods as an aid to the diagnosis of helminthosis, faecal examination for the presence of worm eggs or larvae remains the most common routine aid to diagnosis employed.

COLLECTION OF FAECES

Faecal samples from large animals should preferably be collected from the rectum and examined fresh. If it is difficult to take rectal samples, then fresh faeces can be collected from the field or floor, ideally after observing the animal defecating. A plastic glove is suitable for collection, the glove being turned inside out to act as the receptacle. Individual samples are required and for ruminants, and a minimum of 10 samples in a herd or flock should be sampled. The wide variation in faecal egg counts (FECs) between animals grazing together in the same field means that random sampling effects have a significant impact on the confidence limits surrounding the estimate of the group mean FEC. Ideally, about 5 g of faeces should be collected, since this amount is required for some of the concentration methods of examination.

With poultry, representative samples from a number of birds should be collected from different areas of the house or building. For smaller pets a thermometer or glass rod may be used, or faeces collected from the cage or container in which they are housed.

Since eggs embryonate rapidly, the faeces should be stored in the refrigerator unless examination is carried out within a day. For samples sent through the post, an anaerobic storage system in an airtight container containing tap water will minimise development and hatching.

METHODS OF EXAMINATION OF FAECES

Several methods are available for preparing faeces for microscopic examination to detect the presence of eggs or larvae. However, whatever method of preparation is used, the slides should first be examined under low power since most eggs can be detected at this magnification. If necessary, higher magnification can then be employed for measurement of the eggs or more detailed morphological differentiation. An eyepiece micrometer is very useful for sizing populations of eggs or larvae.

Direct smear method

A few drops of water plus an equivalent amount of faeces are mixed on a microscope slide. Tilting the slide then allows the lighter eggs to flow away from the heavier debris. A coverslip is placed on the fluid and the preparation is then examined microscopically. It is possible to detect most eggs or larvae by this method, but due to the small amount of faeces used it may only detect relatively heavy infections.

Flotation methods

The basis of any flotation method is that when worm eggs are suspended in a liquid with a specific gravity higher than that of the eggs, the latter will float to the surface. Nematode and cestode eggs float in a liquid with a specific gravity of 1.10–1.20; trematode eggs, which are much heavier, require a specific gravity of 1.30–1.35.

The flotation solutions used for nematode and cestode ova are mainly based on sodium chloride (NaCl) or sometimes magnesium sulphate (MgSO₄). A saturated solution of these is prepared and stored for a few days and the specific gravity checked prior to usage. In some laboratories a sugar solution of specific gravity 1.2 is preferred. For trematode eggs, saturated solutions of zinc chloride (ZnCl₂) or zinc sulphate (ZnSO₄) are widely used. Some laboratories use the more expensive and toxic potassium mercury iodine solution.

Whatever solutions are employed, the specific gravity should be checked regularly and examination of the solution containing the eggs or larvae made rapidly, otherwise distortion may take place.

Direct flotation

A small amount of fresh faeces (e.g. approximately 2.0 g) is added to 10 mL of the flotation solution and, following thorough mixing, the suspension is poured into a test tube and more flotation solution added to fill the tube to the top. A coverslip is then placed on the surface of the liquid and the tube and coverslip are left standing for 10–15 minutes. The coverslip is then removed vertically and placed on a slide and examined under the microscope. If a centrifuge is available the flotation of the eggs in the flotation solution may be accelerated by centrifugation. Several commercially available systems, such as Ovassay™ and Ovatec Plus™, use this method for the qualitative examination of faecal samples for the presence of helminth eggs.

Improved modified McMaster method

This quantitative technique is used where it is desirable to estimate worm burdens by counting the number of eggs or larvae per gram of faeces. A number of McMaster methods have been described, and one of the most commonly used methods is as follows.

- 1 Weigh 3.0 g of faeces or, if faeces are diarrhoeic, 3 mL.
- 2 Break up thoroughly in 42 mL of water in a plastic container. This can be done using a homogeniser if available or in a stoppered bottle containing glass beads.
- 3 Pour through a fine mesh sieve (aperture 150 μm , or 100 to 1 inch).
- 4 Collect filtrate, agitate and fill a 15-mL test tube.
- 5 Centrifuge at 1500 rpm for 2 minutes.
- 6 Pour off supernatant, agitate sediment and fill tube to previous level with flotation solution.
- 7 Invert tube six times and remove fluid with pipette to fill both chambers of a McMaster slide (Fig. 4.1). Leave no fluid in the pipette or else pipette rapidly, since the eggs will rise quickly in the flotation fluid.
- 8 Examine one chamber and multiply the number of eggs or larvae under one grid by 100, or two chambers and multiply by 50, to arrive at the number of eggs per gram (epg) of faeces:
If 3 g of faeces are dissolved in 42 mL
Total volume is 45 mL
Therefore 1 g is 15 mL
The volume under the grid is 0.15 mL
Therefore, the number of eggs is multiplied by 100. If two grids are examined, multiply by 50.

Fig. 4.1 McMaster slide for estimating numbers of nematode eggs in faeces.

- 9 If the total number of eggs in one chamber is counted, then multiply by 30. If both chambers are counted then multiply by 15.

An abbreviated version of this technique (modified McMaster) is to homogenise the 3 g of faeces in 42 mL of salt solution, sieve and pipette the filtrate directly into the McMaster slide. Although a faster process, the slide contents are more difficult to 'read' because of their dark colour. A commercially available system for sample preparation for use in the McMaster method is the Parasep Veterinary™.

Improved sensitivity methods

Sensitive centrifugal flotation technique

This method follows the same initial steps described for the improved modified McMaster method.

- 1 Weight 3 g of faeces and break up thoroughly in 42 mL of water in a plastic container.
- 2 Pour through a fine mesh sieve (aperture 150 μm).
- 3 Collect filtrate, agitate and fill a 15-mL test tube.
- 4 Centrifuge at 1500 rpm for 2 minutes.
- 5 Pour off supernatant, agitate sediment and fill tube to previous level with saturated NaCl solution.
- 6 Place the tube in the centrifuge and add further saturated salt until a positive meniscus is formed.
- 7 A thick 19 \times 19 mm coverslip is then placed on the tube, ensuring that no air bubbles are trapped underneath.
- 8 Centrifuge the tube at 1000 rpm for 2 minutes.
- 9 Remove the coverslip by lifting vertically with a deliberate movement.
- 10 Place the coverslip on a glass slide and count all eggs.
- 11 By adding 15 mL of filtrate to the centrifuge tube, it will contain the eggs from 1 g of faeces, and if all of these are recovered then the number of eggs counted is equal to the number of eggs per gram. However about one-sixth of eggs are lost in the process of flotation and a correction factor of $\times 1.2$ should be applied.
If x is the capacity of the tube and y the number of eggs seen, then $\text{epg} = y \times 15/x \times 1.2$.

FLOTAC system

A novel FEC method, the FLOTAC technique, has been described. This method is facilitated by the FLOTAC™ apparatus, which has been designed to carry out flotation in a centrifuge, followed by a transversal cut (i.e. translation) of the apical portion of the floating suspension. The FLOTAC technique allows quantification of nematode eggs (as well as trematode eggs, cysts and oocysts of intestinal protozoa) in up to 1 g of faeces or even more. The FLOTAC apparatus is a cylindrical-shaped device composed of three principal physical components: the body, a translation disc, a reading disc, and other auxiliary physical components. The FLOTAC apparatus holds two sample flotation chambers, each 5 mL, for a total volume of 10 mL, with two ruled grids. Each grid (18 \times 18 mm) contains 12 equidistant ruled lines that are transparent and hence permit the counting of eggs under them. Where the dilution of faeces is 1 in 10, the reading of two grids (total volume 10 mL = 1.0 g of faeces gives a sensitivity of 1 epg; the reading of 1 grid (total volume 5 mL = 0.5 g of faeces) gives a sensitivity of 2 epg.

Other commercially available systems for the improved modified McMaster method that include a centrifugation step include Parasep Veterinary™ and StatSpin Ovatube™.

IDENTIFICATION OF NEMATODE EGGS

The presence of nematode eggs in faeces is a useful aid to diagnosis of worm infections as they can be identified and counted in faecal samples (Figs 4.2, 4.3, 4.4, 4.5, 4.6, 4.7, 4.8, 4.9 and 4.10). Strongyle eggs are approximately 60–80 µm long, oval, thin-shelled, contain 4–16 cells and are not easily differentiated; however, eggs of *Trichuris*, *Nematodirus* spp. and *Strongyloides* can be identified and may be counted and reported separately.

Guide to egg count interpretation in ruminants

It is impossible to calculate from the FEC the actual worm population of the host, since many factors influence egg production of worms and the number of eggs also varies with the species. Nevertheless, in ruminants for example, egg counts in excess of 1000 eggs are generally considered indicative of heavy infections and those over 500 eggs of moderate infection (Tables 4.1 and 4.2). However, a low egg count is not necessarily indicative of very low infections, since patency may just be newly established; alternatively, the egg count may be affected by developing immunity. The eggs of some species, such as certain ascarids, *Strongyloides*, *Oxyuris*, *Trichuris* and *Capillaria*, can be easily recognised morphologically. However, with the exception of *Nematodirus* spp., the common trichostrongyle eggs require measurement for differentiation.

IDENTIFICATION OF TREMATODE EGGS

While the techniques described will detect the eggs and larvae of most nematodes, cestodes and coccidia, they will not demonstrate trematode eggs, which have a higher specific density. For these, a flotation fluid of higher specific gravity such as a saturated solution

Table 4.1 Cattle worm egg counts: guide to interpretation.

| Worm species | Degree of infestation | | |
|------------------------------|-----------------------|----------|-------|
| | Light | Moderate | Heavy |
| Mixed infection | 100 | 200–700 | 700+ |
| <i>Haemonchus</i> | 200 | 200–500 | 500+ |
| <i>Ostertagia ostertagi</i> | 150 | | 500+ |
| <i>Trichostrongylus</i> spp. | 50 | 50–300 | 500+ |
| <i>Bunostomum</i> | 20 | 20–100 | 100+ |
| <i>Cooperia</i> | 500 | 500–3000 | 3000 |

Table 4.2 Sheep worm egg counts: guide to interpretation.

| Worm species | Degree of infestation | | |
|---|-----------------------|-----------|--------|
| | Light | Moderate | Heavy |
| Mixed infection | <250 | 1000 | 2000+ |
| Mixed (<i>H. contortus</i> absent) | <150 | 500 | 1000 |
| <i>Haemonchus contortus</i> | 100–2500 | 2500–8000 | 8000+ |
| <i>Teladorsagia (Ostertagia) circumcincta</i> | 50–200 | 200–2000 | 2000+ |
| <i>Trichostrongylus</i> spp. | 100–500 | 500–2000 | 2000+ |
| <i>Nematodirus</i> spp. | 50–100 | 100–600 | 600+ |
| <i>Strongyloides</i> | | | 10,000 |

of zinc sulphate ($ZnSO_4$) has to be used, or a sedimentation method employed.

Fluke eggs are large, oval and have an operculum at one end. Liver fluke eggs (*Fasciola*) are brown in colour and may need to be differentiated from rumen fluke eggs (*Paramphistomum*, *Cotylophoron*, etc.), whose eggs are much lighter in colour (Fig. 4.3).

Zinc sulphate flotation method for counting fluke eggs

Liver fluke eggs will not float in saturated NaCl solution but will float in saturated $ZnSO_4$ solution, which has a higher specific gravity. The procedure is exactly the same as that described for the improved modified McMaster method, with $ZnSO_4$ replacing NaCl.

- 1 Weight 3 g of faeces and break up thoroughly in 42 mL of water in a plastic container.
- 2 Pour through a fine mesh sieve (aperture 250 µm).
- 3 Collect filtrate, agitate and fill a 15-mL test tube.
- 4 Centrifuge at 1500 rpm for 2 minutes.
- 5 Pour off supernatant, agitate sediment and fill tube to previous level with saturated $ZnSO_4$ solution.
- 6 Invert tube six times and remove fluid with pipette to fill both chambers of McMaster slide.
(One drawback of this method is that the eggs collapse, making identification more difficult, and the collapse may cause the eggs to sink again. This can be prevented with the following steps.)
- 7 Invert tube six times then place the tube in the centrifuge and add further saturated $ZnSO_4$ until a positive meniscus is formed.
- 8 A thick 19 × 19 mm coverslip is then placed on the tube, ensuring that no air bubble is trapped underneath.
- 9 Centrifuge the tube at 1000 rpm for 2 minutes.
- 10 Remove the coverslip by lifting vertically with a deliberate movement and wash off into conical tube with about 10 mL of water.
- 11 Centrifuge the tube at 1500 rpm for 2 minutes and siphon off the supernatant and discard.
- 12 Transfer the sediment in a total volume of about 0.1 mL to a microscope slide. Rinse the tube with a further 0.1 mL water and transfer to slide.
- 13 Place a 22 × 40 mm coverslip over the fluid and count all eggs. Each egg seen represents 1 egg.

Faecal sedimentation method for fluke eggs

- 1 Homogenise 3 g (sheep, goats) or 6 g (cattle) faeces with 50–60 mL of water in a beaker. Agitate or mix the faeces for about 30 seconds until broken down.
- 2 Sensitivity can be improved by increasing the amount of faeces examined.
- 3 Add 2 drops of Teepol detergent to the homogenate to improve the release of eggs from faecal material.
- 4 Pour through a strainer and collect filtrate into beaker or collecting bowl.
- 5 Strain filtrate through a second screen (~250 µm aperture) into a conical flask.
- 6 Half fill the beaker with water and wash through the screen into the conical flask.

Fig. 4.4 Worm eggs from horses.

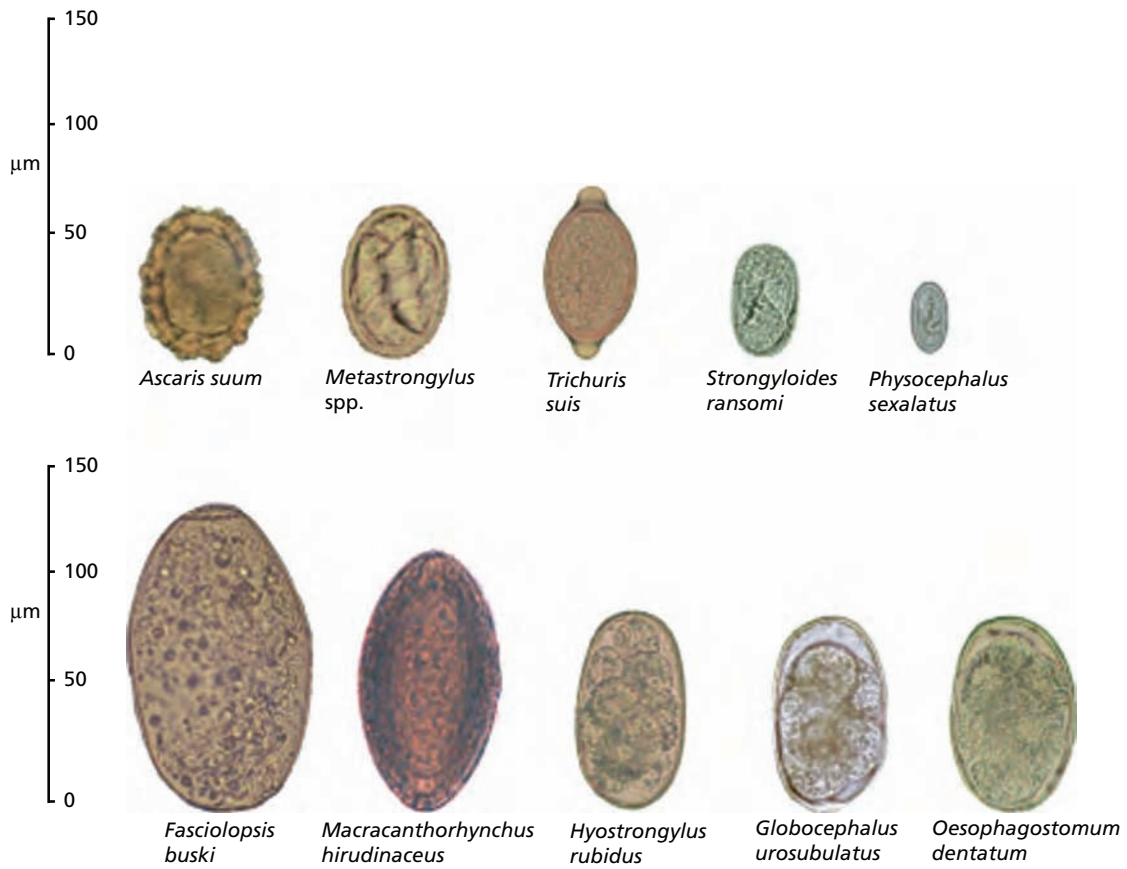

Fig. 4.5 Worm eggs from pigs.

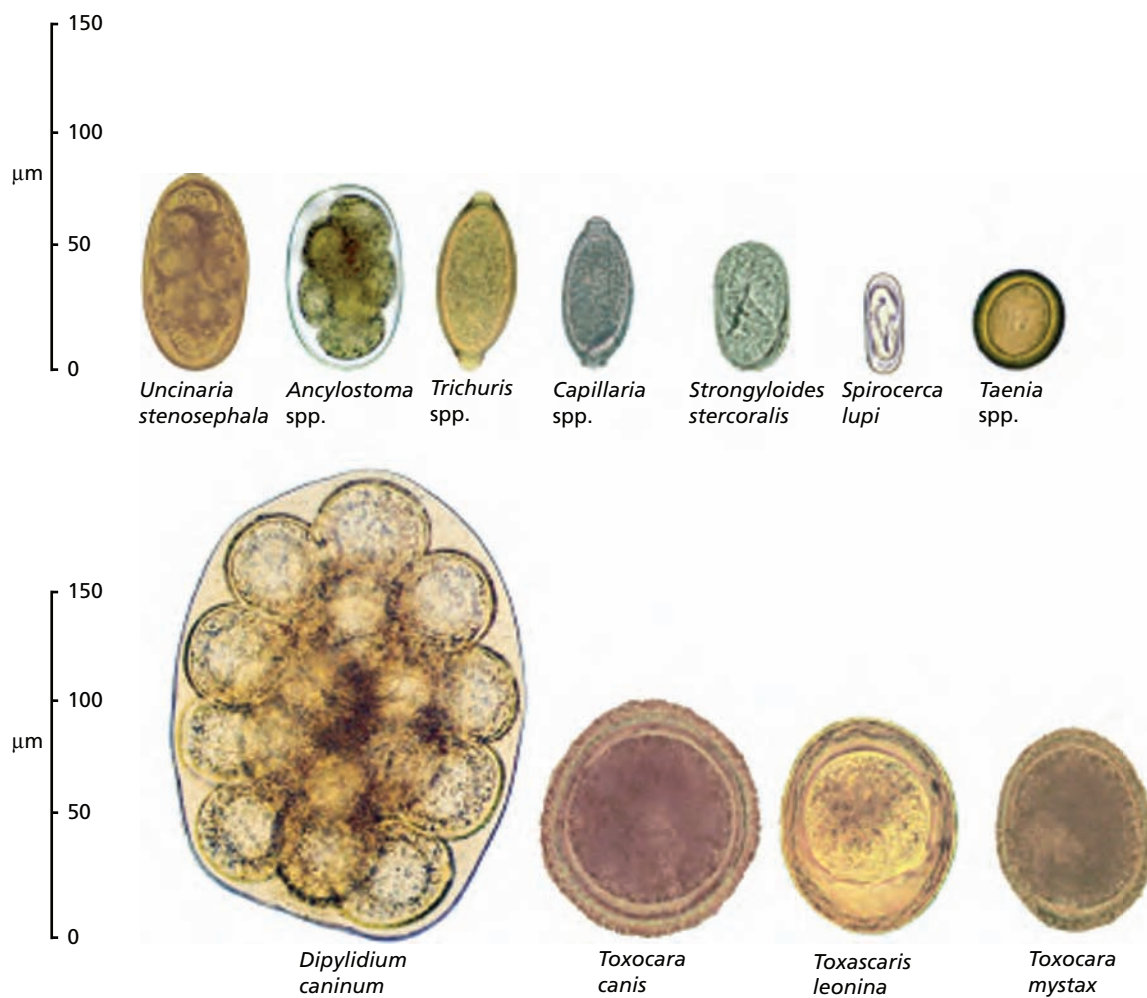

Fig. 4.6 Worm eggs from dogs and cats.

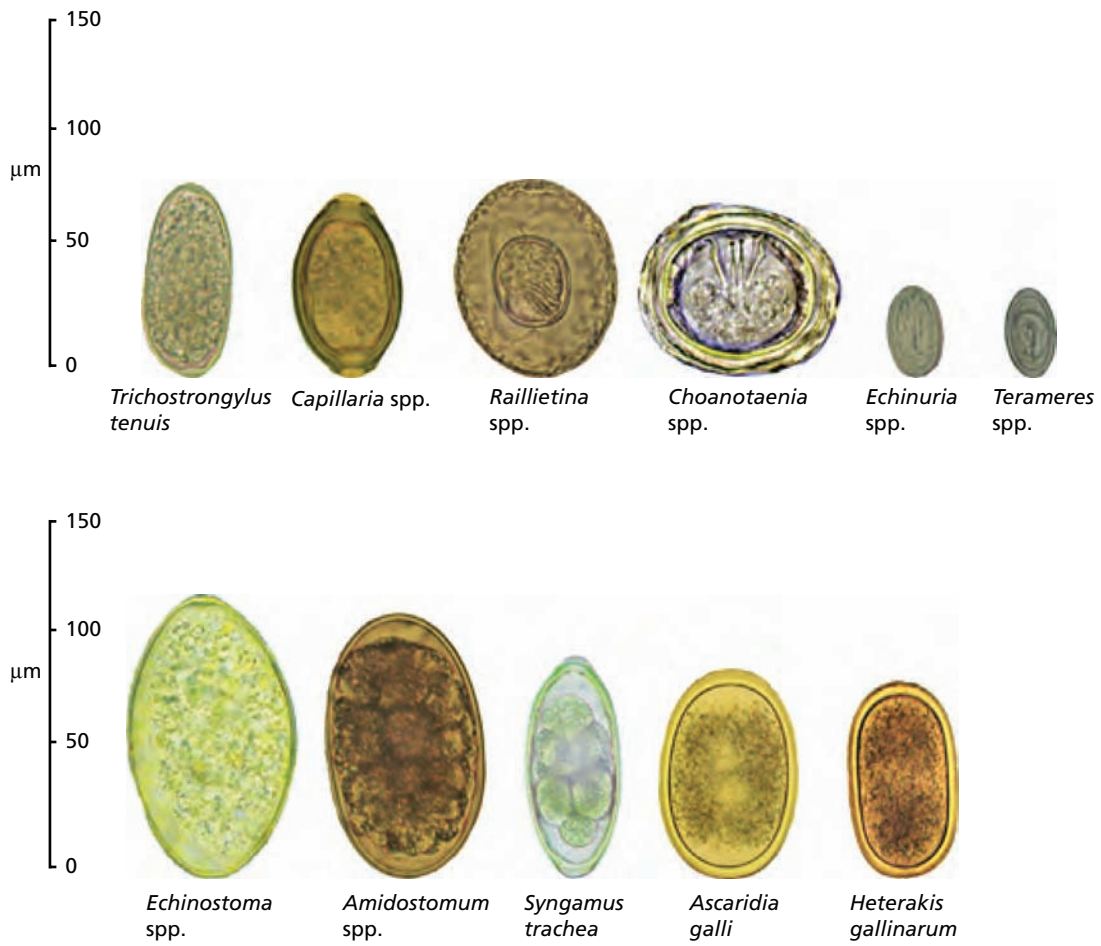

Fig. 4.7 Worm eggs from poultry.

Fig. 4.8 Worm eggs from rabbits.

Fig. 4.9 Worm eggs from rodents.

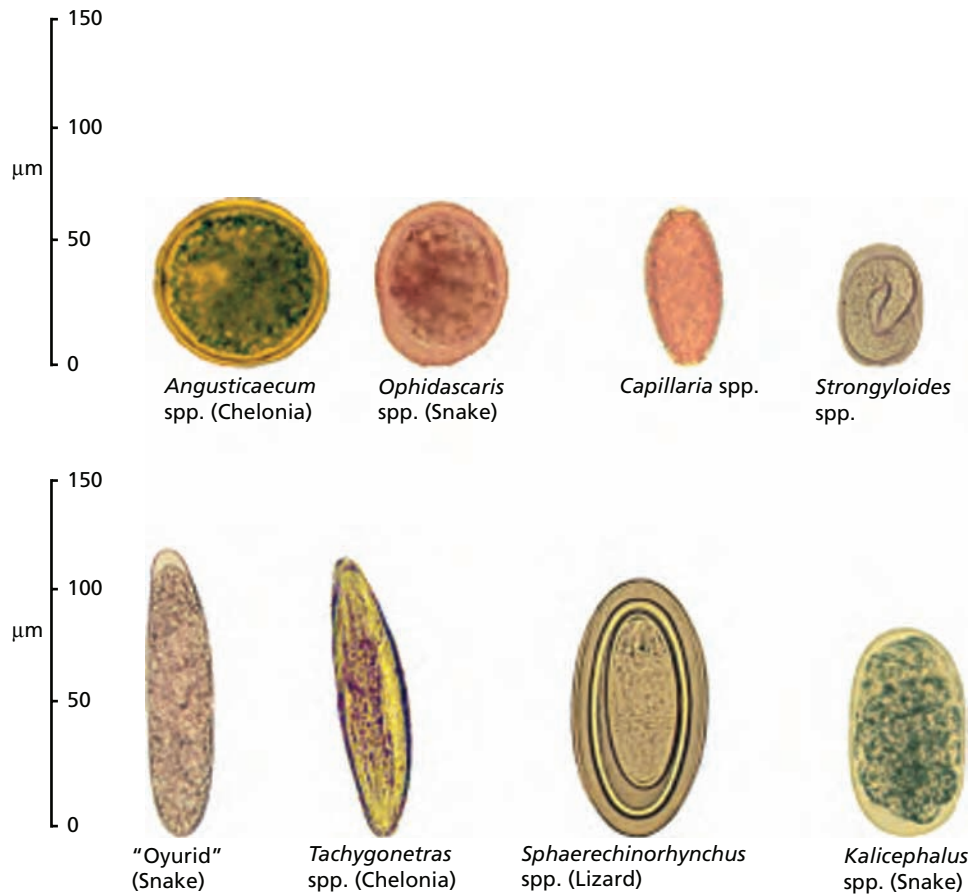

Fig. 4.10 Worm eggs from reptiles.

- 7 Allow filtrate in the conical flask to sediment for 3 minutes.
- 8 Siphon off supernatant with a suction pump, or manually with a large pipette, taking care not to disturb the sediment.
- 9 Step 7 may be repeated by adding more water to the sediment to further clean the sample.
- 10 Differentiation of the eggs can be enhanced by adding a couple of drops of methylene blue to the final sediment.
- 11 The sediment can either be examined in a Petri dish using a dissecting microscope or under a compound microscope by pipetting a small volume on to an ordinary microscope slide with a long coverslip (40 × 22 mm) and repeating until all the sediment has been examined.
- 12 Scan the Petri dish, or slides, systematically for the presence of fluke eggs.

LARVAL RECOVERY

Lungworm larvae can be recovered from fresh faeces with the Baermann apparatus. This consists of a glass funnel held in a retort stand (Fig. 4.11). A rubber tube, attached to the bottom of the funnel, is constricted by a clip. A sieve (aperture 250 µm), or a double layer of cheesecloth, is placed in the wide neck of the funnel, which has been partially filled with water, and a double layer of gauze is placed on top of the sieve. Faeces are placed on the gauze and the funnel is slowly filled with water until the faeces are immersed. Alternatively, faeces are spread on a filter paper, which is then inverted and placed on the sieve. The apparatus is left overnight at room temperature during which the larvae migrate out of the faeces and through the sieve to sediment in the neck of the funnel. The clip on the rubber is then removed and the water in the neck of the funnel collected in a small beaker for microscopic examination in a Petri dish.

Baermann method

- 1 Weigh 10 g of faeces.
- 2 The faeces are placed in the centre of a sieve (150 µm). (Alternatively place the faeces in a double layer of cheesecloth that is folded to form a pouch and is closed with either an elastic band

Fig. 4.11 Baermann apparatus.

or string. A cocktail stick or rod is then placed under the rubber band or string and the pouch suspended in the funnel.)

- 3 Slowly fill the funnel with lukewarm water until the faeces are immersed.
- 4 The apparatus is left overnight at room temperature during which the larvae migrate out of the faeces and through the sieve to sediment in the neck of the funnel.
- 5 The clip on the rubber tubing is then released and the water in the neck of the funnel collected for microscopic examination.
- 6 The sediment can be examined by drawing off a few millilitres and leaving to sediment for 30 minutes.
- 7 Alternatively, 5–10 mL can be drawn off into a centrifuge tube and spun at 1500 rpm for 2 minutes.
- 8 The supernatant is then siphoned off and the sediment transferred to a microscope slide.
- 9 The drops on the slide can be examined without a coverslip for the presence of motile larvae.

A simple adaptation of the above method is to suspend the faeces enclosed in gauze in a wine glass filled with water and leave overnight. The larvae will leave the faeces, migrate through the gauze and settle at the bottom of the glass. After siphoning off the supernatant, the sediment is examined under the low power of the microscope.

Technique for estimating lungworm larvae in faeces (see Fig. 4.12)

- 1 Homogenise 10 g of faeces in approximately 70 mL of water.
- 2 Pour through a fine mesh sieve (aperture 150 µm) and wash into a collecting bowl until it contains 500–600 mL of filtrate.
- 3 Transfer the filtrate to a conical beaker and allow to sediment for at least 3 hours (preferably at 4°C).
- 4 Siphon off the supernatant to leave the sediment in a total volume of approximately 60 mL.
- 5 Divide the sediment evenly between four centrifuge tubes and centrifuge at 1500 rpm for 2 minutes.
- 6 Pour off and discard the supernatant to leave the sediment, which is then thoroughly loosened by gentle agitation.
- 7 Fill the tubes to within 10 mm of the top with saturated NaCl and invert each tube several times with the thumb over the open end, until the sediment is evenly suspended. Avoid shaking, which leads to the formation of bubbles.
- 8 Place the tubes in the centrifuge and add saturated NaCl to each tube until a positive meniscus stands above the edge. Place a thick 19 × 19 mm square coverslip on each tube, ensuring that no bubbles are trapped underneath.
- 9 Centrifuge for 2 minutes at 1000 rpm.
- 10 Remove each of the coverslips in turn by lifting vertically with a deliberate movement and wash off any adhering larvae with 2–3 mL of water into a conical centrifuge tube by means of a pipette or plastic wash bottle. This procedure is repeated with the other three coverslips, washing off the larvae into the same conical tube.
- 11 Centrifuge the conical tube for 2 minutes at 1500 rpm and then carefully siphon off the supernatant and discard.
- 12 Transfer the sediment, which should be in a total volume of approximately 0.1 mL, by pipette to a microscope slide. Rinse the tube with a further 0.1 mL of water and transfer this to the slide.
- 13 Cover with a 22 × 40 mm coverslip and systematically examine the slide. Because losses amounting to 40% occur during the technique, each larva counted is regarded as representing 0.17 larvae per gram of faeces.

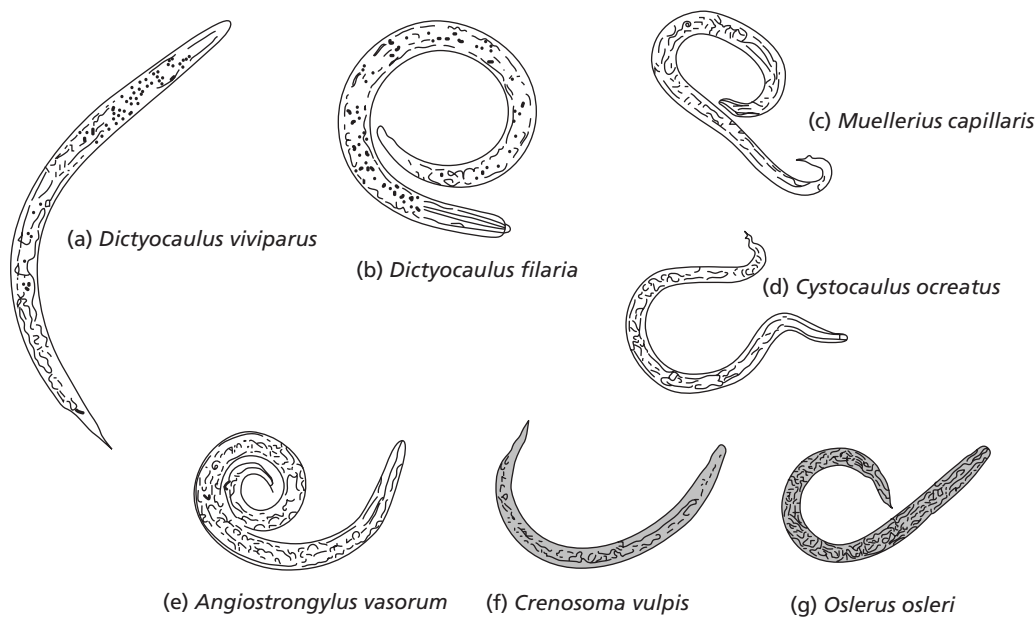

Fig. 4.12 First-stage lungworm larvae.

Culture and identification of infective third-stage larvae

The standard method for identifying eggs of trichostrongyle nematodes in faeces is to culture the faeces for 7–10 days and then isolate the third stage (L₃) larvae from the faeces. The L₃ can then be identified to genus, or in some cases to species. Two techniques are widely used for the culture of infective larvae from nematode eggs.

In the first technique, faeces are placed in a jar with a lid and stored in the dark at a temperature of 21–24°C. The lid should be lined with moist filter paper and should not be tightly attached. After 7–10 days of incubation, the jar is filled with water and allowed to stand for 2–3 hours. The larvae will migrate into the water and the latter is poured into a cylinder for sedimentation. The larval suspension can be cleaned and concentrated by using the Baermann apparatus as described and then killed by adding a few drops of Lugol's iodine and examined microscopically.

An alternative method is to spread faeces on the middle third of filter paper placed in a moistened Petri dish. After storage at 21–24°C for 7–10 days, the dish is flooded with water and the larvae harvested as before.

Ruminant third-stage larval identification

It is often useful to know whether FECs are dominated by worms of one particular genus, particularly on farms where there are worms with high biotic potential, such as *Haemonchus* infections in sheep. If so, larval culture and differentiation can be performed, usually using the faeces from the FEC. This technique takes a further 7–10 days, so results are not available for some time after the FEC is known.

Larval differentiation (Table 4.3; Figs 4.13 and 4.14) requires the hatching of the eggs in the sample, culture (as described above) and the subsequent identification of the developed third-stage larvae. Usually, 50 or 100 larvae are counted, and the percentage of each genus reported. It should be noted that eggs of each genus do not always hatch at the same rate because of differences in temperature requirements for the different genera. Larval culture results should

therefore be used as a general indication of the worm genera present, rather than a precise determination of the proportion of the FEC contributed by each genus. Larvae can be identified in a similar manner for pasture samples (see later).

The technique used is as follows: a small drop of suspension of larvae is placed on a microscope slide and a drop of Gram's iodine added and a coverslip placed over the drops. The iodine kills the larvae and allows for easier identification of the salient features (Fig. 4.14).

RECOVERY OF ALIMENTARY NEMATODES

A technique for the collection, counting and identification of the alimentary nematodes of ruminants is given in the following list. The procedure is similar for other host species, information on identification being available in the text.

- 1 As soon as possible after removing the alimentary tract from the body cavity, the abomasal/duodenal junction should be ligatured to prevent transfer of parasites from one site to another.
- 2 Separate the abomasum, small intestine and large intestine.

Table 4.3 Key characteristics used in the identification of ruminant third-stage larvae (see Figs 4.13 and 4.14).

| Genus | Intestinal cell number | Head characteristics | Sheath tail characteristics |
|--------------------------------|------------------------|--------------------------------|--|
| <i>Nematodirus</i> | 8 | Broad, rounded | Filamentous sheath. Species differentiated by shape of larval tail |
| <i>Ostertagia/Teladorsagia</i> | 16 | Squared | Short sheath |
| <i>Trichostrongylus</i> | 16 | Tapered | Short sheath |
| <i>Haemonchus</i> | 16 | Narrow rounded | Medium offset sheath |
| <i>Cooperia</i> | 16 | Squared with refractile bodies | Medium tapering or finely pointed sheath |
| <i>Bunostomum</i> | 16 | | Short filamentous |
| <i>Oesophagostomum</i> | 32 | Broad, rounded | Filamentous sheath |
| <i>Chabertia</i> | 32 | Broad, rounded | Filamentous sheath |

Fig. 4.13 Third-stage larva.

- 3 Open the abomasum along the side of the greater curvature, wash contents into a bucket under running water and make the total volume up to 2–4 L.
- 4 After thorough mixing transfer duplicate 200-mL samples to suitably labelled containers and preserve in 10% formalin.
- 5 Scrape off the abomasal mucosa and digest in a pepsin/HCl mixture at 42°C for 6 hours; 200 g of mucosa will require 1 L of mixture. Make the digest up to a volume of 2 or 4 L with cold water and again take duplicate 200-mL samples. Alternatively, the Williams technique may be used. In this, the washed abomasum is placed, mucosal surface down, in a bucket containing several litres of normal saline and maintained at 40°C for 4 hours. Subsequently, the abomasum is gently rubbed in a second bucket of warm saline. The saline from both buckets is poured through a sieve (aperture 38 µm, about 600 to 1 inch) and the residue examined.
- 6 Open the small intestine along its entire length and wash contents into a bucket. Treat as for the abomasal contents, but digestion of mucosal scrapings is usually unnecessary.
- 7 The contents of the large intestine are washed into a bucket, passed through a coarse mesh sieve (aperture 2–3 mm) and any parasites present collected and formalised.

Worm counting procedure

- 1 Add 2–3 mL of iodine solution to one of the 200-mL samples.
- 2 After thorough mixing, transfer 4 mL of suspension to a Petri dish, scored with lines to facilitate counting; add 2–3 mL sodium

Fig. 4.14 Key to the identification of third-stage larvae of sheep gastrointestinal nematodes: (A) *Teladorsagia circumcincta*; (B) *Trichostrongylus* spp.; (C) *Haemonchus contortus*; (D) *Cooperia* spp.; (E) *Nematodirus*: (a) *battus*, (b) *filicollis*, (c) *spathiger*; (F) *Oesophagostomum* spp.

thiosulphate solution to decolorise the debris. If necessary, worms may be preserved in an aqueous solution of 10% formalin or 70% alcohol. To clear large worms for microscopic examination, immerse in lactophenol for a suitable period prior to examination.

- 3 Examine for the presence of parasites using a stereoscopic microscope ($\times 12$ objective) and identify and count parasites as male, female and larval stages.

KEY TO THE IDENTIFICATION OF GASTROINTESTINAL NEMATODES OF RUMINANTS

Based on the characters described in Table 4.4(a–c), the following key can be used to differentiate microscopically the genera of some common gastrointestinal nematodes of ruminants.

- Body composed of a long filamentous anterior and a short broad posterior region..... *Trichostrongylus*
 Body not so divided, oesophagus approximately one-third of body length (Fig. 4.15)..... *Strongyloides*
 Short oesophagus and buccal capsule rudimentary *Trichostrongyloidea* (A)
 Short oesophagus and buccal capsule well developed..... *Strongyloidea* (B)

(A) Trichostrongyloidea

- 1 Distinct cephalic vesicle (Fig. 4.16). Spicules very long uniting in a membrane at the tip (Fig. 4.17)..... *Nematodirus*
 Cephalic vesicle small (Fig. 4.18). Spicules relatively short and unjoined posteriorly..... *Cooperia*
- 2 No cephalic vesicle. Excretory notch present in both sexes (Fig. 4.19)..... *Trichostrongylus*
 Absence of excretory notch..... 3
- 3 Dorsal lobe of bursa asymmetrical, barbed spicules (Fig 4.20). Large prominent vulval flap in female (Fig. 4.21)..... *Haemonchus*
 Dorsal lobe of bursa is symmetrical (Fig. 4.22). Vulval flap small or absent..... *Ostertagia*

Fig. 4.15 *Strongyloides* female showing oesophagus approximately one-third length of body.

(B) Strongyloidea

- 4 Buccal capsule cylindrical (Fig. 4.23)..... *Oesophagostomum*
 Buccal capsule well developed..... 5
- 5 Slight dorsal curvature of head and presence of cutting plates (Fig. 4.24)..... *Bunostomum*
 Absence of teeth, rudimentary leaf crowns present (Fig. 4.25)..... *Chabertia*

Table 4.4 Guide to adult alimentary nematodes of ruminants.

Table 4.4(a) Abomasal worms.

| | <i>Ostertagia</i> spp. | <i>Trichostrongylus axei</i> | <i>Haemonchus contortus</i> |
|-------------|---|---|---|
| Mature size | Slender; reddish-brown when fresh | Very small worms, <0.5 cm long, greyish when fresh, tapering to a very fine anterior end | Large worms, reddish when fresh; easily seen, bursa visible with the naked eye |
| | Male 7–8 mm | Male 3–6 mm | Male 10–20 mm |
| | Female 9–12 mm | Female 4–8 mm | Female 18–30 mm |
| Head | Small cervical papillae set more posteriorly; distance from anterior end about five times diameter between papillae Cuticle striations are longitudinal | No cervical papillae Excretory notch visible in oesophageal region Cuticle striations are annular | Prominent large cervical papillae; distance from anterior end about three times the diameter between papillae |
| Female | Small or no vulval flap. Under high magnification tip of tail shows annular rings. In cattle, female has vulval flap of variable size, but usually skirt-like | Simple genital opening with vulval flap absent; gravid worm contains four or five eggs, pole to pole | In sheep, vulval flap, usually linguiform; gravid worm contains several hundred eggs; ovary coiled around intestine resembling 'barber's pole'. In cattle, vulval flap often bulb-shaped or vestigial |
| Male tail | Bursal lobes are symmetrical | Bursal lobes are symmetrical | Dorsal ray of bursa is asymmetric |
| | Spicules vary with species. In sheep species, spicules slender, rod-like (<i>T. circumcincta</i>) or stout with branch near middle (<i>O. trifurcata</i>). In cattle, male has stout, rod-like spicules with expanded tips (<i>O. ostertagi</i>) or very robust spicules, generally rectangular in outline (<i>O. lyrata</i>) | Spicules unequal in length | Spicules barbed near tips |

Table 4.4(b) Small intestinal worms.

| | <i>Trichostrongylus</i> | <i>Cooperia</i> | <i>Nematodirus</i> | <i>Strongyloides</i> | <i>Bunostomum</i> |
|----------------|---|--|--|---|--|
| Mature size | Very small worms, ~0.5 cm long, greyish when fresh, tapering to a very fine anterior end | About 0.5 cm long; slender; greyish; comma or watch-spring shape; coiled in one or two tight coils | About 2 cm long; slender; much twisted, often tangled like cottonwool due to twisting of the 'thin neck' | Only females present | About 2 cm long; stout white worms; head bent slightly |
| | Male 4–5 mm Female 5–7 mm | Male 4–6 mm Female 5–7 mm | Male 10–15 mm Female 15–25 mm | Female 3–6 mm | Male 12–17 mm Female 19–26 mm |
| Other features | Excretory notch present in oesophageal region. Vulval flap absent | Small cephalic vesicle present, giving anterior end a cylindrical appearance; prominent cuticular striations in the oesophageal region | Cephalic vesicle present | Very long oesophagus, one-third to half of total length of the worm | Large buccal cavity has prominent teeth; <i>B. trigonocephalum</i> of sheep and goats has one large and two small teeth; <i>B. phlebotomum</i> of cattle has two pairs of subventral teeth |
| Female | Ovejectors present | Body of female swollen at region of vulva | Female tail has prominent spine protruding from a blunt end. Tip of tail is pointed (<i>N. battus</i>) or truncate with a small spine (other species). Large eggs present | Ovary and uterus show twisted thread appearance behind oesophagus; ovejectors absent. Eggs expressed from females contain a fully developed larva | |
| Mail tail | Spicules leaf-shaped (<i>T. vitrinus</i>) or with 'step' near tip (<i>T. colubriformis</i>) | Male tail has short stout spicules; 'wing' at middle region, bearing striations (<i>C. curticae</i>). Spicules of <i>C. oncophora</i> have a stout bow-like appearance, with small terminal 'feet' | Male tail has very long slender spicules usually extended beyond the bursa. Bursa shows two sets of parallel rays (<i>N. battus</i>) or four sets (other species). Spicules long, slender and fused, with expanded tip which is heart-shaped (<i>N. battus</i>); lanceolate (<i>N. filicollis</i>); bluntly rounded (<i>N. spathiger</i>) (sheep). In cattle, spicules of <i>N. helveticus</i> have a spear-shaped expansion at the tips | | <i>B. trigonocephalum</i> has short twisted spicules; <i>B. phlebotomum</i> has long slender spicules |

RECOVERY OF ADULT LUNGWORMS

For *Dictyoaulus*, this is best done by opening the air passages starting from the trachea and cutting down to the small bronchi with fine, blunt-pointed scissors. Visible worms are then removed from the opened lungs and transferred to glass beakers containing saline. The worms are best counted immediately, failing which they should be left overnight at 4°C which will reduce clumping. Additional worms may be recovered if the opened lungs are soaked in warm saline overnight.

Another method is Inderbitzen's modification of the perfusion technique in which the lungs are perfused. The pericardial sac is

incised and reflected to expose the pulmonary artery in which a 2-cm incision is made. Rubber tubing is introduced into the artery and fixed *in situ* by double ligatures. The remaining large blood vessels are tied off and water from a mains supply allowed to enter the pulmonary artery. The water ruptures the alveolar and bronchiolar walls, flushes out the bronchial lumina, and is expelled from the trachea. The fluid is collected and its contents concentrated by passing through a fine sieve (aperture 38 μm). As before, this is best examined immediately for the presence of adult worms and larvae.

The smaller genera of lungworms of small ruminants are difficult to recover and enumerate, although the Inderbitzen technique may be of value.

RECOVERY OF TREMATODE AND CESTODE PARASITES

For both *Fasciola* and *Dicrocoelium*, the livers are removed and cut into slices approximately 1 cm thick. On squeezing the liver slices, any flukes seen grossly are removed and formalised and the slices immersed in warm water overnight. The gallbladder should also be opened and washed, and any flukes removed.

After soaking, the liver slices are again squeezed, rinsed in clean water and discarded. Both washings are passed through a fine sieve (aperture 100 μm) and the material retained and formalised. In the case of intestinal paramphistomes, the first 4 m of the duodenum should be tied off, opened, washed and examined for adherent trematodes.

Counts are carried out microscopically, entire flukes plus the numbers of heads and tails being recorded. The highest number of either of the latter is added to the number of entire flukes to give the total count.

Cestodes are usually readily visible in the intestine or liver, but whenever possible these should be removed intact so that, if necessary, the head and the mature and gravid segments are all available for specialist examination. In the case of *Echinococcus* in canids, however, the worms are so small that the more detailed examination described in Chapter 12 should be undertaken.

OTHER AIDS TO DIAGNOSIS OF RUMINANT NEMATODES

Several other techniques are useful aids in the diagnosis of trichostrongyle infections in ruminants. All these techniques should be undertaken in a specialist parasitology laboratory, but a short account is given here of the material required for these tests, the basis of the techniques and how the results may be interpreted.

Lectin-binding assay

The standard method for identifying eggs of trichostrongyle nematodes has been described in the section on culture and identification of infective third-stage larvae, whereby eggs are cultured to third-stage larvae (L_3) and identified to genus after 7–10 days of culture. Although this is the most widely used and the best method currently available, it has several shortcomings: it is labour-intensive, time-consuming and requires special training to correctly identify the morphological differences between genera.

A lectin-binding assay has been developed specifically to distinguish *Haemonchus* eggs from other roundworm genera. In

this assay, peanut agglutinin (PNA) specifically binds to *Haemonchus* eggs and not those of other trichostrongyle species. By using the lectin conjugated to fluorescein isothiocyanate (FITC), binding to *Haemonchus* eggs can be visualised under ultraviolet (UV) illumination, without having to resort to larval culture and differentiation.

- 1 Nematode eggs can be extracted from faeces using the sensitive centrifugal flotation technique described in the section on improved sensitivity methods.
- 2 Eggs are then cleaned by removing the coverslip and washing the adhering droplet, containing the eggs, into a conical centrifuge tube with phosphate buffered saline (PBS) solution.
- 3 The volume is made up to 10 mL with PBS and the solution re-centrifuged at 1500 rpm for 2 minutes.
- 4 The supernatant is discarded and the pellet resuspended in 1 mL of PNA-FITC (Sigma).
- 5 Eggs are then incubated for 1 hour under constant agitation at room temperature.
- 6 Samples are washed twice in PBS (as above), and 5 μL of the egg sediment transferred onto a glass slide with 3 μL of fluorescent mounting fluid and then overlaid with a coverslip.
- 7 Specimens are then examined with a fluorescence microscope using FITC filters. *Haemonchus* eggs have a bright fluorescent green outline.

Plasma pepsinogen test

The estimation of circulating pepsinogen is of value in the diagnosis of abomasal damage, and is especially elevated in cases of ostertagiosis. Elevations also occur with other gastric parasites such as *Trichostrongylus axei*, *Haemonchus contortus* and, in the pig, *Hyostrogylus rubidus*.

The principle of the test, which is best carried out by a diagnostic laboratory, is that the sample of serum or plasma is acidified to pH 2.0, thus activating the inactive zymogen, pepsinogen, to the active proteolytic enzyme, pepsin. This activated pepsin is then allowed to react with a protein substrate (usually bovine serum albumin) and the enzyme concentration calculated in international units (μmol tyrosine released per 100 mL serum per minute). The tyrosine liberated from the protein substrate by the pepsin is estimated by the blue colour, which is formed when phenolic compounds react with Folin–Ciocalteu reagent. The minimum requirement for the test, as carried out in most laboratories, is 1.5 mL serum or plasma. The anti-coagulant used for plasma samples is either EDTA or heparin.

In parasitic gastritis of ruminants due to *Ostertagia* spp. and *T. axei*, the levels of plasma pepsinogen become elevated. In parasite-free animals the level is less than 1.0 iu of tyrosine; in moderately infected animals, it is between 1.0 and 2.0 iu and in heavily infected animals it usually exceeds 3.0 iu, reaching as high as 10.0 iu or more on occasion. Interpretation is simple in animals during their first 18 months, but thereafter becomes difficult as the level may become elevated when older and immune animals are under challenge. In such cases the absence of the classical clinical signs of diarrhoea and weight loss indicates that there are few adult parasites present.

Pasture larval counts

For this technique, samples of grass are plucked from the pasture and placed in a polythene bag, which is then sealed and dispatched to a laboratory for processing. It is important to take

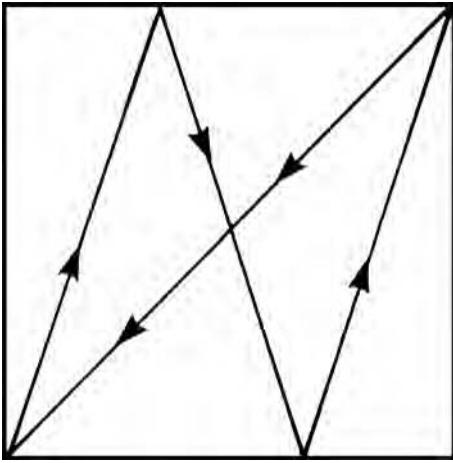

Fig. 4.26 Butterfly route.

a reasonable number of random samples, and one method is to traverse the pasture and remove four grass samples at intervals of about four paces until approximately 400 have been collected (Fig. 4.26). Another method, primarily for lungworm larvae, is to collect a similar number of samples from the close proximity of faecal pats. At the laboratory, the grass is thoroughly soaked, washed and dried and the washings containing the larvae passed through a sieve (aperture 38 μm ; 600 to 1 inch) to remove fine debris. The material retained on the sieve is then processed by the Baermann method and the infective larvae are identified and counted microscopically under the high power of the microscope. The numbers present are expressed as L_3 per kilogram of dried herbage.

Where counts in excess of 1000 L_3/kg of ruminant gastrointestinal trichostrongyles are recorded, the pasture can be regarded as moderately infective, while values of over 5000 L_3/kg can be expected to produce clinical disease in young animals during their first season at grass.

Although this is a useful technique for detecting the level of gastrointestinal nematode L_3 on pastures, it is less valuable for detecting lungworm larvae because of the rapid fluctuations of these larvae on pastures.

A more sophisticated technique, the Jorgensen method, which depends on migration of larvae through an agar medium containing bile, is used in some laboratories for estimating *Dictyocaulus* larval populations on pasture; since most lungworm larvae are concentrated close to faeces, herbage samples should be collected from around faecal deposits. In the present state of knowledge, the detection of any lungworm larvae in herbage samples should be regarded with suspicion and even a negative finding does not necessarily imply that the pasture is free of infection.

Bulk-tank milk tests

Monitoring worm and fluke infections in adult cattle can be used to evaluate the effectiveness of control measures and to target anthelmintic treatments where required. A bulk milk tank test can be used as a guide to identify those dairy herds with potential to increase milk yield in response to anthelmintic treatment.

Bulk-tank milk test for *Ostertagia*

This test measures the level of challenge to the herd from stomach worms (*Ostertagia*). Studies have shown the following.

- 1 Worms reduce milk yield by reducing appetite and the ability of cows to digest forage.
- 2 The milk yield response following treatment is around 1 kg/cow per day.
- 3 The financial benefit from worming is maximised when treatment is applied around calving due to:
 - a greater daily milk yield response
 - b longer duration of milk yield response
 - c opportunity to improve reproductive performance
 - d potential to improve IgG concentrations in colostrum.

Generally, the most appropriate time to collect bulk-tank milk samples for the stomach worm test is in the autumn, prior to housing. A positive treatment response can occur with optical density ratio (ODR) values greater than the cut-off point of 0.5. However, more reliable responses in milk yield generally occur in herds with an ODR value of 0.8 or more.

Fluke bulk-tank milk test

In cattle, fluke infections are generally subclinical, but are considered to produce marked economic effects. Few studies have been conducted to estimate the effect on productivity in adult cattle and control should aim at the reduction of infection to levels that minimise interference on cattle productivity. A positive correlation between *Fasciola*-specific bulk-tank milk antibody levels and herd seroprevalence has been demonstrated and so provides a basis for monitoring herd infection status.

Fluke studies have shown that:

- 1 from a cut-off in ODR of 0.5 onwards, there is an average milk yield loss of 0.11 kg/cow per day for each 0.1 unit increase in the bulk-tank milk ELISA result;
- 2 when the bulk-tank milk ODR result exceeds 0.8:
 - a it is estimated that for 50% of the cows, the number of inseminations is increased by 75%;
 - b the average inter-calving interval of the herd is prolonged by 4–5 days.

Results should be interpreted in the context of management factors specific to the farm concerned, such as the length of the grazing season, previous worming treatments and the risks from other parasites. Note also that results vary between different laboratories so results should be interpreted in accordance with guidelines provided by the laboratory concerned. Table 4.5 provides some general guidance only.

DNA-BASED METHODS

The main goals of diagnosis in veterinary parasitology are to determine the presence or absence of key pathogenic species; and to determine the species composition and resistance status of a given parasite population to antiparasitic drugs. Diagnostic tests to achieve these goals need to be simple, cheap, high-throughput and rapid, in order to encourage uptake in the field. However, most, if not all, of the currently available diagnostic tests have limitations.

Table 4.5 Guide to the interpretation of *Ostertagia* and fluke bulk-tank milk ELISA.

| <i>Ostertagia</i> test result | <i>Fasciola</i> test result | Level of infection | What does it mean? | Recommended action |
|-------------------------------|-----------------------------|--------------------|--|--|
| ODR >0.70 | ODR >0.70 3+ | High | Moderate to high exposure of milking cows with probable subclinical effects on health and production | Parasite control in such herds should be reviewed. It is likely that a substantial positive response to anthelmintic treatment of the dairy herd will result |
| ODR 0.50–0.69 | ODR 0.50–0.69 2+ | Medium | Limited to moderate exposure of milking cows to infection, at levels less likely to have significant impact on the milking herd as a whole | Individual cows may have higher than average levels of infection, with associated effects on health and production, and anthelmintic treatment might be of benefit to them |
| ODR <0.50 | ODR <0.50 – or + | Low | Exposure of adult cows to liver fluke or stomach worm is relatively low | No change to parasite control policy indicated. It is unlikely that herd health or production will respond to anthelmintic treatment |

With veterinary helminths, routine diagnosis still relies heavily on the FEC and microscopic examination of eggs and/or larvae extracted from faecal samples. The morphological identification of nematode eggs and larvae, even to genus level, is a significant diagnostic challenge. In ruminants, for example, with the possible exception of *Nematodirus* whose eggs are morphologically distinct (see Figs 4.2 and 4.3) and *Haemonchus* eggs specifically stained with fluorescent PNA lectin, most trichostrongylid eggs are indistinguishable from one another and require lengthy (7–10 days) coproculture to third-stage larvae to facilitate their identification. Such methods are often labour-intensive and time-consuming and require experienced personnel, making them prohibitively expensive for routine application, whether for use on livestock farms or for large-scale veterinary epidemiological/surveillance purposes. More recently, a number of immunologically based tests have been developed, such as enzyme-linked immunosorbent assay (ELISA), but many of these are only capable of detecting or measuring a single parasite species per test. Parasitic infections often involve multiple species, genera and even taxa, either simultaneously or as overlapping infections throughout the course of the parasite season. Species specificity is not usually an issue for immunologically based diagnostic tests; their major limitation is in their ability to detect current infection, because antibody titres can persist long after infection, even after parasites are removed following successful anthelmintic treatment. A further drawback with immunologically based tests is that, with the exception of bulk-tank milk ELISAs, they involve invasive procedures such as blood sampling, which often requires veterinary supervision, to provide the necessary diagnostic sample. As a result, blood sampling for parasite diagnosis is not routine practice in livestock farming, and is certainly not economically viable for many farmers. Any improvement over currently available tests must use the simplest, most convenient source of sample material, be able to cope with multispecies infections, be much more rapid in turnaround time, be sufficiently inexpensive to encourage uptake and, ideally, have potential for pen-side or point-of-care applications.

Potential of DNA-based testing

DNA-based testing has considerable potential for a number of parasite diagnoses, most notably parasite detection and quantification, species identification and resistance detection, which would represent a considerable advancement over existing methodologies. That said, DNA-based applications in veterinary diagnosis are still very much in their infancy and, currently, none of these applications are widely used in practice or are truly commercially available. Optimally designed DNA-based methods can be extremely

sensitive and specific and can be applied to any parasite life-cycle stage from which DNA can be extracted (eggs, larvae or adults). Moreover, such methods can be readily applied to tiny amounts of starting material, as well as to pooled samples from relatively crude sources (e.g. animal faeces), and they can also operate in a genuine multispecies/multiplex format.

Polymerase chain reaction

Until the advent of polymerase chain reaction (PCR) in the 1980s, most DNA-based diagnostic work was based on radioactive primer/probe hybridisation to DNA targets immobilised on solid supports (e.g. charged nylon membranes) and involved an inherent reliance on gel electrophoresis, radioactive probes and/or X-ray film for detection and quantification. Since then, PCR and PCR-based methods have effectively revolutionised our diagnostic capabilities, especially in the fields of medical virology and bacteriology. Routine application of PCR to medical parasitology has lagged somewhat behind these two disciplines, and its application to veterinary parasitology even more so.

The basic PCR method utilises a thermostable DNA polymerase, usually *Taq* polymerase, to specifically amplify a region of the target DNA, as defined by two opposing nucleotide primers. Under optimal conditions, sequential cycles of DNA template denaturation, primer annealing and extension, achieved through the use of a computer-controlled heating device or 'PCR machine', result in the exponential amplification of the target sequence (Fig. 4.27), such that the PCR product(s) can be visualised through gel electrophoresis or similar methodologies.

A typical PCR reaction comprises a proprietary *Taq* polymerase buffer containing Mg^{2+} ions at the appropriate concentration (this is important for efficient primer/target annealing and can be titrated in the initial optimisation of the PCR assay). The reaction also contains the respective forward and reverse primers, the required nucleotides (A, C, G and T) and the *Taq* polymerase itself. PCR reactions are usually set up as 'mastermixes' and dispensed into the required number of PCR tubes to ensure adequate mixing of reagents and to circumvent problems with pipetting small volumes. Most researchers now utilise commercially available PCR kits to reduce assay-to-assay variability and enhance quality control. The basic PCR method can be made less labour-intensive and achieve higher throughput by the use of multichannel pipettes and microtitre plates for example.

PCR reaction mixtures and assays are set up and customised for specific purposes, but a typical conventional PCR reaction protocol is outlined here.

Fig. 4.27 Schematic diagram of PCR. Each cycle of PCR (heating–denaturing, cooling–annealing and extending) doubles the amount of target DNA, increasing the concentration of target DNA exponentially. (With thanks to Dr P. Skuce.)

Materials/equipment required

- 1 PCR machine.
- 2 Pipettes and pipette tips (capable of dispensing various volumes, e.g. up to 20 μL , 200 μL , 1 mL, ideally with barrier filters to prevent contamination from aerosol DNA).
- 3 PCR tubes: thin-walled Eppendorf type.
- 4 *Taq* polymerase enzyme and proprietary buffer (10 \times).
- 5 50 mmol/L stock MgCl_2 .
- 6 10 $\mu\text{mol/L}$ forward and reverse primers.

- 7 25 $\mu\text{mol/L}$ dNTPs (A, C, G, T).
- 8 Template DNA.
- 9 Sterile, nuclease-free H_2O .

PCR primers are typically designed using proprietary primer design software programs or similar algorithms available freely online. Depending on the application, these programs search for unique stretches of DNA sequence on the opposing DNA strands and select forward and reverse primer pairs that are calculated to function optimally under the same PCR conditions. Factors which affect primer, and hence, PCR sensitivity and specificity include

Table 4.6 A typical PCR 25- μ L reaction mixture.

| Reagent | Test PCR (μ L) | 10 \times 25 μ L Mastermix | Final concentrations |
|---|---------------------------|----------------------------------|----------------------|
| 10 \times Buffer (MgCl ₂) | 2.5 | 25 | 1 \times |
| 50 mmol/L MgCl ₂ | 1 | 10 | 2 mmol/L |
| Forward primer (10 μ mol/L) | 1 | 10 | 0.4 μ mol/L |
| Reverse primer (10 μ mol/L) | 1 | 10 | 0.4 μ mol/L |
| dNTPs (A, C, G, T) @ 2.5 mmol/L | 2 | 20 | 0.2 mmol/L each |
| Taq polymerase | 0.2 | 2.0 | 1.0 unit* |
| Template DNA | 1 | 10 (i.e. 10 \times 1 μ L) | N/A |
| ddH ₂ O | 16.3 (i.e. to 25 μ L) | 163.0 | N/A |
| Total | 25 | 250 | N/A |

* 1.0 unit of polymerase activity is sufficient for amplifying most nucleic acid targets.

the melting temperature (or T_m , the temperature at which double-stranded DNA 'melts' into single strands), primer length (typically 18–22 nucleotides), GC content (ideally ~50%), secondary structure (i.e. predicted loops and/or hairpins that could interfere with primer/target binding), primer dimers (where the primer can bind to itself or its primer partner) and the presence of repetitive sequences (which should be avoided if possible).

Once primers have been designed, the basic PCR must be optimised with respect to the concentration of reagents and the PCR conditions, especially the primer annealing temperature and MgCl₂ concentration, which must be empirically tested. PCR reactions should be set up in separate workstations devoted to DNA template extraction, PCR reaction mastermix, addition of template DNA, thermal cycling and post-amplification analysis, respectively. This is to avoid contamination of PCR reagents and mastermixes with previously amplified DNA, which can require lengthy and expensive troubleshooting to resolve. A typical PCR 25- μ L reaction mixture is shown in Table 4.6, along with a mastermix to cover 10 \times 25 μ L reactions.

PCR set-up

- 1 Reagents are assembled in thin-walled PCR tubes, as required. Tubes are capped and contents centrifuged briefly. This is best carried out on ice to prevent primers annealing to template at suboptimal temperatures. This problem has been largely circumvented by the development of 'hot-start' polymerases, which are protected by an antibody until activated at high

temperature, typically ~94°C. This normally results in increased sensitivity, specificity and yield.

- 2 Tubes are then incubated in a PCR machine programmed with the appropriate thermal cycling conditions. A typical reaction would require 94°C for 2 minutes for initial template denaturation, followed by 25–40 cycles of PCR amplification, for example denature at 94°C for 30 seconds, anneal at 55°C for 30 seconds, extend at 72°C for 1 minute, followed by a 'soak' at 4°C after thermal cycling.
- 3 Following PCR, small aliquots (e.g. 5 μ L) of the respective PCR products are typically electrophoresed on an agarose gel against a molecular weight marker and photographed under UV illumination. Typical PCR gels are shown in Figs 4.28 and 4.29.

Real-time PCR

A number of modifications to the basic PCR method and developments in PCR-based technologies have taken place over recent years. Most notable of these is a move towards quantitative PCR applications, where the amplification of PCR product is monitored during the exponential phase in real time (hence the name), rather than the semi-quantitative end point of the standard PCR. This has been facilitated by developments in DNA primer and probe chemistry such that the specific PCR product is fluorescently labelled and can be quantified accurately by laser throughout the course of the whole PCR process. Real-time PCR has become the benchmark for accurate and sensitive detection of nucleic acids, and has overcome many of the problems inherent in previous molecular genetic approaches. Real-time PCR can be achieved through monitoring a build-up of product through intercalation of a fluorochrome dye such as Sybr-Green. Alternatively, a primer/probe combination can be used, as in TaqMan real-time PCR. Briefly, an oligonucleotide probe, labelled with two fluorescent dyes, is designed to bind within the amplicon specified by the flanking PCR primers. As long as the probe remains intact, the emission of the reporter dye at the 5' end of the probe is quenched by the fluorescent dye at the 3' end. However, as the exponential phase of PCR progresses, the polymerase cleaves the probe, resulting in the release of the reporter dye. This is detected within the real-time PCR machine and normalised against a reference standard. The real-time PCR machine then calculates a threshold at which the baseline fluorescence is exceeded. This is defined as the threshold cycle or C_t , and is directly correlated with the initial quantity of template DNA, i.e. the earlier the fluorescent signal crosses the calculated threshold, the more template DNA was in the sample. The efficiency of primer and probe combinations for real-time PCR

Fig. 4.28 Single-species PCR for sheep gastrointestinal nematodes: screening individual larvae using *Haemonchus contortus*-specific PCR. (Courtesy of L. Melville, Moredun Research Institute, UK.)

Fig. 4.29 Multiplex PCR for sheep gastrointestinal nematode species identification: the banding patterns indicate species identity of individual larvae. (Courtesy of Dr S.A. Bissett, AgResearch New Zealand.)

must be established and the relative quantification and sensitivity determined through standard curve analysis using serial dilutions of the template DNA (Fig. 4.30). The TaqMan and allied real-time PCR method has been extensively used to quantify gene expression and copy number, but also in the detection and quantification of pathogens (see Navarro *et al.*, 2015 for a comprehensive review).

Challenges to DNA-based diagnosis

PCR-based methods have considerable potential applications within the field of veterinary parasitology but are not without their challenges. One of the main challenges is in DNA template preparation. Tiny amounts of PCR-amplifiable DNA can be extracted from relatively crude samples such as individually lysed parasite eggs or larvae. These can be extracted with relatively simple SDS/

NaOH lysis buffers. However, this requires extraction of individual eggs or cysts from faecal samples and/or culturing or excystation, and picking of individual parasites into separate wells/tubes for lysis, which is a time-consuming and labour-intensive process. It would be preferable to extract DNA directly from the faecal sample without any prior extraction of parasite material. A number of commercial DNA extraction kits have the capability to extract amplifiable DNA from faecal samples but, typically, the amount of DNA in the sample is so small and/or the input of faecal material so large that currently the method is less sensitive than some of the established faecal egg counting methods (e.g. McMaster, FLOTAC). This is compounded by the fact that *Taq* polymerase is notoriously sensitive to the presence of PCR inhibitors in faecal material. One possible compromise that has been explored recently is to use Phusion® Hot Start, one of a new generation of polymerase enzymes that are less sensitive to faecal inhibitors, in combination with parasite eggs extracted as a by-product of the routine FEC. These eggs require little or no purification, just a series of freeze–thaw cycles, to release template DNA. This method has been successfully used to detect and quantify gastrointestinal nematode eggs from crude faecal preparations from a number of different host species.

In addition to these technological challenges, the multispecies nature of parasite infections in livestock and companion animals is a significant challenge to DNA-based diagnosis. This feature, coupled with the extreme genetic variability inherent in parasites, both between and within species, can be both a blessing and a curse in attempting to develop species-specific and/or ‘generic’ DNA-based tests. This is partly offset by using molecular targets such as subunits within and spacers between the ribosomal RNA (rRNA) genes of key helminth parasites, for example the internal transcribed spacer (ITS)-1 or ITS-2. Such targets comprise a series of highly

Fig. 4.30 Typical standard curve analysis for real-time PCR. (Courtesy of Dr A. Dicker, Moredun Research Institute, UK.)

conserved regions, ideal for placement of universal flanking primer sets, plus regions that are highly variable within and between species for design of species-specific internal primers and/or probes.

Progress to date

PCR-based methods have been shown to provide accurate, sensitive, reproducible and robust diagnostic results from parasitic helminth material and have the potential to support or even replace conventional coprological assays. The early PCR-based assays were designed to provide species-specific detection of individual parasite eggs, larvae and/or adults of gastrointestinal nematode parasites of sheep and were applied to multiple samples in turn. Careful positioning of species-specific primer pairs provided a range of product sizes, which could be pooled and resolved by DNA capillary electrophoresis, thus providing a 'virtual' multiplex readout. However, this was not a genuine multiplex assay in that multiple species could not be detected simultaneously in the same reaction. Genuine multiplex assays have subsequently been developed to identify sheep gastrointestinal nematode stages to species level but these can only realistically be applied to multiple individual parasite samples, which defeat the purpose to some extent. Attempts to analyse pooled samples, either by gel or capillary electrophoresis, invariably results in the loss of certain individual species' PCR products. An equivalent assay designed to discriminate between gastrointestinal nematodes of cattle was much more successful in this regard, possibly due to the lower number of species involved.

Current state of the art

Careful primer and probe design led to the development of a panel of species-specific real-time PCR assays for the key ovine nematodes, including a multiplex real-time PCR assay capable of detecting and quantifying *Haemonchus contortus* and *Teladorsagia circumcincta* in the same reaction. However, attempts to include further key ovine nematode species proved unsuccessful. This obstacle to progress prompted the development of a testing system

based on the simultaneous application of multiple species-specific assays in a parallel-plex format. The high speed and throughput of the method is enhanced through the application of robotic systems for the DNA extraction and PCR steps, with the added advantage that the process can be overseen by relatively inexperienced personnel in the testing laboratory. This method offers genuine potential to replace coprological assays for sheep and is now being offered as a commercial service to the livestock sector in Australia.

Available/applicable DNA-based methodologies

Pyrosequencing

Pyrosequencing was developed in the mid-1990s and uses a flexible 'sequencing by synthesis' approach to provide genotyping or short-range DNA sequence data. Pyrosequencing can perform rapid and accurate detection of single-nucleotide polymorphisms (SNPs) from multiple individual samples or determine quantitative allele frequency from pooled material. It can also provide short-range (20–30 bases) *de novo* DNA sequence information. The method requires initial PCR amplification of the DNA region of interest, using flanking primers, one of which is biotinylated to facilitate subsequent DNA template purification. This is followed by denaturation of purified PCR product into single strands to permit annealing of a specific pyrosequencing primer. This is typically designed to target a particular SNP or polymorphic sequence, which is normally located within about 10 bases of the 3' end of the pyrosequencing primer. During the pyrosequencing reaction, the respective nucleotides (A, C, G and T) are dispensed in turn (or in order if known). If a nucleotide is successfully incorporated, pyrophosphate is released, which sets off a cascade of enzymatic reactions, leading to the detection of a fluorescent signal by a camera within the pyrosequencer itself. Unincorporated nucleotides are digested by an apyrase enzyme within the pyrosequencing reaction mix. Peak heights on the resultant pyrogram provide a quantitative readout of the nucleotide sequence downstream of the pyrosequencing primer and/or the genotypes of individuals or pools under test (Fig. 4.31).

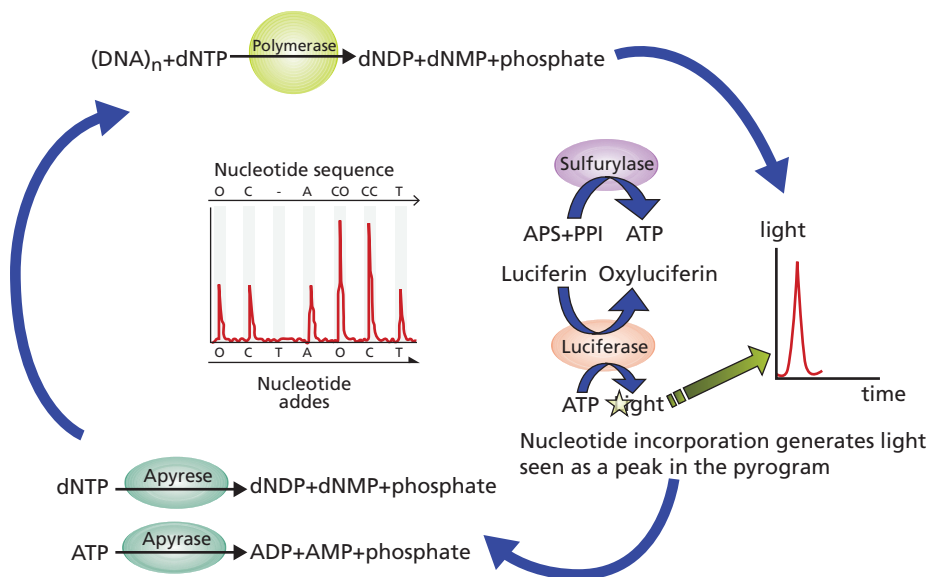

Fig. 4.31 The chemistry behind pyrosequencing and the generation of a pyrogram. Source: <http://www.qiagen.com/resources/technologies/pyrosequencing-resource-center/technology-overview>. (QIAGEN, 2014. © QIAGEN, all rights reserved.)

To date, pyrosequencing has been primarily applied to the detection of anthelmintic resistance, specifically benzimidazole resistance in gastrointestinal nematodes of livestock and horses. This is because anthelmintic resistance has a genetic component and the major genetic determinants of benzimidazole resistance are reasonably well understood at the molecular level. With the possible exception of the new amino-acetonitrile derivative monepantel, we do not understand the precise genetic changes associated with resistance to any of the other anthelmintic classes. In most, if not all, nematode parasites, benzimidazole resistance appears to be conferred by the selection of specific mutations (or SNPs) in the coding sequence of the parasite β -tubulin gene. This is most commonly a change at codon 200 from TTC to TAC, which results in a phenylalanine to tyrosine substitution, the so-called F200Y SNP. Other SNPs have been identified at codons 198 (A198E) and 167 (F167Y), but these appear to be less important. Species-specific benzimidazole resistance pyrosequencing assays have been developed for a number of key sheep nematodes (e.g. *Haemonchus contortus*, *Teladorsagia circumcincta*, *Trichostrongylus* spp., *Nematodirus battus*), cattle nematodes (e.g. *Ostertagia ostertagi*, *Cooperia oncophora*), as well as a number of equine nematode species. Pyrosequencing assays have been used in the field, for example an F200Y assay has been used to genotype *Haemonchus contortus* populations in Swedish sheep, and showed good correlation with equivalent FEC reduction test (FECRT) data. Such assays offer the potential to detect the emergence of anthelmintic resistance, when the frequency of resistance alleles is extremely low, although as yet there are no agreed thresholds to trigger any subsequent management intervention. They also represent excellent research tools to demonstrate the genetic consequences of management strategies (e.g. dose and move, targeted selective treatment) aimed at slowing the spread of anthelmintic resistance. However, if such assays are to find genuine utility in the field, as a proxy or replacement for the FECRT, they must be able to provide allele frequency data from multiple species infections. This remains a significant technological challenge.

Loop-mediated isothermal amplification

Loop-mediated isothermal amplification (LAMP) is a relatively new DNA-based amplification method that has some potential advantages over PCR-based methods. It relies on the DNA strand displacement activity of *Bst* polymerase and related enzymes, so it does not require thermal cycling, and can be carried out at stable isothermal temperature (Fig. 4.32). This also means fewer requirements for sophisticated equipment, such as gel electrophoresis or thermal cycling machines. These features make LAMP an attractive

option for diagnostic/epidemiological studies in the field or for application in less developed countries. The enzyme itself is also significantly less sensitive to faecal inhibitors than *Taq* polymerase and can be several orders of magnitude more sensitive than the equivalent PCR. Furthermore, because a typical LAMP reaction requires a total of six primers, LAMP assays can also be considerably more specific than the equivalent PCR. The exponential build-up of product can be visualised by eye, through turbidity changes in the reaction mixture, or by a colour change following addition of certain dyes or through fluorescence detection under UV light. Under optimal conditions, LAMP assays can produce visible results within 15–30 minutes, giving the method real potential as a pen-side or point-of-care diagnostic test. Moreover, LAMP chemistry can be readily translated onto dipstick or lateral flow-type devices. The product can also be quantified by reading on a turbidity meter, a colorimetric scanner and/or real-time PCR platform. LAMP assays have been reported for the diagnosis of a number of helminth species, for example *Fasciola hepatica*, *Clonorchis sinensis*, *Opisthorchis viverrini* and *Trichinella spiralis*. Careful assay design also allows for presence/absence or quantitative SNP detection for anthelmintic resistance allele frequency studies. One possible drawback is that the LAMP assay is currently only available in isoplex (i.e. single species format), but research is underway into its multiplexing capability.

Microbead-based detection systems

An example is Luminex[®], which is a relatively recent development, combining advances in microfluidics, optics and digital signal processing to provide a flexible multiplex diagnostic platform. The method uses microscopic colour-coded beads (or microspheres), which can be coated with a reagent specific for a given target to allow for capture and laser detection of specific analytes in a sample. Such systems are extremely versatile and can be used to detect and quantify antibody–antigen interactions, enzyme–substrate reactions and nucleic acid primer–probe binding. They can also accommodate multiple analytes (up to 500 at present) in a single sample, and process multiple samples simultaneously in microtitre plate format. Microbead-based systems are now widely used in medical diagnostic laboratories and a number of proprietary diagnostic assays are available commercially. Their utility has been demonstrated recently in the simultaneous detection and quantification of seven intestinal human parasites from faecal samples. Such systems have not yet been used in veterinary parasitology diagnosis, but their potential to deliver rapid, high-throughput, multiplex assays is currently under evaluation.

Fig. 4.32 Primer arrangement for loop-mediated isothermal amplification (LAMP). Internal primers (FOP and BIP) each target two primer binding sites (F1 and F2 and B1 and B2, respectively). The most salient mismatches for target/non-target discrimination should be placed at the positions indicated by the asterisks. *Source:* <http://loopamp.eiken.co.jp/e/lamp/primer.html>. DNA-based diagnosis in veterinary parasitology: specific examples

Rumen fluke species identification

For decades, it had been assumed that the predominant rumen fluke species infecting British and Irish livestock was *Paramphistomum cervi*, which is believed to have a natural wildlife host in deer and to favour planorbid aquatic snails as its intermediate molluscan host (see Chapter 1). Genomic DNA extracted from rumen fluke adults, larvae or eggs collected from faecal samples or from post-mortem material was subjected to PCR, targeting the ITS-2 of the rRNA gene and submitted for DNA sequence analysis. In all cases, the DNA sequences obtained were 100% identical to *Calicophoron daubneyi*, the predominant rumen fluke species found in livestock in mainland Europe. This finding may have implications for rumen fluke epidemiology in Britain and Ireland, because *C. daubneyi* is known to favour the same mud snail intermediate host, *Galba truncatula*, as liver fluke.

Liver fluke detection in faeces

The detection of acute liver fluke disease, caused by the mass migration of the damaging immature stages, represents a significant diagnostic challenge, especially in sheep. Fluke diagnosis is based mainly around invasive blood tests, looking for biochemical evidence of liver and/or bile duct damage, or the presence of anti-fluke antibodies. These methods are relatively non-specific and can be difficult to interpret. Furthermore, the long prepatent period for fluke, typically 8–12 weeks post infection, means that fluke egg counting is of no practical use in acute fluke cases. The aforementioned cELISA has been shown to detect fluke infection several weeks ahead of FEC in experimental challenge models, but this has not yet been observed in the field. However, published evidence suggests that liver fluke DNA, possibly originating from the parasite's gut contents and/or sloughed tegumental material, can be detected in host faeces from as early as 2 weeks post infection. The method involves targeting a mitochondrial gene using a sensitive nested PCR approach and with minimal processing of faecal samples. Subsequently, a second liver fluke-specific PCR assay has been developed, based on an ITS-2 sequence, which shows promise in the sensitive detection of flukicide-resistant *Fasciola* populations.

PROTOZOAL INFECTIONS

The laboratory diagnosis of protozoal diseases is often relatively straightforward and well within the scope of the general practitioner, although on other occasions it may require specialised techniques and long experience. This section is concerned primarily with the former and supplements the information already given in the general text.

EXAMINATION OF FAECAL SAMPLES FOR COCCIDIA

Faecal oocyst counts can help support the diagnosis of coccidiosis but it is important to identify the species present, as not all species

of coccidia are pathogenic. The modified McMaster method is the simplest technique for detecting the presence and estimating the number of coccidial oocysts in faeces. The technique is exactly the same as that described for helminthological diagnosis, although the small size of the oocysts makes the microscopic examination more prolonged. If the animal has acute clinical signs of coccidiosis, such as blood-stained faeces, and many thousands of oocysts are present, one may reasonably consider that the diagnosis is confirmed. Unfortunately, with the more pathogenic species of coccidia, clinical signs may appear during the merogonous phase or when oocyst production has just started, so that a negative or low oocyst count does not necessarily indicate that the clinical diagnosis was wrong. The oocyst count is also of little value in the less acute coccidial infections associated with production losses. In general, because of the limitations of the oocyst count, a postmortem examination, at least on poultry, is always advisable. Descriptive terms used in oocyst identification are shown in Fig. 4.33. Guidelines for the morphological diagnosis of sporulated oocysts from cattle (Fig. 4.34 and Table 4.7), sheep (Fig. 4.35 and Table 4.8), goats (Fig. 4.36 and Table 4.9), pigs (Fig. 4.37 and Table 4.10), rabbits (Fig. 4.38 and Table 4.11) and chickens and turkeys (Tables 4.12 and 4.13) are given on the following pages.

EXAMINATION OF FAECAL SAMPLES FOR OTHER PROTOZOA

For the detection of intestinal protozoa such as *Entamoeba*, *Giardia* or *Balantidium*, a small amount of fresh faeces may be mixed with warm saline and examined under a warm-stage microscope for the presence of trophozoites or cysts. However, their identification requires considerable experience and faecal samples preserved in formalin or polyvinyl alcohol should be sent to a specialist laboratory for confirmation.

The diagnosis of suspected *Cryptosporidium* infection relies on the direct examination of faecal smears, or faecal concentration and microscopic examination. Several stains have been used to differentiate oocysts from faecal debris. A qualitative estimation of oocyst numbers can be obtained by examining air-dried faecal smears stained using a modified Ziehl-Neelsen method. The detection limit (sensitivity) of this method is greater than 100,000 oocysts per gram of faeces. In addition, a range of ELISA coproantigen commercial tests kits is also available.

Fig. 4.33 Schematic diagram of an *Eimeria* oocyst.

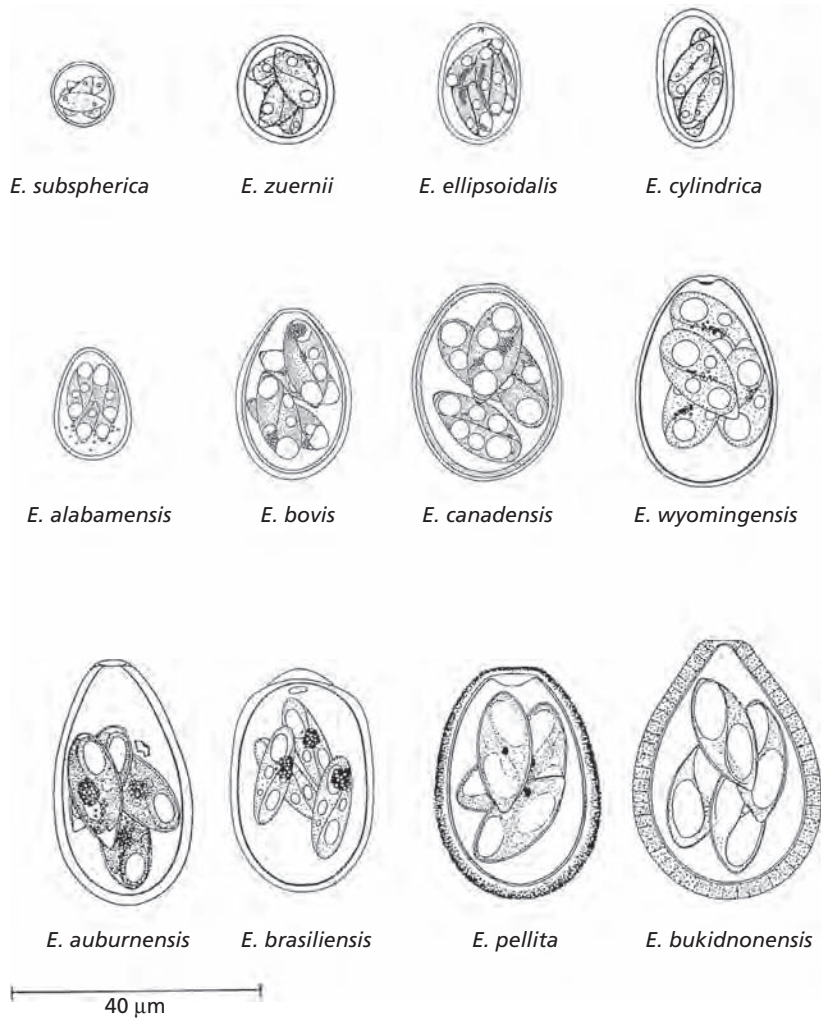

Fig. 4.34 Sporulated oocysts from cattle.

Table 4.7 Identification key for sporulated oocysts of *Eimeria* from cattle (see Fig. 4.33).

| Species | Oocyst description | Mean size (µm) | Sporulation time (days) |
|-------------------------------|--|----------------|-------------------------|
| Pathogenic species | | | |
| <i>Eimeria bovis</i> | Ovoid or subspherical, colourless, and smooth wall with inconspicuous micropyle, no polar granule or oocyst residuum | 28 × 20 | 2–3 |
| <i>E. zuernii</i> | Subspherical, colourless, with no micropyle or oocyst residuum | 18 × 16 | 2–3 |
| <i>E. alabamensis</i> | Usually ovoid with a smooth colourless wall with no micropyle, polar body or residuum | 19 × 13 | 5–8 |
| Non-pathogenic species | | | |
| <i>E. auburnensis</i> | Elongated, ovoid, yellowish-brown, with smooth or heavily granulated wall with a micropyle and polar granule, but no oocyst residuum | 38 × 23 | 2–3 |
| <i>E. brasiliensis</i> | Ellipsoidal, yellowish-brown, with a micropyle covered by a distinct polar cap. Polar granules may also be present, but there is no oocyst residuum | 37 × 27 | 12–14 |
| <i>E. bukidnonensis</i> | Pear-shaped or oval, tapering at one pole, yellowish-brown, with a thick, radially striated wall and micropyle. A polar granule may be present but there is no oocyst residuum | 49 × 35 | 4–7 |
| <i>E. canadensis</i> | Ovoid or ellipsoidal, colourless, or pale yellow, with an inconspicuous micropyle, one or more polar granules and an oocyst residuum | 33 × 23 | 3–4 |
| <i>E. cylindrica</i> | Elongated cylindrical with a colourless smooth wall, no micropyle, and no oocyst residuum | 23 × 12 | 2–3 |
| <i>E. ellipsoidalis</i> | Ellipsoidal to slightly ovoid, colourless, with no discernible micropyle, polar granule or oocyst residuum | 23 × 16 | 2–3 |
| <i>E. pellita</i> | Egg-shaped, very thick, brown wall with evenly distributed protruberances, with a micropyle and polar granule consisting of several rod-like bodies but no oocyst residuum | 40 × 28 | 10–12 |
| <i>E. subspherica</i> | Round or subspherical, colourless, with no micropyle, polar granule, or oocyst residuum | 11 × 10 | 4–5 |
| <i>E. wyomingensis</i> | Ovoid, yellowish-brown, with a thick wall, a wide micropyle but no polar granule or oocyst residuum | 40 × 28 | 5–7 |

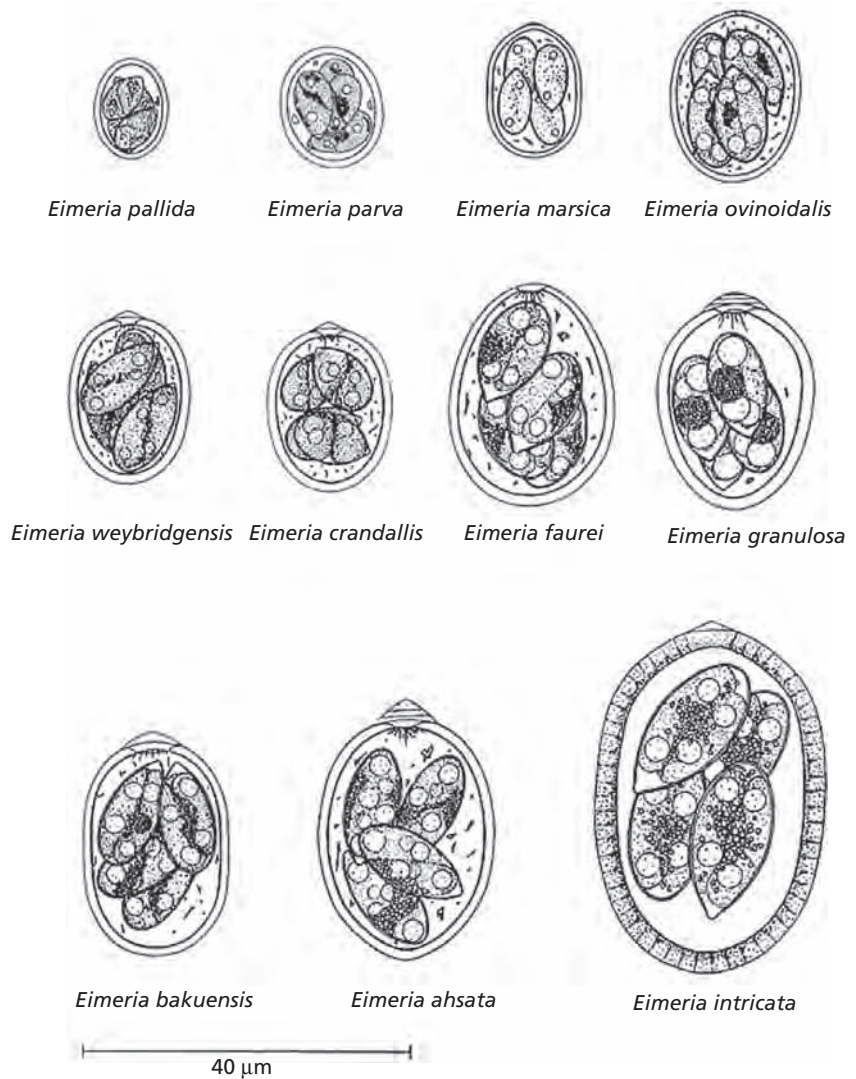

Fig. 4.35 Sporulated oocysts from sheep.

Table 4.8 Identification key for sporulated oocysts of *Eimeria* from sheep (see Fig. 4.34).

| Species | Oocyst description | Mean size (μ m) | Sporulation time (days) |
|-------------------------------|---|----------------------|-------------------------|
| Pathogenic species | | | |
| <i>Eimeria crandallis</i> | Broadly ellipsoidal or subspherical, with or without polar cap, without oocyst residuum, sporocysts very broad, with sporocyst residuum | 22 × 19 | 1–3 |
| <i>E. ovinoidalis</i> | Ellipsoidal indistinct micropyle, colourless or pale yellow, without oocyst residuum, with sporocyst residuum | 23 × 18 | 1–3 |
| <i>E. ahsata</i> | Ovoid with distinct polar cap, yellowish-brown, no oocyst residuum | 33 × 23 | 2–3 |
| Non-pathogenic species | | | |
| <i>E. bakuensis</i> | Ellipsoidal, with polar cap, pale yellowish-brown, without oocyst residuum, with sporocyst residuum | 31 × 20 | 2–4 |
| <i>E. faurei</i> | Ovoid, pale yellowish-brown, without oocyst residuum or sporocyst residuum | 32 × 23 | 1–3 |
| <i>E. granulosa</i> | Urn-shaped with large micropolar cap at broad end, yellowish-brown, without oocyst residuum | 29 × 21 | 3–4 |
| <i>E. intricata</i> | Ellipsoidal, thick and striated wall, brown no oocyst residuum | 48 × 34 | 3–7 |
| <i>E. marsica</i> | Ellipsoidal, with inconspicuous micropyle, colourless or pale yellow, without oocyst or sporocyst residuum | 19 × 13 | 3 |
| <i>E. pallida</i> | Ellipsoidal, thin-walled, colourless to pale yellow, without oocyst residuum, but with sporocyst residuum | 14 × 10 | 1–3 |
| <i>E. parva</i> | Spherical to subspherical, colourless, no oocyst residuum, sporocyst residuum composed of few granules | 17 × 14 | 3–5 |
| <i>E. weybridgei</i> | Broadly ellipsoidal or subspherical, micropyle with or without polar cap, without oocyst or sporocyst residuum | 24 × 17 | 1–3 |

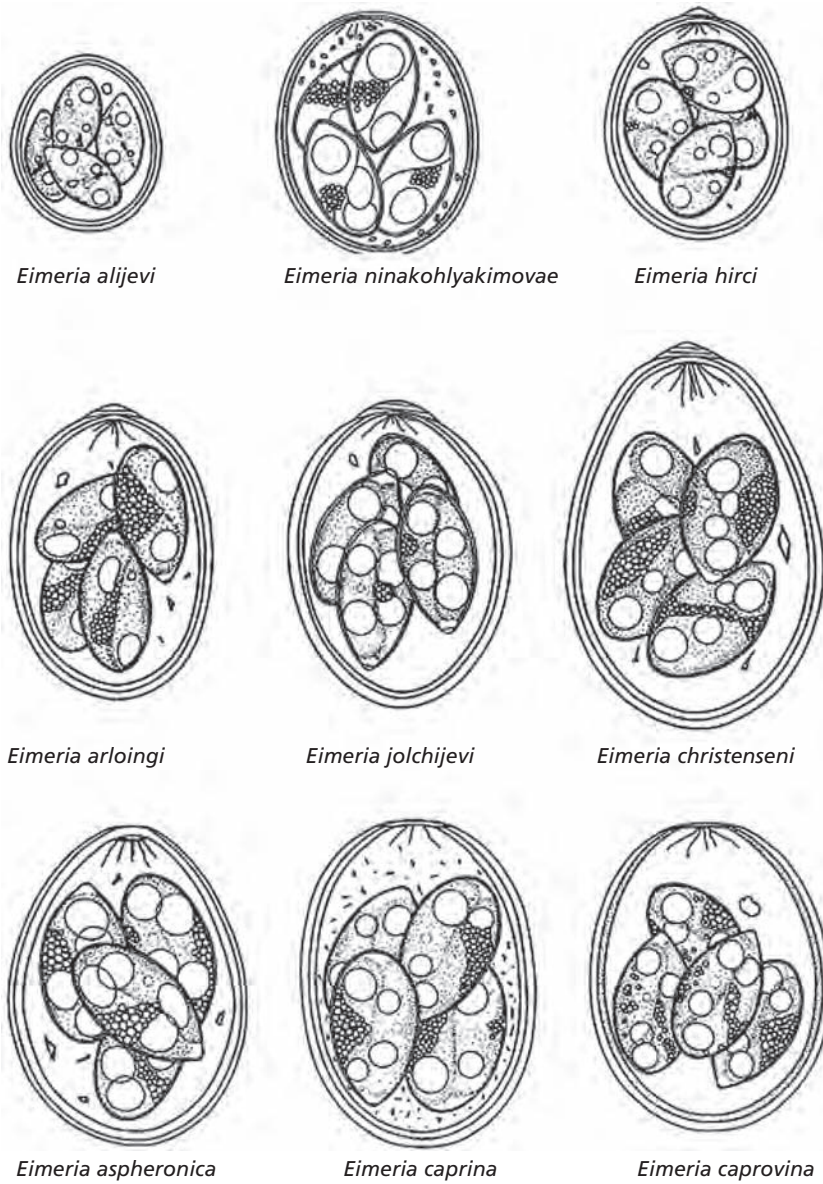

Fig. 4.36 Sporulated oocysts from goats.

Table 4.9 Identification key for sporulated oocysts of *Eimeria* from goats (see Fig. 4.35).

| Species | Oocyst description | Mean size (µm) | Sporulation time (days) |
|-------------------------------|--|----------------|-------------------------|
| Pathogenic species | | | |
| <i>Eimeria caprina</i> | Ellipsoidal, dark-brown to brownish-yellow, with micropyle, without oocyst residuum but with sporocyst residuum | 32 × 23 | 2–3 |
| <i>E. ninakohlyakimovae</i> | Ellipsoidal, thin-walled, colourless, micropyle absent or indistinct, without oocyst residuum but with sporocyst residuum | 21 × 15 | 1–4 |
| <i>E. christenseni</i> | Ovoid, thick wall, colourless to pale yellow, with micropyle and polar cap, without oocyst residuum but with sporocyst residuum | 38 × 25 | 6 |
| <i>E. hirci</i> | Roundish oval, light yellow, with micropyle and polar cap, no oocyst residuum, sporocysts broadly oval with small residuum | 21 × 16 | 2–3 |
| Non-pathogenic species | | | |
| <i>E. alijeui</i> | Ovoid or ellipsoidal, with inconspicuous micropyle, colourless or pale yellow, without oocyst residuum but with sporocyst residuum | 17 × 15 | 1–5 |
| <i>E. arloingi</i> | Ellipsoidal, thick wall with micropyle and polar cap, without oocyst residuum but with sporocyst residuum | 27 × 18 | 1–2 |
| <i>E. aspheronica</i> | Ovoid, greenish to yellow–brown, with micropyle, without oocyst residuum but with sporocyst residuum | 31 × 32 | 1–2 |
| <i>E. caprovina</i> | Ellipsoidal to subspherical, colourless, with micropyle, without oocyst residuum but with sporocyst residuum | 30 × 24 | 2–3 |
| <i>E. jolchijevi</i> | Ellipsoidal or oval, pale yellow, with micropyle and polar cap, without oocyst residuum but with sporocyst residuum | 31 × 22 | 2–4 |

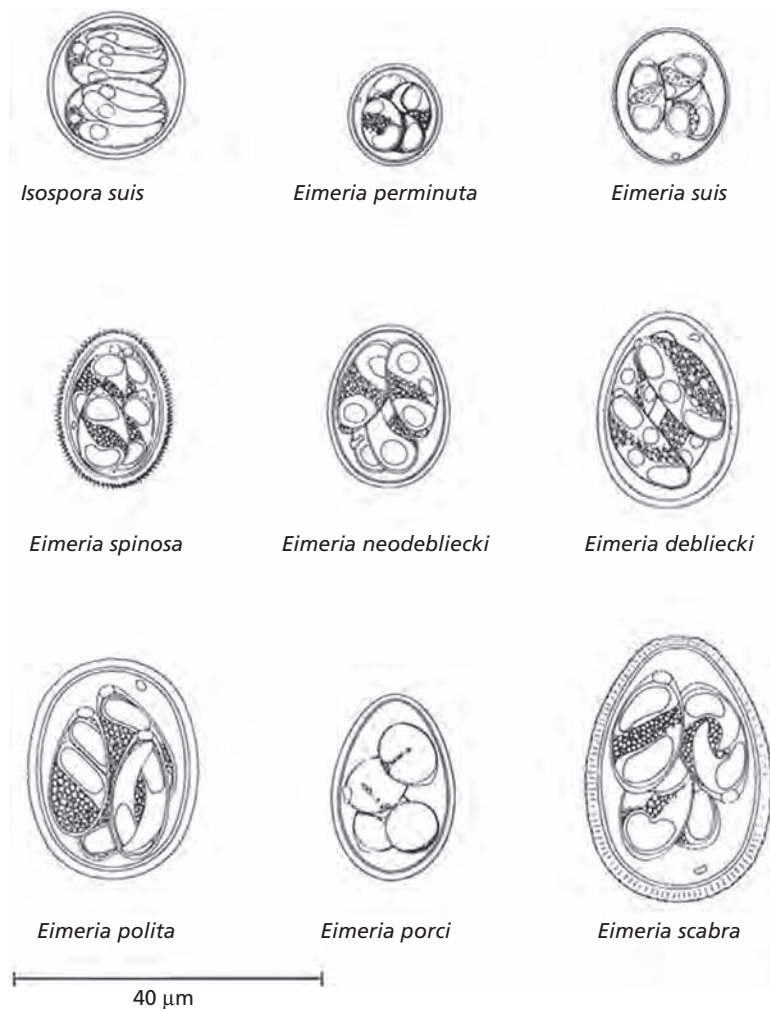

Fig. 4.37 Sporulated oocysts from pigs.

Table 4.10 Identification key for sporulated oocysts from pigs (see Fig. 4.36).

| Species | Oocyst description | Mean size (µm) | Sporulation time (days) |
|--------------------------|---|----------------|-------------------------|
| <i>Isospora suis</i> | Oocysts spherical to subspherical, wall colourless and thin, without a micropyle or residuum and when sporulated contains two sporocysts each with four sporozoites | 21 × 18 | 1–2 |
| <i>Eimeria perminuta</i> | Ovoid to subspherical, yellow in colour, and wall with a rough surface. A polar granule is present but no micropyle or oocyst residuum | 13 × 12 | 10–12 |
| <i>E. suis</i> | Ellipsoidal, wall smooth and colourless with a polar granule but no micropyle or oocyst residuum | 18 × 14 | 5–6 |
| <i>E. spinosa</i> | Ovoid with a thick, rough, brown wall with long spines. There is a polar granule but no micropyle or oocyst residuum | 21 × 16 | 9–10 |
| <i>E. neodebliecki</i> | Ellipsoid, wall smooth and colourless with no micropyle or oocyst residuum but there is a polar granule | 21 × 16 | 13 |
| <i>E. debliecki</i> | Ellipsoid or ovoid, wall smooth and colourless with no micropyle or oocyst residuum but with a polar granule | 19 × 14 | 5–7 |
| <i>E. polita</i> | Ellipsoidal or broad ovoid with a slightly rough yellowish-brown wall with no micropyle, oocyst residuum, although a polar granule may be present | 26 × 18 | 8–9 |
| <i>E. porci</i> | Ovoid, colourless to yellowish-brown, with an indistinct micropyle, a polar granule but no oocyst residuum | 22 × 16 | 9 |
| <i>E. scabra</i> | Ovoid or ellipsoidal, with a thick rough striated wall, yellow–brown in colour with a micropyle and polar granule, but no oocyst residuum | 32 × 23 | 9–12 |

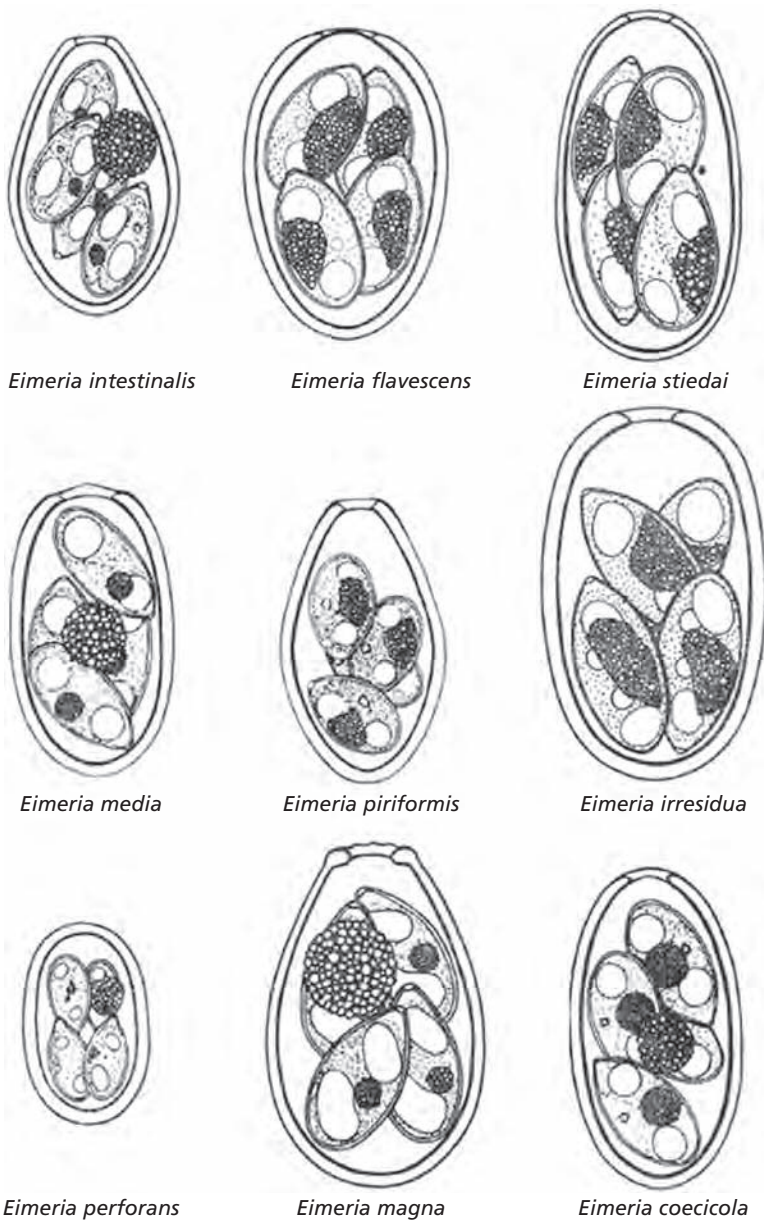

Fig. 4.38 Sporulated oocysts from rabbits.

Table 4.11 Identification key for sporulated oocysts of *Eimeria* from rabbits (see Fig. 4.37).

| Species | Oocyst description | Mean size (µm) | Sporulation time (days) |
|---------------------------------|--|----------------|-------------------------|
| Highly pathogenic | | | |
| <i>Eimeria flavescens</i> | Ovoid, yellowish, with a prominent micropyle at the broad end. There is no polar granule or oocyst residuum | 30 × 21 | 4 |
| <i>E. intestinalis</i> | Pyriform, yellowish-brown, with a micropyle at the narrow end, a large oocyst residuum but no polar granule | 27 × 19 | 3 |
| Pathogenic | | | |
| <i>E. stiedai</i> | Slightly ellipsoidal, colourless or pinkish orange, with an inapparent micropyle and no oocyst residuum | 37 × 20 | 2–3 |
| <i>E. media</i> | Ovoid or ellipsoidal, smooth, light pink with a micropyle with a pyramidal-shaped protruberance, a medium to large oocyst residuum and no polar granule | 31 × 17 | 2 |
| <i>E. piriformis</i> | Piriform, often asymmetrical, yellowish-brown, with a prominent micropyle but no polar granule or oocyst residuum | 30 × 18 | 4 |
| <i>E. irresidua</i> | Ovoid, barrel-shaped, smooth, yellowish, with a wide micropyle, a residuum may be present but there are no polar granules | 39 × 23 | 4 |
| <i>E. magna</i> | Ovoid, dark-yellow, truncated at micropylar end with marked collar-like thickening around micropyle, with very large oocyst residuum but no polar granules | 36 × 24 | 2–3 |
| Slight or non-pathogenic | | | |
| <i>E. perforans</i> | Ellipsoidal to sub-rectangular, smooth, colourless with a uniformly thin wall. There is an inconspicuous micropyle and an oocyst residuum but no polar granule | 22 × 14 | 1.5–2 |
| <i>E. exigua</i> | Spherical or subspherical, colourless, with no micropyle, polar granule or oocyst residuum | 15 × 14 | 1 |
| <i>E. vej dovsi</i> | Elongate or ovoid, micropyle present without collar-like protrusion, and with medium-sized oocyst residuum | 32 × 19 | 2 |
| <i>E. coecicola</i> | Ellipsoidal, light yellow to light brown in colour, with a smooth wall, a distinct micropyle with a slight collar-like protrusion, an oocyst residuum but no polar granule | 34 × 20 | 4 |

Table 4.12 Identification key for sporulated oocysts of *Eimeria* from chickens.

| Species | Oocyst description | Mean size (µm) | Sporulation time (hours) |
|---------------------------|--|----------------|--------------------------|
| <i>Eimeria acervulina</i> | Ovoid, smooth without a micropyle or residuum but with a polar granule | 18 × 14 | 24 |
| <i>E. brunetti</i> | Ovoid, smooth without a micropyle or residuum but with a polar granule | 26 × 22 | 24–48 |
| <i>E. maxima</i> | Ovoid, yellowish and smooth without a micropyle or residuum but with a polar granule | 30 × 20 | 30–48 |
| <i>E. mitis</i> | Subspherical, smooth without a micropyle or residuum but with a polar granule | 16 × 15 | 18–24 |
| <i>E. necatrix</i> | Ovoid, smooth, colourless without a micropyle or residuum but with a polar granule | 20 × 17 | 18–24 |
| <i>E. praecox</i> | Ovoid, smooth, colourless without a micropyle or residuum but with a polar granule | 21 × 17 | 48 |
| <i>E. tenella</i> | Ovoid, smooth, colourless without a micropyle or residuum but with a polar granule | 25 × 19 | 18–48 |

Table 4.13 Identification key for sporulated oocysts of *Eimeria* from turkeys.

| Species | Oocyst description | Mean size (µm) | Sporulation time (hours) |
|--------------------------|--|----------------|--------------------------|
| <i>Eimeria adenoides</i> | Ellipsoidal or ovoid, smooth, colourless with a micropyle, one to three polar granules but with no oocyst residuum | 26 × 17 | 24 |
| <i>E. dispersa</i> | Ovoid, smooth with no micropyle, polar granule or oocyst residuum | 26 × 21 | 48 |
| <i>E. meleagridis</i> | Ellipsoidal, smooth with no micropyle and no oocyst residuum but with one or two polar granules | 23 × 16 | 15–72 |
| <i>E. meleagrimitis</i> | Subspherical, smooth, colourless with no micropyle or oocyst residuum, but with one to three polar granules | 19 × 16 | 24–72 |
| <i>E. gallapovonis</i> | Ellipsoidal, smooth, colourless without a micropyle or oocyst residuum, but with one polar granule | 27 × 17 | 24 |
| <i>E. innocua</i> | Subspherical, smooth, without a micropyle or polar granules | 22 × 21 | 48 |
| <i>E. subrotunda</i> | Subspherical, smooth, without a micropyle or polar granules | 22 × 21 | 48 |

Modified Ziehl–Neelsen method for *Cryptosporidium*

- Place one drop of saline in the centre of a clean slide (slide washed in methylated spirit and air dried).
- Add a small sample of faeces and emulsify the sample in the saline by thorough mixing. For liquid faeces dispense one drop directly onto the slide.
- Smear faeces on the slide in a wavy pattern to ensure there are thick and thin areas.
- Either fix the smear by passing through a Bunsen flame twice, or alternatively air-dry at room temperature and then fix in methanol for 3 minutes.
- Immerse the slide in 3% carbol-fuchsin and stain for 15 minutes (use either a Coplin jar or staining tray).
- Rinse the slide thoroughly in tap water.
- Decolorise in 1% acid methanol for 15–20 seconds.
- Rinse the slide in tap water.
- Counterstain with 0.4% malachite green for 30 seconds.
- Rinse the slide in tap water.
- Air-dry the slide and examine using the ×40 objective lens of a bright-field microscope.
- To aid identification of oocysts, the smear can be examined under the oil immersion objective lens.
- Examine the size and shape of the red-stained bodies. *Cryptosporidium* spp. oocysts stain red on a pale green background (Fig 4.39). The degree and proportion of staining varies with individual oocysts. In addition, the internal structures take up the stain to varying degrees. Some may appear amorphous while others may contain the characteristic crescentic forms of the sporozoites.
- Oocysts of *Cryptosporidium parvum* are 4–6 µm in diameter.

- Yeasts and faecal debris stain a dull red. Some bacterial spores may also stain red, but these are too small to cause confusion.
- A semi-quantitative scoring system can be used based on numbers of oocysts seen. Most clinical infections in calves score 3+ to 4+.

EXAMINATION OF BLOOD AND LYMPH

Thin blood smears stained with Romanowsky dyes, such as Giemsa or Leishmann, and examined under an oil immersion lens are commonly used for the detection of trypanosomes, babesial and theilerial piroplasms, and rickettsial infections such as anaplasmosis, ehrlichiosis and eperythrozoonosis.

**Fig. 4.39** *Cryptosporidium* oocysts (Ziehl–Neelsen stain).

On other occasions, needle biopsies of enlarged lymph nodes may be similarly stained for the detection of trypanosomes (especially *Trypanosoma brucei* or *T. vivax*) or theilerial meronts.

Giemsa method

- 1 Make a thin blood smear and allow to dry.
- 2 Fix the blood smear with methanol for 2 minutes.
- 3 Stain smear with 15% Giemsa (in buffered distilled water, pH 7.2) for 45 minutes.
- 4 Rinse the smear under a gentle stream of cold water, drain and allow to air-dry.
- 5 View under oil using the $\times 100$ objective lens.

Diff-Quick method

- 1 Make thin blood smear and allow to dry.
- 2 Fix the blood smear with methanol for 2 minutes.
- 3 Stain as follows: dip the smear into a container of stain A (orange colour) 15 times, each dip lasting 1 second; immediately switch to stain B (blue colour) and carry out 15 dips, for 1 second each again. (See Chemicals and Solutions at the end of the Chapter for stains details)
- 4 Rinse the smear under a gentle stream of cold water to clean the slide, drain, wipe excess moisture from the back of the slide and allow to air-dry.
- 5 View under oil using the $\times 100$ objective lens.

In trypanosomiosis, the parasitaemia may be light and the chance of a positive diagnosis is increased if a thick blood film, dehaemoglobinised by immersing the slide in water before eosin staining, is used. For this a drop of fresh blood, with no added anticoagulant, is gently stirred on a slide to cover an area of about 10 mm diameter and allowed to dry. Subsequently it may be stained by Field's technique as follows.

Field's technique

See section Chemicals and Solutions at the end of this chapter for details of the solutions.

- 1 Dip slide in solution A for 1–3 seconds.
- 2 Rinse in solution B for 2–3 seconds.
- 3 Dip slide in C for 1–3 seconds.
- 4 Rinse in tap water for 2–3 seconds.
- 5 Stand upright to drain and dry.

This technique is commonly used in large-scale survey work in the field.

A particularly efficient diagnostic technique for trypanosomiosis, described earlier in the text, is the examination, under dark-ground illumination, of the expressed buffy coat of a microhaematocrit tube for the detection of motile trypanosomes.

The inoculation of mice with fresh blood from suspected cases of *Trypanosoma congolense* or *T. brucei* infection is another common technique practised in the field. Three days later the tail blood of such mice should be examined and subsequently daily thereafter for about 3–4 weeks to establish if trypanosomes are present.

The detection of specific antibody in a specialist laboratory may also be useful in the diagnosis of several protozoal diseases such as theileriosis, trypanosomiosis (including *T. cruzi* infection),

babesiosis, cryptosporidiosis, and rickettsial infections such as anaplasmosis and ehrlichiosis. However, a positive result does not necessarily imply the presence of a still active infection, but simply that the animal has at some time been exposed to the pathogen. An exception to this interpretation is the diagnosis of suspected toxoplasmosis in sheep, where rising antibody levels over a period of several weeks are reasonable evidence of recent and active infection.

EXAMINATION OF SKIN

Histological examination of skin biopsies or scrapings from the edges of skin ulcers, suspected to be due to leishmaniasis, may be used to demonstrate the amastigote parasites in the macrophages.

In dourine, caused by *Trypanosoma equiperdum*, fluid extracted from the cutaneous plaques usually offers a better chance of detecting trypanosomes than blood smears.

XENODIAGNOSIS

Finally, although not within the province of the general practitioner, the use of xenodiagnosis as a diagnostic technique should be noted. This is used to detect protozoal infections such as babesiosis, theileriosis or *Trypanosoma cruzi* infection where the parasite cannot be found easily. It involves allowing the correct intermediate host, such as a tick or a haematophagous bug, to feed on the animal. These arthropod vectors have of course to be reared in the laboratory so that they are free from infection. After feeding, the arthropod host is maintained for several weeks to allow any ingested organisms to multiply, after which it is killed and examined for evidence of infection. Although a valuable technique, especially for the detection of carrier states, the method has the disadvantage that the diagnosis may take several weeks.

ECTOPARASITES

Arthropods of veterinary interest are divided into two major groups, the Insecta and the Arachnida. Most are temporary or permanent ectoparasites, found either in or on the skin, with the exception of some flies whose larval stages may be found in the somatic tissues of the host. Parasitic insects include flies, lice and fleas, while the two groups of arachnids of veterinary importance are the ticks and mites. In all cases, diagnosis of infection depends on the collection and identification of the parasite(s) concerned.

INSECTS

Flies

Adult dipteran flies visiting animals are usually caught either by netting or after being killed by insecticides. Flying insects can be caught with a hand net but the technique depends on the behaviour of the species required. Flies which settle on buildings, animals or plants are best caught with a single sweep net.

In some situations, continuous sampling may be required and flies can be caught in large numbers by means of a Manitoba-type trap consisting of a wigwam held 1 m above the ground and below

which is suspended a black or red sphere over a slow release of carbon dioxide from a box containing dry ice ('cardice') blocks or pellets. Flies which feed or oviposit on carrion or dung can be caught in baited light traps.

Insect larvae may be collected in areas where animals are housed or directly from animals where the larval stages are parasitic. Special methods are useful in certain cases; warble fly larvae, for example, may be obtained by carefully squeezing from the live animal or from fresh skins at an abattoir. Where insects (or mites) have developmental stages in soil, woodland litter or faeces, various modifications of the Berlese funnel may be used. This consists of a metal funnel with a perforated screen tray inside carrying the litter sample. The funnel is heated and, owing to their increased activity, insect larvae, mites and other arthropods fall through the screen tray into a container. The technique may be more simply adapted to large field samples (e.g. turf or manure) by placing these in wire trays over water. An electric lamp positioned a few centimetres above the tray then provides light and warmth and repels moving arthropods, which again drop through the wire tray into the water.

Identification of the common flies of veterinary interest, at least to generic level, is fairly simple, the key characters being described in the guide below. Identification of larvae to generic and species level is rather more specialised and depends on examination of certain features such as the structure of the posterior spiracles. Publications dealing with this may be found in the References and further reading section.

Guide to the families of adult Diptera of veterinary importance

- 1 Insects with one pair of wings on the mesothorax and a pair of club-like halteres on the metathorax..... 2
Wingless insects; may be with or without halteres; body clearly divided into head, thorax and abdomen; three pairs of legs; dorsoventrally flattened; brown in colour; 5–8 mm in length; resident on sheep, horses, deer, goats or wild birds (Fig. 4.40)..... 5
- 2 Antennae composed of three segments; third segment usually with an arista; foot with two pads (Fig. 4.41).....
.....**Brachycera (Cyclorrhapha) 3**
Antennae composed of three sections; third antennal section enlarged and composed of four to eight segments; palps two-jointed with the second segment enlarged; foot with three pads; vein R_{4+5} forks to form a large 'Y' across the wing tip (Fig. 4.42); large stout-bodied flies with large eyes **Tabanidae 12**

Fig. 4.40 Adult sheep ked, *Melophagus ovinus*.

- Antennae long, slender and composed of many articulating segments; palps composed of four to five segments; small slender flies with long narrow wings..... **Nematocera 13**
- 3 Frons with ptilinal suture (Fig. 4.43)..... Series **Schizophora 4**
 - 4 Second antennal segment usually with a groove (Fig. 4.43); thoracic transverse suture strong (Fig. 4.44); thoracic squamae usually well developed (Fig. 4.45)..... **Calypterae 5**
Second antennal segment usually without a groove; thoracic transverse suture weak; thoracic squamae often vestigial..... **Acalypterae**
 - 5 Thorax broad and dorsoventrally flattened; may appear spider or tick-like; often wingless (Fig. 4.39); wings when present with venation abnormal, with veins crowded into leading half of wing **Hippoboscidae**
Wings with veins not crowded together towards the leading edge; thorax not dorsoventrally flattened..... 6
 - 6 Proboscis long, forwardly directed and embraced by long palps; arista with feathery short hairs present only on dorsal side; discal medial cell of wings characteristically hatchet-shaped (Fig. 4.46); found only in sub-Saharan Africa..... **Glossinidae**
Discal medial cell of wings widening gradually and more or less regularly from the base 7
 - 7 Mouthparts small, usually functionless; head bulbous; antennae small; flies more or less covered with soft hair; larval parasites of vertebrates..... **Oestridae**
Mouthparts usually well developed; antennae not small; flies with strong bristles 8
 - 8 Hypopleural bristles present (Fig. 4.44b) 9
Hypopleural bristles absent..... 11
 - 9 Post-scutellum strongly developed; larval parasitoids of insects..... **Tachinidae 3**
Post-scutellum weak or absent 10
 - 10 Dull grey appearance; three black stripes on the scutum; abdomen usually with chequered or spotted pattern (Fig. 4.47); larval parasites of vertebrates..... **Sarcophagidae**
Metallic, iridescent appearance (blue–black, violet–blue, green); larval parasites of vertebrates..... **Calliphoridae**
 - 11 Wings with vein A_1 not reaching the wing edge; strong curved A_2 vein the tip of which approaches A_1 (Fig. 4.48); arista bare **Fanniidae**
Wings with vein A_1 not reaching the wing edge; A_2 vein not strongly curved (Fig. 4.49); arista bilaterally plumose to the tip..... **Muscidae**
 - 12 Antennal flagellum with four segments (Fig. 4.42b); wings mottled; proboscis shorter than head..... **Haematopota (Tabanidae)**

Fig. 4.41 Variations in the antennae found in the three suborders of Diptera.

Fig. 4.47 (a) Adult of the flesh fly *Sarcophaga carnaria* (from Castellani and Chalmers, 1910). (b) *Wohlfahrtia magnifica*, abdomen of adult (from Smart, 1943).

Fig. 4.48 Wing venation typical of species of *Fannia* showing the characteristic convergence of the anal veins.

Antennal flagellum with five segments (Fig. 4.42a); apical spurs on tibiae are small and may be hidden by hair; wings usually with costal region dark and a single dark broad transverse band; proboscis shorter than head ***Chrysops* (Tabanidae)**

Antennal flagellum with five segments (Fig. 4.42c); no apical spurs on hind tibiae; wings usually clear but may be dark or banded; proboscis shorter than head ***Tabanus* (Tabanidae)**

- 13 Small, hairy, moth-like flies; numerous parallel wing veins running to the margin; wings pointed at the tip **Psychodidae** 14
Not like this 15
- 14 Palps five-segmented; biting mouthparts at least as long as head; antennal segments almost cylindrical; two longitudinal wing veins between radial and medial forks (Fig. 4.50) **Phlebotominae** 15
- 15 Ten or more veins reaching the wing margin 16
Not more than eight veins reaching the wing margin 17
- 16 Wing veins and hind margins of wings covered by scales (Fig. 4.51); conspicuous forward-projecting proboscis **Culicidae** 17
- 17 Wings broad; wing veins thickened at the anterior margin; antennae not hairy; thorax humped; antennae usually with 11 rounded segments; palps long with five segments extending beyond the proboscis; first abdominal tergite with a prominent basal scale fringed with hairs (Fig. 4.52) **Simuliidae** 18
Wings not particularly broad, antennae hairy 18
- 18 Front legs often longer than others; median vein not forked (non-biting midges) **Chironomidae** 19
Front legs not longer than others; wings with median vein forked; antennae with 14–15 visible segments; palps with five segments; female mouthparts short; legs short and stout; two radial cells and cross vein r-m strongly angled in relation to media; at rest wings close flat over abdomen (Fig. 4.53) **Culicoides (Ceratopogonidae)** 20

Guide to third-stage larvae causing myiasis in domestic animals

The guide to larvae presented below applies specifically to recognition of the third stage. This stage is usually of the longest duration and, since the larvae are approaching their maximum size or are beginning to wander, is usually the stage when they are most commonly observed. It should be noted that because the external structure of larvae may change over the course of their growth and development, first- and second-stage larvae may not key out appropriately.

- 1 Body more or less cylindrical; no obvious head capsule 2
Fly larvae with an obvious head capsule; rarely found associated with livestock myiasis **Diptera, Nematocera or Brachycera**
- 2 Body with obvious fleshy processes 3
Body without fleshy processes 4

Fig. 4.49 (a) Female house fly, *Musca domestica*. (b) Wing venation typical of species of *Musca* showing the strongly bent vein M ending close to R₄₊₅. (Adapted from Smart, 1943.)

- 3 Third-stage larvae large, up to 18 mm long; large, pointed fleshy processes laterally and dorsally (Fig. 4.54); posterior spiracular plate without button (Fig. 4.55); peritremes with a narrow opening; in carrion or secondarily in cutaneous myiasis of sheep; distribution: Afro-tropical, Australasian and Oriental ***Chrysomya albiceps* and *C. rufifacies* (Calliphoridae)** 3
Third-stage larvae 7–8 mm in length; body flattened, with long processes (Fig. 4.56); posterior spiracles on short stalks on terminal segment; uncommon in livestock myiasis ... **Fanniidae** 4
- 4 Posterior spiracles with a large number of small pores or many short intertwining slits arranged in three groups on each spiracular plate (e.g. Fig. 4.57) 5
Posterior spiracles with up to three straight or curved slits (e.g. Fig. 4.58) 7
- 5 Mouth hooks well developed, strongly hooked 6
Mouth hooks poorly developed; third-stage larvae 20–30 mm in length (Fig. 4.59); in subcutaneous swellings or warbles; on cattle or deer ***Hypoderma* spp. (Oestridae)** 6
- 6 Body with weak spines in distinct regions; posterior spiracles with many small pores (Fig. 4.57); in nasal myiasis of sheep; distribution worldwide ***Oestrus ovis* (Oestridae)** 6
Body spines stronger and more evenly distributed; posterior spiracles with many small slits; found in dermal myiasis; in rodents and rabbits; distribution: New World ... ***Cuterebra* spp. (Oestridae)** 7
- 7 Posterior spiracles with straight or arced slits 8
Posterior spiracles with serpentine slits; anterior spiracles in the form of membranous stalks bearing finger-like processes; body with obvious spines; furuncular myiasis of dogs, rats and humans; distribution: sub-Saharan Africa ***Cordylobia* spp. (Calliphoridae)** 8
Posterior spiracles with serpentine slits (Fig. 4.60); anterior spiracles not as above; uncommon in livestock myiasis **Muscidae** 9
- 8 Posterior spiracles sunk in a deep cavity which may conceal them (Fig. 4.61); slits more or less parallel 9
Posterior spiracles visible, either exposed on surface or set in a ring of tubercles 11
- 9 Body with strong spines 10
Body with short spines; obligate agent of cutaneous myiasis; primarily in sheep and goats; distribution worldwide ***Wohlfahrtia* spp. (Sarcophagidae)** 10

Fig. 4.50 (a) Adult female sandfly, *Phlebotomus papatasi*. (b) Wing venation typical of species of *Phlebotomus* (Psychodidae). (From Smart, 1943.)

Fig. 4.61 *Wohlfahrtia magnifica*: posterior spiracles deeply sunk in a cavity.

- 10 Posterior spiracles with slits bowed outwards at the middle; body oval; found in the pharynx or digestive tract of equids ***Gasterophilus* spp. (Oestridae)**
Posterior spiracles with slits relatively straight; body enlarged anteriorly and tapering posteriorly (Fig. 4.62); distribution: New World..... ***Dermatobia hominis*. (Oestridae)**
- 11 Posterior spiracles with straight slits 12
Posterior spiracles with arced slits; uncommon in livestock myiasis **Muscidae**
- 12 Posterior spiracles with a fully closed peritremal ring (Fig. 4.63) 13
Posterior spiracles with an open peritremal ring (Fig. 4.64) 14
- 13 Cephalopharyngeal skeleton with pigmented accessory oral sclerite (Fig. 4.65b); distribution worldwide ***Calliphora* spp. (Calliphoridae)**
Cephalopharyngeal skeleton without pigmented accessory oral sclerite (Fig. 4.65a); distribution worldwide..... ***Lucilia* spp. (Calliphoridae)**
- 14 Tracheal trunks leading from posterior spiracles without dark pigmentation 15
Tracheal trunks leading from posterior spiracles with conspicuous dark pigmentation extending forwards as far as segment 9 or 10 (Fig. 4.64); obligate primary agent of traumatic livestock myiasis; distribution: Neotropical and Nearctic..... ***Cochliomyia hominivorax* (Calliphoridae)**
- 15 Posterior margin of segment 11 with dorsal spines 16
Posterior margin of segment 11 without dorsal spines; a secondary facultative agent of cutaneous livestock myiasis; distribution: Neotropical and Nearctic ***Cochliomyia macellaria* (Calliphoridae)**
- 16 Posterior spiracles with distinct button 18
Posterior spiracles without distinct button 17
- 17 Body without fleshy processes; segments with belts of strongly developed spines (Fig. 4.58); anterior spiracle with four to six branches; an obligate primary agent of cutaneous livestock myiasis; distribution: Afro-tropical and Oriental ***Chrysomya bezziana* (Calliphoridae)**
Anterior spiracle with 11–13 branches; largely saprophagous; an occasional facultative ectoparasite causing cutaneous myiasis; distribution: Oriental and Australasian..... ***Chrysomya megacephala* (Calliphoridae)**
- 18 Posterior margins of segment 10 with dorsal spines; length of the larger tubercles on upper margin of posterior face of terminal segment greater than half the width of a posterior spiracle; causes facultative cutaneous myiasis of cattle, sheep and reindeer (Fig. 4.66a); distribution: northern Holarctic..... ***Protophormia terraenovae* (Calliphoridae)**
Posterior margins of segment 10 without dorsal spines; length of the larger tubercles on upper margin of posterior face of terminal segment less than half the width of a posterior spiracle (Fig. 4.66b); distribution: Holarctic..... ***Phormia regina* (Calliphoridae)**

Guide to the adult Diptera causing myiasis in domestic animals

- 1 Insects with one pair of wings on the mesothorax and a pair of club-like halteres on the metathorax (Fig. 4.44); antennae composed of three segments, third segment usually with an arista (Fig. 4.43); foot with two pads; frons with ptilinal suture;

- second antennal segment usually with a groove; thoracic transverse suture strong; thoracic squamae usually well developed (Fig. 4.45) **Calyptrate Diptera 2**
- 2 Mouthparts small, usually functionless; head bulbous; antennae small; flies more or less covered with soft hair 3
Mouthparts usually well developed; antennae not small; flies with strong bristles; hypopleural bristles present (Fig. 4.44); post-scutellum weak or absent..... 7
- 3 Vein M bent towards vein R_{4+5} 4
Vein M not bent towards vein R_{4+5} ; squamae small; cross-vein dm-cu absent; ovipositor strongly developed in female (Fig. 4.67) ***Gasterophilinae* spp. (Oestridae)**
- 4 Sharp bend of vein M towards vein R_{4+5} but the two do not meet before the margin 5
Vein M joins vein R_{4+5} before the margin; vein dm-cu in line with deflection of vein M; vein A_1+CuA_2 does not reach the margin (Fig. 4.68); frons enlarged; frons, scutellum and dorsal thorax bear small wart-like protruberances; eyes small; abdomen brownish black **Oestrinae spp. (Oestridae)**
- 5 Blue–black colour **Cuterebrinae spp.**
Not blue–black 6
- 6 Vein A_1+CuA_2 reaches the margin; vein dm-cu in line with deflection of vein M (Fig. 4.69); hairy bee-like flies with a light–dark colour pattern; fan of yellow hypopleural hairs; palps absent..... **Hypodermatinae spp. (Oestridae)**
- 7 Metallic, iridescent appearance (blue–black, violet–blue, green) 8
Dull grey appearance; three black stripes on the scutum; abdomen usually with chequered or spotted pattern..... 13
Flies of predominantly reddish-yellow or reddish-brown colour, not metallic; distribution: tropical Africa..... ***Cordylobia* spp. (Calliphoridae)**
- 8 Wing with stem vein (base of R) entirely bare (Fig. 4.45) 9
Wing with stem vein with fine hairs along margin 10
- 9 Flies with metallic green or coppery green thorax and abdomen (see Fig. 17.6b); thoracic squamae bare; found in cutaneous myiasis, particularly of sheep; distribution worldwide..... ***Lucilia* spp. (Calliphoridae)**
Flies with black–blue thorax and blue or brown abdomen (see Fig. 17.6a); thoracic squamae with long dark hair on upper surface; may be secondary invaders of cutaneous myiasis; distribution worldwide..... ***Calliphora* spp. (Calliphoridae)**
- 10 Head with almost entirely black ground colour and black hair; thoracic squamae bare; alar squamae hairy on outer half or dorsal surface..... 12
Head with ground colour of at least lower half entirely or mainly orange or orange–red and with white, yellow or orange hair; thoracic squamae bare on dorsal surface..... 11
- 11 Thoracic squamae hairy on whole dorsal surface; scutum of thorax without bold black stripes (see Fig. 4.36); distribution: Afro-tropical, Oriental, Australasian, southern Palaearctic ***Chrysomya* spp. (Calliphoridae)**
Thoracic squamae hairy only at the base, usually concealed by the alar squamae; scutum of thorax with three bold black stripes (see Fig. 4.6d); distribution: Nearctic and Neotropical..... ***Cochliomyia* spp. (Calliphoridae)**
- 12 Thorax with anterior spiracle black or reddish-brown; alar squamae with obvious dark hair dorsally; distribution: Palaearctic and Nearctic only ***Protophormia* spp. (Calliphoridae)**

Fig. 4.68 (a) Adult female *Oestrus ovis* and (b) wing venation typical of *Oestrus* showing the strongly bent vein M joining R₄₊₅ before the wing margin. (From Castellani and Chalmers, 1910.)

Fig. 4.69 (a) Adult female of *Hypoderma bovis* (from Castellani and Chalmers, 1910). (b) Wing venation typical of *Hypoderma* showing the strongly bent vein M not joining R₄₊₅ before the wing margin and vein A₁+CuA₂ reaching the wing margin.

Thorax with anterior spiracle yellow or orange; thoracic squamae with white–yellow hair dorsally; distribution: Palearctic and Nearctic only ***Phormia* spp. (Calliphoridae)**

- 13** Arista almost bare; abdomen with pattern of black spots (Fig. 4.47b) ***Wohlfahrtia* spp. (Sarcophagidae)**
 Arista with long and conspicuous hairs, at least on the basal half; abdomen with dark and light chequered pattern (Fig. 4.47a) ***Sarcophaga* spp. (Sarcophagidae)**

Lice and fleas

The detection of small ectoparasites such as lice and fleas depends on close examination; in the case of lice, the eggs, commonly known as ‘nits’, may also be found attached to the hair or feathers. Fleas may be more difficult to detect, but the finding of flea faeces in the coat, which appear as small dark pieces of grit and which, on contact with moist cottonwool or tissue, produce a red coloration due to ingested blood, allow confirmation of infection. Collection may be straightforward as in the case of many lice, which may be brushed from the

coat or removed by clipping hairs or feathers. Fleas may be removed by brushing or vacuum cleaning. Alternatively, in the case of small animals, the parasites may be readily recovered if the host is placed on a sheet of paper or plastic before being sprayed with an insecticide.

The gross characteristics of biting and sucking lice, and a key to the fleas commonly found on domestic animals are described in the following sections.

Guide to the recognition of common lice of veterinary importance

The identification of lice is complex and the features used to describe many genera are obscure. However, because lice in general are highly host-specific, in many cases information relating to the species of host and the site of infestation will provide a reliable initial guide to identification. The various species of lice are usually found in all geographical regions of the world in which their host occurs.

- 1** Head broad, equal or almost equal in width to abdomen **2**
 Head elongated, much narrower than abdomen **12**
- 2** Antennae hidden in antennal grooves; antennae four-segmented; maxillary palps present **Amblycera 3**
 Antennae not hidden in grooves; antennae three- to five-segmented; maxillary palps absent **Ischnocera 6**
- 3** On birds **4**
 On mammals **5**
- 4** Small lice, adults about 2 mm in length; abdomen with sparse covering of medium-length setae (Fig. 4.70); found on thigh or breast feathers; on birds, especially poultry ***Menopon* spp. (Menoponidae)**
 Large lice, adults about 3.5 mm in length; abdomen with dense covering of medium-length setae (Fig. 4.71); found on the breast, thighs and around vent; on birds, especially poultry ***Menacanthus* spp. (Menoponidae)**
- 5** On guinea pigs; oval abdomen, broad in middle; six pairs of abdominal spiracles are located ventrolaterally within poorly defined spiracular plates (Fig. 4.72) ***Gyropus* spp. (Gyropidae)**
 On guinea pigs; slender body, with sides of the abdomen parallel; five pairs of abdominal spiracles located ventrally within distinct sclerotised spiracular plates (Fig. 4.73) ***Gliricola* spp. (Gyropidae)**
 On dogs; relatively large, adults about 3 mm in length; abdomen with a dense covering of thick, medium and long setae (Fig. 4.74) ***Heterodoxus* spp. (Boopidae)**
- 6** On birds; antennae five-segmented; tarsi with paired claws **Philopteridae 7**
 On mammals; antennae three-segmented; tarsi with single claws **Trichodectidae 10**
- 7** Hindlegs similar in length to first two pairs **8**
 Hindlegs at least twice as long as first two pairs; body long and narrow; head with small narrow projections in front of antennae; first segment of antennae considerably longer than following four segments (Fig. 4.75); on poultry; distribution, worldwide ***Lipeurus* (Philopteridae)**
- 8** Three long bristles projecting from each side of the dorsal surface of the head; rounded body; adult about 2 mm in length (Fig. 4.76); on poultry ***Cuclotogaster* (Philopteridae)**
 Two long bristles projecting from each side of the dorsal surface of the head **9**
- 9** Head with prominent angles and a distinct hollow margin posterior to the antennae; adult about 5 mm in length (Fig. 4.77); on poultry ***Goniodes* spp. (Philopteridae)**

Fig. 4.70 Adult *Menopon gallinae* (dorsal view).

- Head lacking prominent angles; adult about 2 mm in length (Fig. 4.78); on poultry ***Goniocotes* (Philopteridae)**
- 10 Head rounded anteriorly..... 11
 Head sharply angled anteriorly; legs small; abdomen smooth, with only three pairs of spiracles (Fig. 4.79); on cats ***Felicola* spp. (Trichodectidae)**
- 11 Setae of abdomen large and thick (Fig. 4.80); on dogs..... ***Trichodectes* spp. (Trichodectidae)**
 Setae of abdomen small or of medium length (Fig. 4.81); on mammals..... ***Bovicola* spp. (Trichodectidae)**
- 12 Distinct ocular points present behind the antennae; all legs of similar size; adult up to 5 mm in length; distinct paratergal plates visible on abdominal segments; ventral surface of the thorax with a dark coloured plate (Fig. 4.82)..... ***Haematopinus* spp. (Haematopinidae)**

- No ocular points behind the antennae; forelegs small 13
- 13 Two rows of ventral setae on each abdominal segment..... 14
 One row of ventral setae on each abdominal segment; paratergal plates absent; spiracles on tubercles which protrude from the abdomen; distinct five-sided sternal plate on the ventral surface of the thorax (Fig. 4.83); on cattle..... ***Solenopotes* spp. (Linognathidae)**
- 14 Paratergal plates absent; ventral sternal plate of thorax is narrow or absent (Fig. 4.84); on cattle, sheep, goats and dogs..... ***Linognathus* spp. (Linognathidae)**
 Paratergal plates present; ovoid sternal plate on the ventral surface of the thorax (Fig. 4.85); on rodents ***Polyplax* spp. (Polyplacidae)**

Fig. 4.84 Dorsal view of adult female *Linognathus*. (From Séguy, 1944.)

Fig. 4.85 Adult female *Polyplax* in dorsal view.

Guide to the flea species of veterinary importance

The physical differences between flea species and even between families tend to be small and there may be considerable variation between individuals within a species. Identification is therefore often difficult. The following is a general diagnostic guide to the adults of the most common species of veterinary importance found as parasites on domestic and companion animals.

- 1 Ctenidia absent..... 2
Ctenidium present, at least on the pronotum..... 4
- 2 Pleural ridge absent 3
Pleural ridge present *Xenopsylla cheopis*
- 3 Frons sharply angled (Fig. 4.86); head behind the antenna with two setae and, in the female, usually with a well-developed occipital lobe; the maxillary laciniae are broad and coarsely serrated; adult females embedded in the skin in aggregations on bare areas; found on birds, especially poultry, also on cats, dogs, rabbits and humans *Echidnophaga gallinacea*
Frons smoothly rounded; head behind antennae with only one strong seta; conspicuous ocular seta below the eye; a single, much reduced spine on the genal margin (Fig. 4.87); on pigs, badgers, humans *Pulex irritans*
- 4 Genal ctenidium present..... 5
Genal ctenidium absent; pronotal ctenidium with 18–20 spines; head with a row of three strong setae below the eye (Fig. 4.88); frontal tubercle on head of both sexes conspicuous; three to four conspicuous bristles on the inner surface of the hind femur; on rodents *Nosopsyllus fasciatus*
Genal ctenidium absent; pronotal ctenidium with more than 24 spines; head with a row of three strong setae below the eye (Fig. 4.89); on poultry *Ceratophyllus* spp.
- 5 Genal ctenidium formed of eight or nine spines oriented vertically..... 6
Genal ctenidium with four to six oblique spines; frontal tubercle conspicuous on head of both sexes (Fig. 4.90); on rabbits *Spilopsyllus cuniculi*
Genal ctenidium with three very short oblique spines; single vestigial spine on the genal lobe; single short pronotal spine (Fig. 4.91); on hedgehogs, dogs and cats *Archaeopsylla erinacei*

- 6 Head strongly convex anteriorly in both sexes and not noticeably elongate; hind tibia with eight seta-bearing notches along the dorsal margin (Fig. 4.92); on cats and dogs *Ctenocephalides canis*
Head not strongly convex anteriorly and distinctly elongate, especially in the female; hind tibia with six seta-bearing notches along the dorsal margin (Fig. 4.93); on cats and dogs..... *Ctenocephalides felis*

TICKS AND MITES

Ticks and mites belong to the class Arachnida, subclass **Acari** (sometimes also called Acarina).

Guide to the suborders of Acari

- 1 Hypostome of the gnathosoma without backwardly directed barbs. Stigmata present or absent; when present not opening on stigmatal plates; if stigmata lateral to coxae 2 and 3 then with peritremes. Tarsi of first pair of legs without sensory pit 2
Hypostome of the gnathosoma with backwardly directed barbs. Stigmatal shields present behind coxae of the fourth pair of legs or laterally above the coxae of legs 2 or 3; stigmata without peritremes. Tarsi of the first pair of legs with a sensory pit **Ixodida (Metastigmata)**
- 2 Idiosoma without conspicuous shields. Legs with coxae fused to body wall. Palps without an apotele 3
Idiosoma with sclerotised areas forming distinct shields (darkened brown colour). Legs with free coxae articulated to the idiosoma. Palps with an apotele **Gamesid mites (Mesostigmata)**
- 3 Stigmata absent. Palps small, inconspicuous and pressed against the sides of the hypostome. Legs usually with three claws and with a complex pulvillus (varying from pad-like to trumpet like). Body never worm-like..... **Sarcoptiformes (Astigmata)**
Palps usually well developed. Chelicerae usually adapted for piercing, sometimes pincer-like. Legs with one or two claws, without a complex pulvillus. Body sometimes worm-like. Stigmata present or absent; when present positioned between the bases of the chelicerae or on the upper surface of the propodosoma..... **Trombidiformes (Prostigmata)**

Fig. 4.86 The sticktight flea, *Echinophaga gallinacea*: female head and thorax (arrow marks angulation of the frons). (Adapted from Smart, 1943.)

Fig. 4.93 The cat flea, *Ctenocephalides felis felis*: (a) front of male head; (b) female head and pronotum; (c) hind tibia.

Ticks

Feeding or engorged ticks of all three stages (larva, nymph, adult) can be collected by carefully removing them from the host. Care should be taken in their removal since their mouthparts are usually firmly embedded in the skin. A useful method is to grip the capitulum firmly, but lightly, by means of forceps, turn the tick over on to its back and then pull out sharply, perpendicularly away from the skin. The tick may be persuaded to withdraw its mouthparts if a piece of cotton wool, soaked in anaesthetic, is placed around it or, alternatively, if something hot is held near its body. On sheep or cattle, the ticks are often found in the axillary and inguinal regions and on the neck or brisket.

One of the simplest methods used to recover ticks from pasture is to drag a blanket over the ground to which the unfed ticks become attached as they would to a host. Every 45 m the drag should be turned over and examined for ticks. A white or cream-coloured drag is preferred to a darker colour for easier finding of the ticks on the material. Ticks to be kept alive for rearing should be confined in a moisture-saturated atmosphere. A small plug of damp cottonwool, placed in a vial with the ticks, serves this purpose. Ticks, even in a tube half full of water, can survive periods of up to 48 hours.

Guide to the ticks of veterinary importance

Specific identification of the large variety of ticks which parasitise domestic animals is a specialised task. The guide presented here and the species descriptions given in the following pages are intended as a general guide to the ticks of veterinary interest only. Specialist texts are required for more detailed descriptions of species and their immature stages.

- 1 Hypostome with backwardly directed barbs; stigmatal shields present behind coxae of the fourth pair of legs or laterally above the coxae of legs 2 or 3; stigmata without peritremes; tarsi of the first pair of legs with a sensory pit..... **Metastigmata (Ixodida)**

Gnathosoma projecting anteriorly and visible when specimen seen from above; scutum present, covering the dorsal surface completely (male) or the anterior portion only (female); stigmatal plates large, situated posteriorly to the coxae of the fourth pair of legs (Figs 4.94 and 4.95)..... **Ixodidae 2**

Gnathosoma ventral and not visible when adult is viewed from above; scutum absent; dorsal integument leathery; stigmatal plates small, situated anteriorly to the coxae of the fourth pair of legs; eyes, if present, in lateral folds..... **Argasidae 11**

- 2 Anal groove surrounding the anus distinct, both anteriorly and posteriorly (Figs 4.94 and 4.95)..... Ixodes
 - Anal groove entirely posterior to the anus..... 3
- 3 Eyes absent..... 4
 - Eyes present..... 5
- 4 Palps short and broad, about twice as wide as segment 2 with obvious outer angulation at the base (Figs 4.96g and 4.97)..... **Haemaphysalis**
- 5 Palps wider than long or, at most, only slightly longer than their width..... 6
 - Palps much longer than wide..... 10
- 6 Basis capituli usually hexagonal dorsally (Fig. 4.96); medium-sized or small ticks, usually without colour patterns..... 7

Fig. 4.94 Ventral view of a generalised male ixodid tick.

Fig. 4.95 Dorsal view of a generalised female ixodid tick.

Fig. 4.96 Diagrammatic dorsal view of the gnathosoma of seven genera of ixodid ticks: (a) *Ixodes*; (b) *Hyalomma*; (c) *Dermacentor*; (d) *Amblyomma*; (e) *Rhipicephalus* (*Boophilus*); (f) *Rhipicephalus*; (g) *Haemaphysalis*. (From Smart, 1943).

- Basis capituli rectangular dorsally (Fig. 4.96c); large ticks with definite colour patterns (Fig. 4.98) ***Dermacentor***
- 7 Festoons absent; stigmatal plates round or oval; anal groove faint or obsolete **8**
- Festoons present; stigmatal plate with a tail-like protrusion; anal groove distinct **9**
- 8 Palps with dorsal and lateral ridges; male with normal legs ***Rhipicephalus (Boophilus)***
- 9 Basis capituli without pronounced lateral angles (Fig. 4.96f); males with ventral plates; males with coxae of fourth pair of legs normal (Fig. 4.99d) ***Rhipicephalus***
- 10 Palps with second segment less than twice as long as third segment (Fig. 4.96b); scutum without pattern ***Hyalomma***

- Palps with second segment more than twice as long as third segment (Fig. 4.96d); scutum with pattern; male without ventral plates ***Amblyomma***
- 11 Body periphery undifferentiated, without a definite suture distinguishing the dorsal from ventral surface **12**
- Body surface flattened and usually structurally different from the dorsal surface, with a definite suture distinguishing dorsal and ventral surface (Fig. 4.100) ***Argas***
- 12 Adult integument is granular; hypostome vestigial; nymphal integument spiny; hypostome well developed ***Otobius***
- Adult and nymph integument leathery (Fig. 4.101); hypostome well developed ***Ornithodoros***

Mites

Free-living mites often found on animal hair usually originate from food, or dust from animal accommodation. The mites can be seen under the low power of the microscope and can be recovered by a suitable sieving technique as described for insects.

For parasitic mites present on the animal, visual examination of the hair, or fleece, may reveal the larger mites such as *Psoroptes*, but in most cases it is necessary to take scrapings for examination in the laboratory. An indication of the presence of mites is the reaction of the host to scratching or rubbing of the affected skin by the operator: it responds by nibbling the tongue or scratching itself. Scrapings are taken from the affected areas. The area selected for scraping should be at the edge of a visible lesion and the hair over this area should be clipped away. The presence of unnecessary hair is an encumbrance but on occasions it may be useful to examine this for mites or other parasites. The area of skin selected should be the moist part, or edge of the lesion. In sarcoptic mange, the scrapings should be taken from the edge of a hairless area or where pruritis or pimples are seen. A drop of lubricating oil such as liquid paraffin is placed on a microscope slide and a clean scalpel blade dipped in the oil before using it to scrape the surface of a fold of affected skin. Scraping should be continued until a slight amount of blood oozes from the skin surface and the material obtained then transferred to the oil on the slide. In animals suspected of chorioptic or psoroptic mange, a sharp scalpel should be used with the blade held at an acute angle, shaving rather than scraping off the outer epidermis together with the hair stumps. The specimen should be transferred or scraped directly into a small tube that can be securely stoppered or into a self-sealing polythene bag.

In the laboratory, scrapings are transferred to a slide, a coverslip then applied and the sample examined under low magnification ($\times 100$). If during this initial examination no mites are detected, a further sample may be heated on a slide with a drop of 10% caustic potash. After allowing this preparation to clear for 5–10 minutes, it should be re-examined.

Some non-burrowing mites such as *Otodectes* and *Cheyletiella* can be found by close examination. For example, *Otodectes* may be seen either on examination of the external auditory canal using an auroscope or on microscopic examination of ear wax removed by means of a swab; likewise, rigorous brushing of the coat and subsequent microscopic examination of this material will usually

confirm infection with *Cheyletiella*. In pustular demodectic mange, the mites are usually abundant and can be demonstrated on examination of the cheesy contents of an expressed or incised pustule. In the case of squamous lesions, a deep scraping is necessary.

Guide to the mite species and families of veterinary importance

The identification of mites can be difficult. However, since mites in general tend to be relatively host-specific, a good first practical indication of the likely identity of any species in question can be the species of host and the location of the mite on that host. The following is a general guide to the adults of the most common species and genera of ectoparasitic mites likely to be encountered. It is important to note that this guide is not comprehensive and if in doubt more specialist keys should be used.

- 1 Stigmata absent posterior to the second pair of legs..... 2
Stigmata present as one lateral pair between the bases of legs II and IV 3
- 2 Legs without claws; palps with two segments; stigmata absent..... 14
Some or all legs with claws; palps with more than two segments; stigmata present or absent, when present they open on the gnathosoma or the anterior part of the idiosoma (Fig. 4.102)..... 20
- 3 Genital plate rudimentary or absent 4
Genital plate well-defined 5
- 4 Genital plate present although rudimentary; in lungs of canary *Sternostoma tracheacolum* (**Rhinonyssidae**)
Genital plate absent; palps elongated with five segments; in nasal passage of dogs *Pneumonyssoides caninum* (**Halarachnidae**)
- 5 Chelicerae long and whip-like; chelae at tips absent or very small..... 6
Chelicerae not long and whip-like, shorter and stronger; chelae blade-like at tips 7
- 6 Dorsal surface of body with one shield; anal shield not egg-shaped and with anal opening at posterior end (Fig. 4.103); parasite of birds *Dermanyssus gallinae* (**Dermanyssidae**)

- 7 Dorsal shield not nearly covering dorsal body surface; genitoventral shield narrowed posteriorly; chelicerae with toothless chelae 8
 Dorsal shield virtually covering dorsal body surface; genitoventral shield not narrowed posteriorly; chelicerae usually with toothed chelae..... 10
- 8 Dorsal shield broad, its setae short..... 9
 Dorsal shield narrow and tapering posteriorly, its setae long; parasite of rats, mice, hamsters *Ornithonyssus bacoti* (**Macronyssidae**)
- 9 Sternal shield with two pairs of setae (Fig. 4.104); parasite of birds..... *Ornithonyssus sylviarum* (**Macronyssidae**)
 Sternal shield with three pairs of setae; parasite of birds *Ornithonyssus bursa* (**Macronyssidae**)
- 10 Genitoventral shield widened posteriorly, with more than one pair of setae..... 11
 Genitoventral shield not widened posteriorly, one pair of setae; on small rodents, weasels and moles *Hirstionyssus isabellinus* (**Laelapidae**)
- 11 Body densely covered in setae..... 12
 Body with few setae (these arranged in transverse rows)..... 13
- 12 Genitoventral shield with pear-shaped outline; on rodents..... *Haemogamasus pontiger* (**Laelapidae**)
 Genitoventral shield with large subcircular outline; on rodents..... *Eulaelaps stabularis* (**Laelapidae**)
- 13 Genitoventral shield with concave posterior margin, surrounding anterior part of anal shield; on rodents *Laelaps echidninus* (**Laelapidae**)
- 14 Legs short and stubby; genital opening of female a transverse slit paralleling body striations; dorsal striations broken by strong pointed scales; dorsal setae strong and spine-like; anus terminal (Fig. 4.105); on mammals *Sarcoptes scabiei* (**Sarcoptidae**)
 Dorsal setae not spine-like 15
 Legs not short and stubby..... 17
- 15 Anus terminal; tarsi claw-like, with terminal setae 16
 Anus dorsal; dorsal striations broken by many pointed scales; dorsal setae simple, not spine-like (Fig. 4.106); on rats and guinea pigs *Trixacarus caviae* (**Sarcoptidae**)
 Anus dorsal; dorsal striations not broken by pointed scales; dorsal setae simple, not spine-like; tarsi with long pretarsi on legs I and II (Fig. 4.107); on cats *Notoedres cati* (**Sarcoptidae**)
- 16 Dorsal striations simple, unbroken (Fig. 4.108); on poultry..... *Knemidocoptes gallinae* (**Knemidocoptidae**)
 Dorsal striations broken, forming scale-like pattern; on poultry..... *Knemidocoptes mutans* (**Knemidocoptidae**)
 Dorsal striations broken, forming scale-like pattern; on caged birds *Knemidocoptes pilae* (**Knemidocoptidae**)
- 17 Pretarsi with short stalks..... 18
 In the adult female, pretarsi of I, II and IV with three-jointed long stalks; tarsi III with two long terminal whip-like setae; legs of equal sizes; genital opening an inverted 'U'. In the adult male, pretarsi on legs I, II and III with three-jointed long stalks; long setae on legs IV which are smaller than others (Fig. 4.109); on domestic mammals *Psoroptes* spp. (**Psoroptidae**)
- 18 In the adult female, tarsi I, II and IV with short-stalked pretarsi; tarsi III with a pair of long terminal whip-like setae; legs I and II stronger than the others; legs III shortest; legs IV with long slender tarsi; genital opening almost a transverse slit. In the adult male all legs with short-stalked pretarsi; fourth pair of legs short (Fig. 4.110); on domestic animals..... *Chorioptes* spp. (**Psoroptidae**)
 Legs I and II with short-stalked pretarsi; legs III and IV with a pair of terminal whip-like setae; legs IV much reduced; genital opening transverse (Fig. 4.111); found in the ears of cats and dogs..... *Otodectes cynotis* (**Psoroptidae**)
- 19 Mouthparts not well developed, reduced; small oval nude mites; all tarsi with pretarsi (Fig. 4.112); in the tissues of birds *Cytodites nudus* (**Cytoditidae**)
 Mouthparts well developed; elongated mites; body setae long; tarsi I and II claw-like distally; tarsi III and IV with long spatulate pretarsi (Fig. 4.113); in the tissues of birds..... *Laminosioptes cysticola* (**Laminosioptidae**)
- 20 Body not unusually elongated, with setae 21
 Body unusually elongated and crocodile-like with annulations, without setae (Fig. 4.114); in skin pores of mammals..... *Demodex* spp. (**Demodicidae**)
- 21 Gnathosoma and palps conspicuous; body with feathery setae; three pairs of legs when attached to host (larval forms) (Fig. 4.115)..... species of **Trombiculidae**
 Gnathosoma and palps conspicuous; body not with feathery setae; stigma opening at base of chelicerae 22
 Gnathosoma and palps inconspicuous; body with simple non-feathery setae; not ectoparasitic..... *Pyemotes tritici* (**Pyemotidae**)
- 22 Palps with thumb-claw complex 23
 Palps without thumb-claw complex 24
- 23 Chelicerae fused with rostrum to form cone; palps opposable, with large distal claws; peritreme obvious, M-shaped on gnathosoma (Fig. 4.116)
 On rabbits..... *Cheyletiella parasitivorax* (**Cheyletiellidae**)
 On cats *Cheyletiella blakei* (**Cheyletiellidae**)
 On dogs..... *Cheyletiella yasguri* (**Cheyletiellidae**)
- 24 Legs normal, for walking 25
 First pair of legs highly modified for clasping hairs of host; body elongate, with transverse striations; on mice and rats..... **Myobidae**
 Legs I and II and tarsi IV adapted for clasping hairs (Fig. 4.117); on guinea pigs *Chirodiscoides caviae* (**Listrophoridae**)
 Legs III and IV of female modified for clasping hairs (Fig. 4.118); on mice..... *Myocoptes musculus* (**Listrophoridae**)
- 25 Small round mites with short stubby radiating legs, each with a strong hook; female with two pairs of posterior setae, male with a single pair of posterior setae (Fig. 4.119)
 On sheep..... *Psorobia ovis* (**Psorergatidae**)
 On cattle..... *Psorobia bovis* (**Psorergatidae**)

MOUNTING AND PRESERVATION

It is important that collection details (habitat, locality, date, time and identification) should be noted at the time of collection and entered on a standard label on the main pin. Large insects should be mounted correctly in an entomological storage box, and should not be left in glass or plastic tubes for more than 24–48 hours, as their condition rapidly deteriorates in humid conditions. If they are allowed to become dry in an open container, subsequent attempts to pin them will result in excessive damage and fragmentation. However, dried specimens can be relaxed to some extent by placing them in a humid atmosphere. A receptacle containing wet cork or cottonwool, with an antifungal agent (e.g. merthiolate), will suffice. Large insects are normally pinned through the thorax using fine entomological pins. Smaller insects are held by a fine pin inserted in a small block of styrofoam held in turn by a stout main pin. Most small flies including muscids (house fly, stable fly) are mounted in this way. An alternative method, essential for very small insects such as biting midges (*Simulium*, *Culicoides*), is to attach them to the tip of a card ‘point’ using a soluble gum.

Small unmounted hard-bodied specimens (e.g. small flies and various insect larvae) are often better preserved for diagnostic and identification purposes if they are kept in 70% alcohol (with 5% glycerine); 10% formalin or 10% formol saline is preferred if they are soft-bodied. Although they will be slow to die, the use of 90% alcohol may be sufficient to kill and preserve soft-bodied insect

larvae (e.g. maggots) from general collections of soil- or manure-breeding insects. Various killing fluids have been suggested to overcome these problems. A mixture of four parts 90% ethyl alcohol and one part ethyl acetate is an effective killing and relaxing agent for soft-bodied larvae. The addition of a little glacial acetic acid improves fixation and retains colour. A further fixative which can be used for killing and fixing soft larvae without severe contraction is Peterson's KAA fluid (10 parts 95% ethyl alcohol, 2 parts glacial acetic acid and 1 part kerosene). Preservation should finally be in 70% alcohol.

Small arthropods for microscopic examination on slides may be mounted in the following.

- 1 Melted glycerine jelly, and sealed with nail varnish.
- 2 Berlese's fluid. This clears specimens but delicate insects may deteriorate after a short period.

If little detail can be made out, the specimen can be first cleared by placing it in 10% caustic potash on a slide and warming it for a few minutes or in a tube in a water-bath at 70°C. A more gentle action can be obtained by leaving the specimen in caustic solution at 37°C for several hours.

CHEMICALS AND SOLUTIONS

Phosphate buffered saline (10 mmol/L)

- 1 Dissolve the following in 800 mL distilled H₂O:
 - a 8 g of NaCl
 - b 0.2 g of KCl
 - c 1.44 g of Na₂HPO₄
 - d 0.24 g of KH₂PO₄
- 2 Adjust pH to 7.4 with HCl.
- 3 Adjust volume to 1 L with additional distilled water.
- 4 Sterilise by autoclaving.

Potassium bichromate

Dissolve 1 g of potassium bichromate in 100 mL of distilled water.

FLOTATION SOLUTIONS

Saturated salt (NaCl) solution, 1.20 specific gravity

- 1 Dissolve 400 g NaCl in 1000 mL of water, heat and allow to cool.
- 2 Decant off solution from any precipitate.

Magnesium sulphate (MgSO₄) solution, 1.28 specific gravity

- 1 Dissolve 400 g MgSO₄ in 1000 mL of boiling water.
- 2 Add 20 g potassium bichromate to prevent crystallisation.

Sugar (Sheather's) solution, 1.27 specific gravity

- 1 Dissolve 500 g sugar (sucrose) in 1000 mL boiling water.
- 2 Add approximately 6 mL of 37% formaldehyde or phenol crystals to prevent mould formation.

Saturated zinc sulphate (ZnSO₄) solution, 1.36 specific gravity

Add 700 g ZnSO₄ to 1000 mL of slowly boiling water and allow to cool.

Zinc sulphate (ZnSO₄) solution, 1.20 specific gravity

Add 330 g ZnSO₄ to 1000 mL water.

WORM COUNT SOLUTIONS

Pepsin/hydrochloric acid (HCl)

- 1 Dissolve 80 g of pepsin powder in 3 L of cold water.
- 2 Add 240 mL concentrated HCl slowly and stir well.
- 3 Make final volume up to 8 L. Store at 4°C.

Iodine solution

- 1 Dissolve 907 g of potassium iodide in 650 mL boiling water.
- 2 Add 510 g iodine crystals and make up to 1 L.

Sodium thiosulphate solution

Dissolve 100 g of sodium thiosulphate in 5 L of water.

STAINS

Field's technique stains

Solution A

|--|---------|
| Na ₂ HPO ₄ ·12H ₂ O | 25.2 g |
| KH ₂ PO ₄ | 12.5 g |
| Distilled water | 1000 mL |

Solution C

| | |
|------------|--------|
| Eosin | 0.5 g |
| Solution B | 250 mL |

These solutions do not keep and should be freshly prepared each day.

Ziehl-Neelsen acid-fast stain for *Cryptosporidium*

Strong carbol-fuchsin

Dissolve 20 g basic fuchsin in 200 mL absolute methanol. Add 125 mL liquid phenol (GPR [80% w/w in distilled water]) carefully until well mixed. The stock reagent should be stored in a dark cupboard at room temperature. Often the concentration of basic fuchsin can vary within the acceptable range of 1–3%.

1% acid methanol

Add 20 mL hydrochloric acid (GPR/SLR) to 1980 mL of absolute methanol.

0.4% malachite green

Add 2 g malachite green to 480 mL deionised water.

***Peanut agglutinin–fluorescein isothiocyanate
(PNA-FITC)***

Sigma Cat. No. L-7381 lectin from *Arachis hypogaea*, reconstituted at 5 mg per 1 mL PBS.

Diff-Quick stain

Diff-Quick is a commercially available Romanowsky-type stain available from a number of suppliers. The kits usually comprise:

Fixative: methanol

Stain A: buffered eosin stain (eosinophilic)

Stain B: buffered Azure B stain (basophilic).

CHAPTER 5

Antiparasitics

It is not practical to give full efficacy data and methods of application of the large number of drugs currently available against the vast range of parasites which parasitise domestic animals. As the number of compounds and their various formulations are continually changing, it is perhaps more appropriate to discuss the use of antiparasitics in general terms, according to the groups of parasites they target. For the purposes of this chapter, antiparasitics are grouped as **anthelmintics**, **antiprotozoals** and **ectoparasiticides**. Details of their use against individual species or groups of parasites have been described under the appropriate sections of the host chapters.

ANTHELMINTICS

The control of parasitic helminths in domestic animals relies largely on the use of anthelmintic drugs administered as chemotherapy or as chemoprophylaxis. Although anthelmintics are used in all domestic species, the largest market is undoubtedly the ruminant market, especially cattle, where millions of pounds are spent annually in an effort to reduce the effects of parasitism.

ANTHELMINTICS AND THEIR MODE OF ACTION

The mode of action of many anthelmintics basically depends on interference with essential biochemical processes of the parasite or

cell integrity, but not, or to a lesser extent, those of the host. Many of the drugs target the nervous system of the parasite, resulting in paralysis and hence expulsion from the host. The nervous system is well conserved between species and is very complex in terms of its neurochemicals, possessing many receptor and transmitter interactions that are not found in mammalian hosts. In some cases the pharmacokinetic properties of the drug within the host result in the parasite being exposed to higher concentrations of the compound than the cells of the host.

The major groups of anthelmintics currently in use against nematodes, trematodes and cestodes are shown in Table 5.1.

Benzimidazoles/pro-benzimidazoles (Group 1-BZ)

The benzimidazoles include **thiabendazole**, **parbendazole**, **oxibendazole**, **fenbendazole**, **oxfendazole**, **albendazole**, **triclabendazole** and **ricobendazole** (albendazole oxide). Three other chemicals, **febantel**, **netobimin** and **thiophanate** (pro-benzimidazoles), are also included in this group because they are metabolised in the body to active benzimidazole metabolites. Modification of a particular benzimidazole can affect the pharmacokinetic behaviour of the drug through changes in relative insolubility, slowing the elimination of the parent drug and/or active metabolites. The greater efficacy and wider spectrum of activity of the most recently introduced (second-generation) benzimidazoles appears to be due to the relative insolubility of these chemicals, which affects the

Table 5.1 Anthelmintic groups.

| Chemical group | Group code | Nematodes | Trematodes | Cestodes | Ectoparasites |
|---|------------|-----------|------------|----------|---------------|
| Broad-spectrum | | | | | |
| Benzimidazole and pro-benzimidazoles | 1-BZ | + | ± | ± | – |
| Imidazothiazoles | 2-LV | + | – | – | – |
| Tetrahydropyrimidines | | + | – | – | – |
| Avermectins/milbemycins | 3-ML | + | – | – | + |
| Aminoacetyl derivatives | 4-AD | + | – | – | – |
| Spiroindoles | 5-SI | + | – | – | – |
| Narrow-spectrum | | | | | |
| Salicylanilides and substituted phenols | | ± | + | ± | ± |
| Piperazines | | ± | – | – | – |
| Organophosphates | | + | – | – | + |
| Arsenicals | | + | – | – | – |
| Others | | + | – | + | – |

absorption, transport and excretion of the anthelmintic compound from the host.

Benzimidazoles are poorly soluble and are generally given orally as a suspension. Netobimin can be solubilised and administered via drinking water. Benzimidazoles have also been incorporated into a range of controlled-release devices for use in cattle. All are effective against nematodes affecting domestic animals and are ovicidal. Most are also effective against tapeworms and some have activity against adult liver fluke (*Fasciola*) in ruminants at increased dose rates.

All members of the benzimidazole class have a similar mode of action and act by disrupting energy metabolism in worms by binding to parasite tubulin, a constituent protein present in microtubules and in plasma and mitochondrial membranes. The formation of microtubules is a dynamic process involving the polymerisation of tubulin rings at one end and depolymerisation at the other end. Benzimidazole anthelmintics bind to β -tubulin causing capping and inhibition of further microtubule formation. The resultant effect is starvation of the parasite due to inhibition of glucose uptake, protein secretion and microtubule production. There is also a reduction in enzyme activity such as acetylcholinesterase secretion, and carbohydrate catabolism by the fumarate reductase system. As the mode of action of all the above benzimidazoles is similar (all affecting the β -tubulin receptor protein), extensive cross-resistance occurs between members of this group of drugs. The mode of action of triclabendazole on *Fasciola hepatica* is at present unknown. It appears to have no tubulin-binding properties, unlike other members of this group, and it must therefore act along alternative pathways.

Benzimidazoles have low toxicity, and in some cases can be used at over 10 times the recommended dose rate. Parasite resistance to anthelmintics has most frequently been associated with repeated use of these drugs against nematodes of sheep, goats and horses and in many countries has limited both their effectiveness and use.

Imidazothiazoles/tetrahydropyrimidines (Group 2-LV)

The imidazothiazole group contains two members, **tetramisole** and **levamisole**. Tetramisole is a racemic mixture of dextro and laevo forms. Levamisole is the laevo-isomer and it is with this form that anthelmintic potency resides. The dose rate of levamisole is therefore half that of tetramisole, and it has twice the safety index.

Levamisole is used mainly in cattle and sheep and has good activity against a range of gastrointestinal nematodes and is also highly effective against lungworms. Levamisole can be administered orally, by injection or pour-on, combined in a number of products with a specific flukicide (oxyclozanide or triclabendazole) to form a broad-spectrum drench for worms and fluke. Unlike the benzimidazoles it is not ovicidal. Levamisole is non-teratogenic and is therefore safe to use in pregnant animals. The therapeutic index in relation to other anthelmintics is, however, low. Animals given levamisole may be hyperactive for a few minutes after receiving the recommended therapeutic dose. Toxic signs, due to a stimulant effect on nerve ganglia, may manifest as salivation, bradycardia, muscular tremors and, in extreme cases, death from respiratory failure. Injectable levamisole may cause inflammation at the site of injection.

The drug is rapidly absorbed and excreted, most of the dose being lost from the system within 24 hours of administration. Because

of the mode of action of these compounds, nematode paralysis occurs quickly and removal of the worms is rapid. In addition to its anthelmintic properties, levamisole has been shown to stimulate the mammalian immune system by increasing cellular activity. The relationship between the immunostimulatory and nematocidal properties of levamisole is unknown.

Pyrantel and **morantel** are members of the tetrahydropyrimidine group. **Morantel** is used for the treatment of gastrointestinal worms of cattle and sheep but is not effective against mucosal or arrested stages or against established lungworm infections. Like levamisole, it has no activity against tapeworms and fluke. **Pyrantel** is used for the treatment and control of nematode and tapeworm infections in horses and nematodes in dogs. It is also active against nematodes in ruminants and pigs. Pyrantel salts (tartrate or pamoate) are active against adult and larval stages of large and small strongyles, ascarids, tapeworms (*Anoplocephala*) at double the regular dose, and benzimidazole-resistant strains of cyathostomes in the horse. None of these drugs are particularly toxic and they can be used safely in pregnant and young animals.

The mode of action of the imidazothiazoles and tetrahydropyrimidine derivatives is as selective cholinergic agonists, targeting nicotinic acetylcholine receptors of nematodes, initially causing sustained muscle contractions, followed by neuromuscular depolarisation resulting in a rapid reversible spastic paralysis. Paralysed worms are expelled by normal gut peristalsis. Because these nicotinic acetylcholine receptors are diverse in their location in nematodes (neuromuscular junction, nerve ring and pharynx) and also in their pharmacology, this may explain why resistance to one drug does not necessarily lead to cross-resistance to other related drugs. Studies on neuromuscular nicotinic acetylcholine receptors in *Haemonchus contortus* and *Ascaris suum* have indicated that resistance to levamisole might increase susceptibility to pyrantel and vice versa.

Avermectins/milbemycins (Group 3-ML)

These are a series of macrocyclic lactone derivatives that are fermentation products of the actinomycete *Streptomyces avermitilis* (avermectins) and *Streptomyces cyanogriseus* (milbemycins). Avermectins differ from each other chemically in side-chain substitutions on the lactone ring, while milbemycins differ from the avermectins through the absence of a sugar moiety from the lactone skeleton. The avermectins include **abamectin**, **doramectin**, **eprinomectin**, **selamectin** and **ivermectin**, and are active against a wide range of nematodes and arthropods. **Moxidectin** is a milbemycin and has a similar wide-ranging activity.

The macrocyclic lactones have been shown to have excellent activity, at very low dose rates, not only against a wide range of nematodes but also against certain arthropod parasites and hence are sometimes referred to as endectocides. They are active against adult and larval gastrointestinal roundworms and lungworms of ruminants, horses and pigs, although none of these compounds have activity against tapeworms or liver fluke. Eprinomectin has a zero withdrawal time for meat and milk and is often the drug of choice in lactating dairy cattle. Avermectins are also active against filarial worms (*Parafilaria*) in cattle, microfilariae of the canine heartworm (*Dirofilaria*) in dogs and cats and spiruroid worms, including *Habronema* and *Draschia*, in horses.

The ectoparasites these compounds have activity against include warbles (*Hypoderma* spp.) in cattle, sucking lice (*Haematopinus*,

Linognathus, *Selenopotes* spp.) and mange mites (*Psoroptes*, *Sarcoptes*, *Chorioptes*) in cattle, sheep and pigs. More detailed information on the efficacy of the endectocides against ectoparasites is provided in the section on ectoparasiticides.

Selamectin is used as a preventive against heartworm disease in dogs and is effective against hookworms (*Ancylostoma*, *Uncinaria*) and ascarid roundworms (*Toxocara*, *Toxascaris*) in dogs and cats. Selamectin has been specifically developed for use in dogs and cats and is also active against fleas and mites in these hosts (see section Ectoparasiticides). It does not appear to exhibit toxicity in ivermectin-sensitive collie dogs, at the recommended dose rates.

Macrocyclic lactones are highly lipophilic and, following administration, are stored in fat tissue from where they are slowly released, metabolised and excreted. Ivermectin is absorbed systemically following oral, subcutaneous or dermal administration, but is absorbed to a greater degree, and has a longer half-life, when given subcutaneously or dermally. A temporary depot appears to occur in the fat and liver, from which there is a slow release. Excretion of the unaltered molecule is mainly via the faeces, with less than 2% excreted in the urine. The reduced absorption and bioavailability of ivermectin when given orally in ruminants may be due to its metabolism in the rumen. The affinity of these compounds for fat explains their persistence in the body and the extended periods of protection afforded against lungworms and stomach worms in cattle and sheep. Individual variations in these periods of protection reflect differences in drug distribution, metabolism and excretion. In cattle, injectable and pour-on preparations provide protection for up to 42 days for lungworms and 35 days for stomach worms depending on the product and formulation. The prolonged half-life of these compounds also determines levels of residues in meat and milk, and subsequent compulsory withdrawal periods following treatment. With the exception of eprinomectin, which has a zero milk withdrawal period, treatment with this class of compounds cannot be given to lactating cattle, or during the last 2 months of pregnancy.

Their mode of action has been studied but has still not been completely elucidated. Ivermectin is known to act on γ -aminobutyric acid (GABA) neurotransmission at two or more sites in nematodes, blocking interneuronal stimulation of excitatory motor neurones and thus leading to a flaccid paralysis. It appears to achieve this by stimulating the release of GABA from nerve endings and enhancing the binding of GABA to its receptor on the postsynaptic membrane of an excitatory motor neurone. The enhanced GABA binding results in an increased flow of chloride ions (Cl^-) into the cell leading to hyperpolarisation. In mammals, GABA neurotransmission is confined to the central nervous system; the lack of effect of avermectin on the mammalian nervous system at therapeutic concentrations is probably because, being a large molecule, it does not readily cross the blood-brain barrier. More recent evidence suggests that the hydrophobic macrocyclic lactones dissolve in the plasma membrane of the cell and bind to glutamate-gated chloride channel receptors at the pore region of the receptor. This binding opens the channel and allows the influx of chloride ions and the resulting hyperpolarisation of the cell causes a flaccid paralysis. This paralysis can occur in body wall muscle, uterine muscle and the pharyngeal muscle.

Amino-acetonitrile derivatives (Group 4-AD)

The novel anthelmintic **monepantel** became available in 2010. Its mode of action is similar to the paralysis that occurs with the 2-LV

group of anthelmintics but it acts via a previously unknown neuronal nicotinic acetylcholine receptor site (MPTL-1) that is specific to nematodes. When monepantel interferes with this subunit, the receptor allows Na^+ and K^+ cations freedom to pass through the cell wall leading to nematode paralysis. There is some evidence that the target receptor ligand may not be acetylcholine but choline. The paralysis could be due to the activation of neurones which control nematode movement or because the choline receptor is expressed also on muscle cells. Monepantel has been shown to be effective against parasites which are resistant to other nicotinic drugs. The safety index of the drug is high.

Spiroindoles (Group 5-SI)

Derquantel is a semi-synthetic derivative of paraherquamide (2-desoxoparaherquamide) that belongs to the family of spiroindoles. Derquantel was launched in 2012 as a 'dual active' product in combination with abamectin (3-ML group). Both active components have similar pharmacokinetic profiles. Derquantel interferes with β -sub-type nicotinic acetylcholine receptors leading to flaccid paralysis in nematodes. This mode of action is different to other chemical groups and as such offers activity against resistant strains of parasites. A study has shown that abamectin and derquantel appear to interact at nicotinic acetylcholine receptors and that the effect of the combination is significantly higher than the predicted additive effect of both drugs at higher acetylcholine concentrations, suggesting that synergism can occur. The combination drench offers a high level of efficacy in killing worms including those resistant to benzimidazole (1-BZ), levamisole (2-LV) and macrocyclic lactone (3-ML) anthelmintics.

Salicylanilides/substituted phenols

The salicylanilides/substituted phenols can be regarded as close analogues and include the **bromsalans**, **clioxanide**, **oxyclozanide**, **brotianide**, **niclosamide**, **rafoxanide** and **closantel** (salicylanilides), and **nitroxynil**, **disophenol**, **bithionol**, **hexachlorophene**, and **niclofolan** (phenol derivatives). With the exception of niclosamide, the salicylanilides and substituted phenols are usually marketed as flukicides for cattle and sheep, being highly effective against adult and, to a lesser extent, immature flukes (*Fasciola*). Some also possess activity against blood-sucking nematodes such as *Haemonchus*. **Disophenol** has been used for treatment of dogs infected with hookworms, and is also effective against mature *H. contortus* and may be used in sheep for treatment of benzimidazole-resistant *H. contortus* infections. **Niclosamide** is highly effective against tapeworms in cattle, sheep, horses, poultry and possibly against immature paramphistomes in ruminants. In a number of countries, it is used mainly for the treatment of tapeworms in dogs and cats.

Salicylanilides and substituted phenols appear to be extensively bound to plasma proteins (>99%), which may explain their high efficacy against blood-feeding parasites. Fasciolicidal activity is dependent on the extent to which these drugs persist in the plasma. Rafoxanide and closantel have long plasma half-lives when compared with oxyclozanide. Evidence suggests that the apparent efficacy of these drugs, particularly against immature fluke (*Fasciola*), may be due more to their persistence in the plasma and the effect they have on maturing adult flukes when they reach the bile ducts, rather than the effect they have on the immature stages themselves.

Young flukes probably ingest mainly liver cells, which contain little anthelmintic. As they grow and migrate through the liver they cause extensive haemorrhage and come into contact with anthelmintic. Finally, when the flukes reach the bile ducts they are in contact with even greater concentrations of anthelmintic as the bile ducts are important in the excretion of these compounds, as evidenced by the high proportion of these, and their metabolites, excreted in the faeces rather than the urine.

Salicylanilides and substituted phenols uncouple oxidative phosphorylation and therefore decrease the availability of high-energy phosphate compounds such as adenosine triphosphate (ATP) and reduced nicotinamide adenine dinucleotide (NADH⁻) in the mitochondria. They act as protonophores enabling hydrogen ions to pass through the inner mitochondrial membrane. They have also been shown to inhibit succinate dehydrogenase activity and the fumarate reductase system, which is associated with oxidative phosphorylation. Because of the long half-life of the plasma protein-bound molecules, the parasites experience prolonged exposure to the drugs, which reduces the energy available to the parasites.

Plasma binding reduces incorporation of the drugs into host tissues and accounts for the selective parasite toxicity. Looseness of faeces and slight loss of appetite may be seen in some animals after treatment at recommended dose rates. High doses may cause blindness and signs of uncoupled oxidative phosphorylation, such as hyperventilation, hyperthermia, convulsions, tachycardia and ultimately death.

Dichlorophen is a chlorinated phenol and is active against tapeworms (*Dipylidium*, *Taenia*) in dogs and cats. Its mode of action is thought to be similar to that of the salicylanilides, interfering with oxidative phosphorylation.

Piperazines

Piperazine salts have a narrow spectrum of activity and have been widely used against ascarids, particularly in dogs and cats, acting as an agonist at GABA receptors, thus blocking neuromuscular transmission by hyperpolarisation of the nerve membrane and thus inducing a flaccid paralysis. Piperazine also inhibits the production of succinate by the parasite, which leads to depletion of energy. Piperazine adipate has been widely used in horses and is effective against adult stages of small strongyles and *Parascaris*. In pigs, the drug is active against *Ascaris* and nodular worms *Oesophagostomum* spp. after a single treatment. It has also been widely used in poultry, dogs and cats.

Diethylcarbamazine is still marketed in certain parts of the world for the treatment of lungworm infections in cattle. It is primarily active against immature lungworms and because it has to be given over a period of 3 days to achieve its effect, it has been replaced by more modern anthelmintics. The action of diethylcarbamazine on immature lungworm larvae is thought to induce a flaccid paralysis due to hyperpolarisation of neuronal postsynaptic membranes resulting from an increased flow of Cl⁻ into the cell. It can be used as a preventive for heartworm disease when given to dogs in low daily doses throughout the mosquito season and for 2 months subsequently. The mode of action is incompletely understood, but it is thought to enhance phagocytosis of the microfilariae by the host immune system. However, it is strictly contraindicated in microfilariae-positive dogs because of a possible but rare shock-type reaction that is sometimes fatal, produced by liberation of substances from dying or dead microfilariae following treatment. It has

also been reported to be effective against the lungworm *Crenosoma vulpis* of dogs and farmed foxes.

Organophosphates

Several organophosphate compounds (see section Ectoparasitocides) are active against nematodes, but are becoming less widely available in many countries. Compounds used in the treatment of nematode infections include **coumaphos**, **trichlorphon**, **haloxon** and **dichlorvos**. They act by inhibiting cholinesterase, via phosphorylation of esterification sites, resulting in a build-up of acetylcholine, which leads to neuromuscular spastic paralysis of nematodes and their expulsion. This group of drugs is relatively toxic and has been used most frequently in horses, because of the additional insecticidal action against larvae of horse bots.

Coumaphos has been widely used as an ectoparasitic in livestock. It exhibits a cumulative effect on trichostrongyle nematodes if given in feed daily for 1 week; there is a good activity against *Haemonchus* spp. and *Cooperia* spp. in cattle and sheep, but it is less effective against *Trichostrongylus*, *Ostertagia* spp. and *Oesophagostomum* spp. Anthelmintic activity can be enhanced if the drench passes via the closed oesophageal groove directly to the abomasum, with either sodium bicarbonate in cattle or copper sulphate in sheep. It is also effective against *Capillaria*, *Ascaridia* and *Heterakis* in chickens. The drug is toxic and may cause mortality in ruminants. Coloured breeds of egg-laying hens are more susceptible to the drug than white breeds and birds should not be treated while they are in lay.

Haloxon is still used in many countries for treatment of nematodes. In cattle, sheep and goats, there is good activity against adult *Haemonchus*; also *Cooperia* spp. in sheep and *Neoascaris* in cattle. There is a moderate effect against *Ostertagia*, *Bunostomum*, *Trichostrongylus* and *Oesophagostomum* but little effect against *Nematodirus*, *Trichuris* and *Chabertia*. It is highly effective against adult stages of *Strongylus vulgaris*, most small strongyles (also benzimidazole-resistant strains), *Parascaris* and *Oxyuris* in the horse. Haloxon is also effective against *Capillaria* infections of birds (chicken, turkey, quail and pigeons) but is ineffective against *Heterakis*. In pigs, it is active against adult *Ascaris* and *Oesophagostomum* spp. but there may be delayed neurotoxicity (posterior paralysis). It is used in some countries in chickens, turkeys, quail and pigeons against *Capillaria*. The recommended dose range for birds (50–100 mg/kg) is lethal for geese and possibly waterfowl.

Trichlorphon is effective against adult and immature *Parascaris* and adult pinworms (*Oxyuris*), and against bots (larvae of *Gasterophilus*) and, at higher doses, large strongyles (*S. vulgaris*) and small strongyles in horses. In some countries, trichlorphon is used in combination with various benzimidazoles, pyrantel pamoate or piperazine/phenothiazine for removal of ascarids, pinworms, small strongyles (cyathostomes) and all three species of large strongyles. It shows good efficacy against adults of *Ascaris*, *Trichuris* and *Hyostrongylus* in pigs. At therapeutic doses, there may be mild adverse effects such as transient softening of faeces and mild colic for several hours.

Dichlorvos is an aliphatic organophosphate. It has a similar spectrum of activity to trichlorphon in horses and pigs; formulation in a slow-release resin increases activity against large and small strongyles and safety in pigs. However, the resin pellets, which appear in the faeces, are toxic to other animals, especially chickens.

Arsenicals

Thiacetarsamide is an arsenical compound that has been used for many years as an adulticidal drug for treatment of heartworm (*Dirofilaria*) in dogs. Its efficacy varies depending on the sex and age of worm, and there is a risk to treated animals of pulmonary embolism in the first month following treatment. The drug is highly irritant to subcutaneous tissues and is both hepatotoxic and nephrotoxic, with mortality during or following therapy related to the degree of clinical manifestation of heartworm disease. It is now no longer available.

Melarsomine dihydrochloride is a new generation arsenical adulticide that can be used for treatment of canine heartworm disease. It is less nephrotoxic and hepatotoxic than thiacetarsamide and has a higher efficacy using a two-dose strategy. It is generally well tolerated, causing only minor tissue reactions and is normally administered intramuscularly into the lumbar muscles.

Other drugs

Phenothiazine was the first broad-spectrum anthelmintic and was used for many years but has now virtually disappeared. It is still available in some countries in combination with trichlorphon and piperazine and can be used for treating benzimidazole-resistant strains of small strongyles. The drug is active against adult stages of small strongyles but has little or no effect on large strongyles, immature stages of small strongyles and *Parascaris*. At therapeutic doses there may be side effects, such as anorexia, muscular weakness, icterus or anaemia, but seldom mortality.

Epsiprantel is an isoquinoline-pyrazine anthelmintic compound active against tapeworm infections in dogs and cats. It is generally formulated and administered with pyrantel pamoate to give a broader range of activity against both roundworms and tapeworms of dogs and cats. It should not be used in kittens and puppies younger than 7 weeks old.

Praziquantel is an acetylated quinoline-pyrazine and is active against a wide range of adult and larval tapeworms in dogs and cats and at higher dose rates against tapeworms of ruminants. It is the drug of choice against multilocular echinococcosis (*Echinococcus multilocularis*) and is also active against lung flukes (*Paragonimus*) and intestinal fluke (*Nanophyetus*) in dogs. Praziquantel modulates cell membrane permeability causing spastic paralysis of muscle cells in the parasite and, like a number of other cestodicidal drugs, causes damage to the parasite tegument. It also exhibits activity against trematodes of the genus *Schistosoma*.

Nitroscanate is marketed for treatment of common roundworm and tapeworm infections of dogs. Although active in cats, its use in this species is contraindicated due to adverse side effects including posterior paralysis, inappetence and vomiting.

Emodepside is a semi-synthetic compound belonging to a new group of chemicals called the depsipeptides. This anthelmintic requires a voltage-gated ion channel for its activity. The effects are manifested through activation of the *SLO-1* gene, which encodes a calcium- and voltage-activated potassium channel. Latrophilin receptors may also be a target for emodepside in some parasites. The effects are often multiple, influencing feeding, locomotion and egg laying by the parasite and leading to paralysis and death. This suggests that more than one target may be activated. Emodepside is active against roundworms, hookworms and certain tapeworms of dogs and cats.

Clorsulon is a benzene sulphonamide compound and has been used in the treatment of mature adult liver fluke (*Fasciola hepatica*) infections in cattle and sheep. It does not exhibit activity against young immature stages, but is effective against adult and immature flukes over 8 weeks of age. It has been shown to inhibit the glycolytic enzyme phosphoglyceromutase and 2,3-diphosphoglycerate leading to gradual suppression of motility and paralysis.

PROPERTIES OF ANTHELMINTIC COMPOUNDS

An ideal anthelmintic should possess the following properties.

- 1 It should be efficient against all parasitic stages of a particular species.** It is also generally desirable that the spectrum of activity should include members of different genera, for example in dealing with the equine strongyles and *Parascaris equorum*. However in some circumstances, separate drugs have to be used at different times of year to control infections with unrelated helminths; the trichostrongyles responsible for ovine parasitic gastroenteritis and the liver fluke *Fasciola hepatica* are examples.
- 2 It is important that any anthelmintic should be non-toxic to the host,** or at least have a wide safety margin. This is especially important in the treatment of groups of animals such as a flock of sheep, where individual body weights cannot easily be obtained, rather than in the dosing of individual companion animals such as cats or dogs.
- 3 In general, an anthelmintic should be rapidly cleared and excreted by the host,** otherwise long withdrawal periods would be necessary in meat- and milk-producing animals. However, in certain circumstances and in certain classes of animals, drug persistence is used to prophylactic advantage, for example the use of closantel to control *Haemonchus* in sheep.
- 4 Anthelmintics should be easily administered,** otherwise they will not be readily accepted by owners; different formulations are available for different domestic animal species. Oral and injectable products are widely used in ruminants, and pour-on preparations are available for cattle. Anthelmintic boluses are also available for cattle and sheep. Palatable in-feed and paste formulations are convenient for use in horses, while anthelmintics are usually available as tablets for dogs and cats.
- 5 The cost of an anthelmintic should be reasonable.** This is of special importance in pigs and poultry where profit margins may be narrow.

USE OF ANTHELMINTICS

Anthelmintics are generally used in two ways: therapeutically, to treat existing infections or clinical outbreaks, or prophylactically, in which the timing of treatment is based on knowledge of the epidemiology. Clearly, prophylactic use is preferable where administration of a drug at selected intervals or continuously over a period can prevent the occurrence of disease.

Therapeutic usage

When used therapeutically, the following factors should be considered.

- If the drug is not active against all stages, it must be effective against the pathogenic stage of the parasite.

- Use of the anthelmintic should, by successfully removing parasites, result in cessation of clinical signs of infection, such as diarrhoea and respiratory distress; in other words, there should be a marked clinical improvement and rapid recovery after treatment.

Prophylactic usage

Several points should be considered where anthelmintics are used prophylactically.

- The cost of prophylactic treatment should be justifiable economically, by increased production in food animals, or by preventing the occurrence of clinical or subclinical disease in, for example, horses with strongylosis or dogs with heartworm disease.
- The cost–benefit of anthelmintic prophylaxis should stand comparison with the control, which can be achieved by other methods such as pasture management or, for example in the case of dictyocaulosis, by vaccination.
- It is desirable that the use of anthelmintics should not interfere with the development of acquired immunity, since there are reports of outbreaks of disease in older stock that have been over-protected by control measures during their earlier years.
- It is also important that the status of anthelmintic resistance on the farm is known and dosing strategies undertaken to maintain a proportion of the worm population *in refugia*.
- Prolonged prophylactic use of one drug should be avoided as this may encourage the development of anthelmintic resistance.

METHODS OF ADMINISTRATION

Traditionally, anthelmintics have been administered orally or parenterally, usually by subcutaneous injection. Oral administration is common by drenching with liquids or suspensions, or by the incorporation of the drug in the feed or water for farm animals and by the administration of tablets to small animals. More recently, paste formulations have been introduced especially for horses and there are now several compounds which have systemic action when applied as pour-on or spot-on formulations to the skin. Methods for injecting compounds directly into the rumen of cattle have also been marketed. A number of rumen-dwelling boluses are available, mainly for cattle, and to a lesser extent for sheep. These are designed to deliver therapeutic doses of anthelmintic at intervals (pulse-release) or low doses over prolonged periods (sustained-release); both prevent the establishment of mature parasite populations and thus limit the contamination of pastures and the occurrence of disease. An apparatus for the delivery of anthelmintics into drinking water at daily or periodic intervals has also been developed.

Combination products

Some products are marketed for cattle and sheep and consist of a mixture of roundworm anthelmintics for the control of multiple-resistant nematode worms. Alternatively, a combination of a roundworm drug and a fluke drug may be given, but the timing of treatments for roundworms or flukes, whether curative or prophylactic, is often different and the requirement for such combination compounds is therefore limited to situations where both types of parasites are present.

A combinations of two or three anthelmintics with differing spectrums of activity (roundworms, hookworms, heartworm, tapeworms) has proved useful in dogs.

Multiple active products

The term ‘multiple actives’ refers to formulations that are a mixture of two or more distinct anthelmintic classes with a similar spectrum of activity against roundworms only. Multiple active products can be used in sheep, or cattle, in an attempt to delay the increase in anthelmintic resistance in those circumstances where the prevalence of resistant parasites is currently at a low level. The administration of anthelmintic combinations with a similar spectrum of activity and different mechanisms of action and resistance has been suggested as a potential means of delaying the development of anthelmintic resistance. Multiple actives are commercially available in several countries such as Australia and New Zealand and include dual actives or even triple actives.

There are two main justifications for the use of multiple actives: (i) to enable the effective control of nematodes in the presence of single or multiple drug resistance; and (ii) to slow the development of anthelmintic resistance to the component anthelmintic classes. The rationale for using multiple active formulations to delay the development of resistance was initially inspired by research into insecticide resistance. Results from several modelling studies with insecticides suggested that multiple actives were always more effective at delaying the development of resistance than using the same actives in different patterns of rotation (alternating the use of different chemical classes) or sequentially (where one chemical class is used exclusively until resistance develops and its use is then replaced by the introduction of a different chemical class), provided certain conditions were met.

Potential pharmacodynamic interactions between co-administered anthelmintics include indifference, antagonism, additive and synergistic effects. An additive effect occurs when the combined effect of two drugs equals the sum of their independent activities measured separately. For example, if co-administered actives have independent modes of action and mechanisms of resistance, nematodes which survive one treatment will be killed by the other, provided they are not multi-resistant. The expected efficacy of a multiple active anthelmintic formulation can be approximated as follows: if two anthelmintics have efficacies a and b , respectively, where efficacy is expressed as the proportion of worms killed, the expected efficacy for the combination, assuming additive effects of the drugs, is given as:

$$\text{Efficacy (A + B)} = \{1 - [(1 - a)(1 - b)]\} \times 100$$

The use of multiple active formulations in resistance management is not a panacea and, like all anthelmintic products, maximum benefit will be realised when they are introduced before resistance is detectable and when they are used in accordance with guidelines for sustainable parasite control.

ANTIPROTOZOALS

Unlike other antiparasitic agents, for which a few chemical structural classes exhibit a wide spectrum of biological activity, antiprotozoal activity exists in a wide range of chemical classes, each of

which possess only a narrow spectrum of activity. The classification of antiprotozoal compounds is complex and for the purposes of this chapter they are divided into eight main groups, each of which may be further subdivided on the basis of structural similarities.

ANTIPROTOZOALS AND THEIR MODE OF ACTION

Antimonials and arsenicals

Antimonials contain the group V metal antimony, and have been used extensively for the treatment of leishmaniasis. The antimonials selectively inhibit enzymes that are required for glycolytic and fatty acid oxidation in tissue amastigotes found within macrophages.

Tartar emetic (antimony potassium tartrate) was the first antimonial used for this purpose in cases of human leishmaniasis. It was also used in the treatment of *Trypanosoma congolense congolense* and *Trypanosoma vivax vivax* infections in cattle and *Trypanosoma brucei evansi* infections in camels. Extravascular injection causes severe necrosis and the compound has a narrow chemotherapeutic index resulting in about 6% mortality during routine treatment.

The pentavalent antimony compounds **meglumine antimoniate (Glucantime or N-methylglucamine antimoniate)**, **sodium antimony gluconate** and **sodium stibogluconate (Pentostam)** have been the first-line drugs for the treatment of leishmaniasis in humans and are the principal antimonials used for the treatment of canine leishmaniasis. The precise chemical structure of these drugs is difficult to identify. Drug tolerance to antimonials in human and canine leishmaniasis is known and there may be considerable rates of treatment failure and relapses. These drugs may show marked toxic effects such as arthralgia, nephrotoxicity and cardiotoxicity, leading rarely to sudden death. Antimonials are administered either by intralesional infiltration in simple single cutaneous lesions or by intramuscular injection in all cases with systemic involvement. Antimony is excreted quickly from the body so that daily treatment is necessary throughout each course of treatment. Meglumine antimoniate and allopurinol given simultaneously have been shown to maintain dogs in clinical remission.

Arsenicals are substituted benzene arsonic acid salts or esters and have been used in the treatment of trypanosomiasis (**trypanamide**, **melarsomine**) and coccidiosis (**arsenilic acid**, **roxarsone**). **Melarsomine** is effective against trypanosomes of the *T. brucei* group (*T. b. evansi*). **Roxarsone** was used primarily as a growth promoter but had some activity against *Eimeria tenella* and *E. brunetti* in chickens when used alone or in combination with nitroimidazole or dinitolmidazole. Arsenicals have a low safety index and have been superseded by comparatively less toxic compounds.

Substituted aromatics

Amidines and diamidines

Pentamidine has the widest spectrum within the group with activity against *Leishmania*, *Trypanosoma*, *Babesia* and *Pneumocystis*, and is used mainly in human medicine. **Stilbamidine** has been used for the treatment of leishmaniasis. **Amicarbalide** is active against *Babesia* and **diminazene aceturate** is active against both *Babesia* and *Trypanosoma*. Very little is known about the mode of action of this class of compounds. Antiparasitic activity may be related to

interference with aerobic glycolysis as well as interference with synthesis of parasite DNA.

Diminazene is highly active against babesiosis in cattle, sheep, pigs, horses and dogs, although the small *Babesia* spp. are generally more refractory to treatment than large ones. There appears to be a wide range of individual animal tolerance to the drug; it is well tolerated in horses at the recommended dose, although higher doses may cause severe side effects. Various treatment regimens are used for eliminating babesiosis in cattle, horses and dogs. In most cases the recommended dose is given in divided doses (e.g. 5 mg/kg, twice at 24-hour intervals) to eradicate *Babesia* spp. infections in horses, or 1.75 mg/kg twice at 24-hour intervals to reduce or avoid neurotoxic side effects in horses (lethargy, incoordination and seizures) and dogs (ataxia, opisthotonus, nystagmus, extensor rigidity, coma and even death). Local reactions can occur in cattle and in horses there may be skin sloughing and abscessation following injection. In camels there may be mortality at the recommended dose rate.

Diminazene is also effective against *T. c. congolense* and *T. v. vivax*, but is less active against *T. b. brucei* and *T. b. evansi* infections and shows no activity against *T. c. simiae*. Widespread use may lead to development of diminazene-resistant *T. v. vivax* and *T. c. congolense* strains. As a rule, diminazene-resistant strains are susceptible to isometamidium. Trypanosomes resistant to other drugs (except quinapyramine) are commonly susceptible to diminazene.

Phenamidine is used for treating canine and equine babesiosis and has also been used in *Babesia bigemina* infections in cattle. Frequent relapses may occur in *B. gibsoni* infections in dogs. The mechanism of drug action is uncertain but may be similar to that of pentamidine and diminazene.

Arylamides and urea derivatives

Nitroimidazole and **dinitroimidazole** are arylamides (nitrobenzamides) used as coccidiostats in poultry, appearing to affect first-generation meronts; they are active against *Eimeria tenella* and *E. necatrix* infections but have limited activity against *E. acervulina*. Both drugs have been used in combination with roxarsone as in-feed coccidiostats for use in chickens.

Nicarbazin (phenylurea) is also used as a coccidiostat in the control of coccidiosis in poultry, appearing to affect first-generation meronts (starter feed only) usually in the winter and for that reason resistance of coccidia to nicarbazin has not been that widespread. It is also used in combination with narasin as it shows synergistic effect with the ionophores. It affects second-generation meronts, impairing oocyst formation and allowing treated birds to develop immunity against coccidia. There may be problems with side effects, as it can cause increased sensitivity to heat stress during summer, which results in growth depression and mortality in broilers. The drug should not be fed to laying hens because of toxic side effects (reduced hatchability, interruption of egg-laying).

Imidocarb dipropionate is a phenylurea and is the drug of choice for the treatment of babesiosis in cattle, horses and dogs. It appears to act directly on the parasite leading to an alteration in morphology, and is effective in both treatment and prevention without interfering with the development of immunity.

Ethopabate is an arylamide and has a similar mode of action to the sulphonamides, acting as a *para*-aminobenzoic acid (PABA) agonist, blocking the utilisation of PABA into amino acids and DNA synthesis. It has been administered in combination with amprolium

to achieve a broader spectrum of activity for the prophylaxis and treatment of coccidiosis in chickens and turkeys. With chicken coccidia, it has good innate activity against *Eimeria acervulina*, is less active against *E. maxima* and *E. brunetti* and has no activity against *E. tenella*.

Quinuronium sulphate was for many years the drug of choice in treating bovine babesiosis (*B. bigemina*, *B. bovis*, *B. divergens*); it is also active against large *Babesia* spp. of pigs, horses and dogs. The drug has a low therapeutic index and may stimulate the parasympathetic nervous system resulting in excessive salivation, frequent urination, or dyspnoea caused by anticholinesterase activity. The mode of action is unknown.

These compounds have similar modes of action and act by uncoupling oxidative phosphorylation through inhibition of glycerol phosphate oxidase and glycerol phosphate dehydrogenase, which prevents reoxidation of NADH and decreases ATP synthesis.

Sulphonic acids

Suramin and **trypan blue** were amongst the first antiprotozoals. **Suramin** was one of the first antitrypanosomal drugs developed and shows high efficacy against trypanosomes of the subgenus *Trypanozoon* (*T. b. brucei*, *T. b. evansi*, *T. equiperdum*) and is the drug of choice for *T. b. evansi* infections (surra) in camels and horses. The drug inhibits enzymes in the glucose metabolism pathway, preventing reoxidation of NADH and decreased ATP synthesis. It may be toxic in horses, causing oedema of sexual organs, lips and eyelids or painful hoofs. Intramuscular administration can cause severe necrosis at the injection site and suboptimal dosing (<1 g per 100 kg body weight) may lead to suramin-resistant strains.

Trypan blue is an azo-naphthalene dye used for the treatment of babesiosis and was the first specific drug with activity against *B. bigemina* in cattle, but its use leads to blue staining of meat and milk, and it has been largely replaced by the diamidines.

Naphthoquinones

Menoctone, **parvaquone** and **buparvaquone** are naphthoquinones with marked anti-theilerial activity. They appear to block electron transport at the ubiquinone level. The mechanism of selective toxicity might be due to a difference between parasite and mammalian ubiquinone.

Menoctone was the first drug with high anti-theilerial activity, causing marked degeneration in appearance of macroschizonts and suppression of parasitaemia in established *Theileria parva parva* infections in cattle. Its use has now been discontinued.

Parvaquone is highly active against theileriosis (*Theileria p. parva* and *T. annulata*) infections in cattle when treatment is performed in the early stage of infection, allowing development of protective immunity without apparent clinical signs.

Buparvaquone is an analogue of parvaquone with a substituted alkyl group, and slows down metabolic degradation of the parent compound, increasing efficacy against these species.

Miscellaneous diphenyls

Robenidine is a guanidine derivative and affects the late first-generation and second-stage meronts of *Eimeria*. It is both coccidiostatic

and coccidiocidal and is used for the treatment of coccidiosis in chickens, turkeys and rabbits. It has a broad spectrum of activity but in rabbits it is active against intestinal *Eimeria* spp. only. It is thought to interfere with energy metabolism by inhibition of respiratory chain phosphorylation and ATPase activity.

Dapsone and **acedapsone** are sulphones active against *Plasmodium* and are generally used in combination products only for treating human malaria. Their mode of action is similar to the sulphonamides, acting as antifolate drugs by blocking the incorporation of PABA to form dihydrofolic acid.

Pyridine derivatives

Decoquinat and **methylbenzoquat** are 4-hydroxyquinolones that act on the sporozoites and first-generation meronts of *Eimeria*, interfering with electron transport at the cytochrome B level and mitochondrial metabolism. Hydroxyquinolones are almost entirely coccidiostatic with activity against sporozoites and trophozoites of all *Eimeria* spp. As single compounds they have had only limited success as a result of serious and immediate drug resistance in the field, such that methylbenzoquat-resistant *Eimeria* cannot be controlled by the drug at any level.

Decoquinat has been used for the control of coccidiosis in poultry and is used for the prevention and control of coccidiosis in cattle and sheep. It should not be administered to lactating animals or laying poultry.

Methylbenzoquat is usually administered in combination with clopidol or meticlorpindol, mainly in shuttle or rotation programmes to achieve a broader spectrum of activity for the prophylaxis and treatment of coccidiosis in chickens and turkeys.

Iodoquinol is a 4-hydroxyquinolone that is active against *Entamoeba*.

Quinine, **chloroquine**, **hydroxychloroquine**, **primaquine** and **mefloquine** are quinolines used primarily as antimalarial treatments in human medicine, inhibiting electron transport processes by inhibiting pyrimidine synthesis.

Primaquine diphosphate is active against tissue stages of *Plasmodium*, but is much less active against erythrocytic stages. It has been shown to be active against *Babesia felis* in cats at 0.5 mg/kg by intramuscular injection, although doses above 1 mg/kg caused mortality. It has also been used in the treatment or prevention of avian malaria (100 mg/kg orally).

Clopidol and **meticlorpindol** are pyridinols and are active against first-generation meronts, arresting sporozoite and trophozoite development; they are effective against all *Eimeria* spp. in chickens, although resistance problems limit their use to shuttle programmes. Both compounds need to be given before or shortly after exposure and are used as a coccidiostats. Clopidol is used in the prevention of coccidiosis in chickens, partridge, guinea fowl, pheasants and rabbits with a high safety index.

Emetine and **dehydroemetine** are isoquinolines with activity against *Entamoeba*. The acridine derivative, **quinacrine**, is active against *Plasmodium* and *Giardia*. **Acriflavine** hydrochloride is active against *Babesia bigemina* and other large *Babesia* spp.

Pyrimidine derivatives

Amprolium is structurally similar to thiamine (vitamin B₁) and is a competitive thiamine antagonist. Because of the relatively high

thiamine requirement of rapidly dividing coccidian cells compared with most host cells, the drug has a high safety margin. Amprolium acts on first-generation meronts, thereby preventing differentiation of merozoites, but has poor activity against some *Eimeria* spp. It is often used in combination with ethopabate but its use has declined in many countries for safety and tolerance reasons in food-producing animals. Amprolium, and amprolium plus ethopabate, have been used as feed additives for use in chickens, guinea fowl and turkeys for the prevention of coccidiosis, showing activity against *Eimeria tenella* and *E. necatrix*, and to a lesser extent against *E. maxima* of chickens, and also the pathogenic *Eimeria* spp. of turkeys.

Amprolium plus ethopabate have been combined with sulphamethoxazole and pyrimethamine to extend their activity spectrum and to improve efficacy against amprolium-resistant *Eimeria* spp., but such combinations have been discontinued in some countries because of residue problems.

Amprolium, and amprolium plus ethopabate, have also been used for the treatment and control of coccidiosis in pheasants (but are not active against all *Eimeria* spp.); in lambs and calves; in sows to control disease in suckling pigs before and after farrowing; and in rabbits to control intestinal *Eimeria* spp., but they are ineffective against hepatic coccidiosis in rabbits.

Pyrimethamine and **trimethoprim** are both folate antagonists with activity against *Pneumocystis* and are useful for treating various types of coccidiosis (eimeriosis, toxoplasmosis, sarcocystiosis, neosporosis), malaria and bacterial infections. These compounds target the enzyme dihydrofolate reductase, inhibiting pyrimidine biosynthesis and DNA metabolism, and are usually used in combination with long-acting sulphonamides. As antifolates they synergise the anticoccidial action of sulphonamides by blocking the same biosynthetic pathway.

Halofuginone is a quinazoline affecting first- and second-generation meronts of *Eimeria* and is used in the control of coccidiosis in chickens and turkeys. The drug has also been shown to possess marked anti-theilerial activity in cattle, and is available in some countries for the prevention and treatment of cryptosporidiosis in calves. It has also been shown to be effective against acute sarcosporidiosis in goats and sheep (*Sarcocystis capracanis* and *S. ovicanis*, respectively, at 0.67 mg/kg on two successive days). The therapeutic index of halofuginone is low and overdose may produce severe diarrhoea and cachexia.

Allopurinol is a pyrazolopyrimidine and is a xanthine oxidase inhibitor, used alone or in combination with meglumine antimoniate for the treatment of leishmaniasis in dogs.

Aprinocid is no longer available due to the rapid emergence of resistant strains, but it was used as a feed additive for the prevention of coccidiosis in broiler chickens, with a broad spectrum of activity except against *Eimeria tenella*. The compound inhibits sporulation of oocysts and may be coccidiostatic after a short medication period or coccidiocidal after long periods of medication. Arprinocid acts against coccidia by inhibiting hypoxanthine transport.

Phenathridiums

This group of compounds, which includes **isometamidium**, **homidium** and **quinapyramine**, has been used exclusively in the treatment of trypanosomosis. The mode of action appears to be interference with nucleic acid synthesis by intercalative DNA binding. Other drugs of this series – **pyrithidium**, **phenidium chloride** and **dimidium bromide** – were replaced because of a high incidence

of delayed toxicity, including marked liver damage and severe local reaction at the injection site.

Isometamidium is a synthetic hybrid of the diazotised *p*-amino-benzamidine moiety of diminazene molecule linked with homidium chloride. The drug is highly active against *T. v. vivax* infections in ruminants and horses as well as against *T. c. congolense* infections in ruminants, horses and dogs. It is less active against *T. b. brucei* and *T. b. evansi* infections in horses, ruminants, camels and dogs. The recommended dose is usually well tolerated by cattle. However, intramuscular injection can cause severe local reactions at the injection site. Intravenous injection in horses and camels may avoid local reaction but may cause systemic toxicity (salivation, tachycardia, profuse diarrhoea, hindleg weakness and collapse due to histamine release).

Homidium salts (bromide or chloride) are effective against *T. v. vivax* infections in cattle but less so against *T. c. congolense* and *T. b. brucei*. Their limited protective activity in cattle depends on severity of challenge and may last 3–5 weeks. Homidium can also be used for treating *T. v. vivax* and *T. c. congolense* infections in horses and dogs. Widespread use in cattle resulted in the appearance of resistant *T. c. congolense* strains in East and West Africa. Homidium-resistant trypanosomes can be controlled by diminazene or isometamidium at increased dose rates. The drug is generally well tolerated at the recommended dose and also at higher dose levels, but may be irritant at sites of injection. Deep intramuscular injection effectively reduces local irritations. Severe reactions may occur in horses after intramuscular injection, whereas intravenous injection seems to be well tolerated.

Quinapyramine is highly active against *T. c. congolense*, *T. v. vivax*, *T. b. brucei* and *T. b. evansi* and reaches therapeutic levels quickly. The target of action of quinapyramine is protein synthesis, displacing magnesium (Mg^{2+}) ions and polyamines from cytoplasmic ribosomes, leading to extensive loss of ribosomes and condensation of kinetoplast DNA. The drug can cause local and systemic reactions (salivation, shaking, trembling, diarrhoea, collapse) in cattle, horses, dogs and pigs within minutes of treatment. Unexpected acute toxicity and the rapid development of drug-resistant strains of *T. c. congolense* have limited its usefulness in treating trypanosomosis in cattle. However, the drug seems to be safe and efficient for treating surra (*T. b. evansi*) in camels and horses as well as *T. b. evansi* infections in pigs. Quinapyramine-resistant strains are usually controlled by isometamidium. Quinapyramine is active against suramin-resistant strains of *T. b. evansi* and *T. b. brucei*.

Triazones

Asymmetrical triazones

Diclazuril and **clazuril** are asymmetrical triazones with a broad spectrum of activities against various coccidia in birds and animals at low concentrations (0.5–2 ppm in feed). **Diclazuril** has strong anticoccidiocidal activity and has been developed as a feed additive for the prevention of coccidiosis in chickens and turkeys. It is active against developing first- and second-generation meronts and gamonts of *Eimeria tenella* and other pathogenic *Eimeria* spp. of chickens, but developmental stages most affected by diclazuril varies with the *Eimeria* species. It is highly effective against all stages of *E. tenella* but only against gamont stages of *E. maxima*. Because of the development of resistance, it is used frequently in shuttle programmes. Diclazuril is also used for the treatment of rabbit

coccidiosis, showing high activity against hepatic and intestinal coccidiosis, and in the treatment and prevention of coccidiosis in sheep and cattle.

Clazuril has only limited action against some chicken coccidia, but is highly active against coccidiosis in pigeons.

Symmetrical triazones

Toltrazuril is a symmetrical triazone compound and is active against all intracellular stages of coccidia found in chicken, geese, ducks and cattle, sheep, goats and pigs. Toltrazuril is generally used therapeutically for the treatment of outbreaks of coccidiosis. In some species, it can be administered via drinking water and, because of its long residual activity, can be used intermittently to allow the development of protective immunity.

Benzimidazoles

The benzimidazoles have been described in detail in the section on anthelmintics at the beginning of this chapter.

Benzimidazoles such as **mebendazole**, **fenbendazole** and **alben-dazole** are active against *Giardia* infections in humans, farm animals and dogs; however, repeat treatments may be necessary to eliminate parasites because of reinfection.

Antibacterials

Sulphonamides

Sulphonamides, such as **sulphadimidine**, **sulphamethoxy-pyridazine**, **sulphaguanidine**, **sulphaquinoxaline** and **sulphachloropyrazine**, are structural antagonists of para-aminobenzoic acid (PABA), which is incorporated into folic acid. They inhibit the conversion of dihydrofolic acid to tetrahydrofolic acid at the dihydropyrimidate synthase step. Tetrahydrofolate is an important cofactor in many active single-carbon transfer reactions required for the synthesis of certain amino acids, purines and especially the synthesis of deoxythymidylate required for DNA synthesis. Large doses used for therapeutic applications often cause toxicity (haemorrhagic syndrome, kidney damage and growth depression).

Sulphonamides were among the first anticoccidials and are active against first- and second-stage meronts, being coccidiostatic at low doses and coccidiocidal at higher doses. Many of the compounds used in chickens had a broad spectrum of activity against intestinal *Eimeria* spp. but only a moderate effect on *E. tenella* in chickens, but their use has been stopped in many countries. Sulphonamides have also been used in the treatment of coccidiosis in cattle, sheep, pigs, dogs, cats and rabbits. When given in combination with pyrimethamine and other diaminopyrimidines, long-acting sulphonamides (e.g. sulphadoxine or sulphamethoxine) are highly active antibacterials, antimalarials and anticoccidials.

Nitroimidazoles

The nitroimidazoles include **dimetridazole**, **ornidazole**, **ronidazole**, **tinadazole**, **carnidazole** and **metronidazole**, which appear to interfere with RNA synthesis, and **nifursol**, which acts by causing damage to lipids and DNA within the cells.

These compounds exhibit potent activity against trichomonads, *Histomonas*, *Spirotrunculus* and *Giardia*, and were the drugs of choice for these infections in turkeys and gamebirds. Ronidazole, dimetridazole and nifursol were used in the treatment of *Histomonas* infections in turkeys and gamebirds (pheasants, partridge); however, because of concerns over mutagenicity their use has been suspended in many countries. Carnidazole is used for the treatment of trichomonosis in pigeons. Metronidazole, ornidazole and tinazole are used in humans for the treatment of giardiasis and amoebiasis.

Nitrofurans

The nitrofurans, which include **furazolidone**, **nitrofurazone** and **nitrofurantoin**, are relatively broad-spectrum bactericidal drugs and have coccidiostatic activity; concerns over toxicity and carcinogenicity have restricted their widespread use and they are prohibited from use in many countries. **Furazolidone** has been used for the prevention and treatment of coccidiosis in chickens, turkeys and pigs and for the treatment of bacterial digestive tract infections and giardiasis. **Nitrofurazone** is active against second-generation meronts of *Eimeria tenella* and *E. necatrix* infections in poultry, and has been used for control of coccidiosis in lambs and goat kids.

Ionophores

The polyether ionophores are fermentation products of *Streptomyces* or *Actinomadura*. These are currently the most widely used anticoccidial compounds, mainly for the control of poultry coccidiosis. **Monensin**, **narasin**, **salinomycin**, **maduramicin** and **semduramicin** are 'monovalent' ionophores preferentially binding to the monovalent ions sodium and potassium (Na^+ , K^+), although divalent cations are also bound. **Lasalocid** has the ability to complex divalent cations (Ca^{2+} , Mg^{2+}) and is termed a 'divalent' ionophore. The effect is to destroy cross-membrane ion gradients. They may also block host carbohydrate transport and hence deprive carbohydrate supply from intracellular parasites.

Ionophores act on the intestinal free forms of coccidian stages (sporozoites, merozoites and gametocytes) when the drug comes into contact with them in the intestinal lumen.

These compounds are extremely toxic to horses. Ionophores such as monensin, narasin and salinomycin may cause severe growth retardation when administered with tiamulin, and most of the ionophores may interact with sulphonamides, chloramphenicol and erythromycin.

Monensin has been used extensively in the broiler industry but drug tolerance, as with other ionophores, limits its use to shuttle programmes. It is effective against coccidia in cattle, sheep and rabbits when used prophylactically in feed.

Narasin is given in combination with nicarbazine to improve coccidiosis control, and the drug combination may be used in the starter phase of shuttle programmes followed by a different ionophore in the grower–finisher phase.

Salinomycin has broad-spectrum activity and better activity against *Eimeria tenella* and *E. acervulina* than other related ionophores, including drug-tolerant *Eimeria* spp. in the field. In turkeys, it may cause severe toxicity with growth depression, excitement,

paralysis of head and legs and death if feed containing recommended or lower doses is fed for long periods.

Lasalocid may alter water excretion in treated birds via dietary electrolytes to the extent that wet litter may be a problem at higher drug concentrations. At concentrations of 75 ppm, activity against *E. tenella* is good but insufficient against *E. acervulina*. In the field, lasalocid may improve control of coccidiosis where *E. tenella* strains show tolerance to other ionophores.

Macrolide and lincosamide antibiotics

This group of compounds is better known and more widely applied for the treatment of bacterial and fungal infections. The mode of action appears to be inhibition of protein synthesis. **Spiramycin** inhibits protein synthesis by inhibiting the translocation of peptidyl-tRNA. It has been used for the treatment of *Toxoplasma* infections. **Clindamycin** is a lincosamide with a similar mode of action, and has been used to treat *Plasmodium*, *Babesia* and *Toxoplasma* infections. It is considered the antiparasitic of choice for the treatment of clinical toxoplasmosis in cats and dogs.

Amphotericin B is a polyene macrolide antibiotic used mainly as an antifungal agent but is also used as a second-line drug for the treatment of *Leishmania*. The drug is extremely nephrotoxic but lipid and unilamellar liposome formulations of amphotericin B have been developed with lower toxicity.

Aminoglycoside antibiotics

Aminoglycoside antibiotics are bactericidal agents and are widely applied for the treatment of Gram-negative bacterial infections. Aminoglycosides are not absorbed from the gastrointestinal tract and treatment via this route is reserved for the treatment of gastrointestinal infections. **Paromomycin** has activity against *Entamoeba*, *Giardia*, *Balantidium* and *Leishmania*.

Tetracycline antibiotics

The tetracyclines are broad-spectrum antibacterials active against a range of Gram-positive and Gram-negative bacteria, but also against the Rickettsiales (*Rickettsia*, *Ehrlichia*, *Anaplasma*), and *Mycoplasma* and *Chlamydia*. The mode of action is thought to be via inhibition of protein synthesis.

Oxytetracycline, **tetracycline** and **chlortetracycline** have similar properties and may be given orally or by intramuscular injection. **Doxycycline** is more lipophilic than the other tetracyclines and is better absorbed orally and penetrates better into the lung and cerebrospinal fluid. Members of this group exhibit the broadest antiprotozoal activity and have been used for the treatment of *Plasmodium*, *Balantidium*, *Theileria* and *Entamoeba* infections. Oxytetracycline has been shown to control active *Babesia divergens* infections in cattle by continuous administration of 20 mg/kg every 4 days.

USE OF ANTIPROTOZOALS

The use of antiprotozoals as therapeutic or prophylactic agents is similar to that described for anthelmintics.

Table 5.2 Trypanocidal drugs.

| Generic name | Dosage rate (mg/kg) | Route | Remarks |
|-------------------------------|---------------------|-------|--|
| Suramin | 10 | i.v. | Mainly used against <i>T. evansi</i> in camels. Some activity against <i>T. brucei</i> in camels and <i>T. equiperdum</i> in horses |
| Diminazene aceturate | 3.5–7 | i.m. | Mainly used in cattle and small ruminants against <i>T. vivax</i> , <i>T. congolense</i> and <i>T. brucei</i> |
| Homidium bromide | 1 | i.m. | Mainly used in cattle and small ruminants against <i>T. vivax</i> , <i>T. congolense</i> and <i>T. brucei</i> . Should be dissolved in hot water. Potentially carcinogenic |
| Homidium chloride | 1 | i.m. | Mainly used in cattle and small ruminants against <i>T. vivax</i> , <i>T. congolense</i> and <i>T. brucei</i> , but soluble in cold water |
| Quinapyramine methyl sulphate | 5 | s.c. | Active against <i>T. vivax</i> , <i>T. congolense</i> and <i>T. brucei</i> in cattle. Now mainly used against <i>T. evansi</i> , <i>T. brucei</i> in camels and horses; activity against <i>T. equiperdum</i> in horses |
| Isometamidium chloride | 0.25–0.5 | i.m. | Used mainly in cattle (<i>T. vivax</i> , <i>T. congolense</i>), as a curative at lower rates, as a prophylactic at higher rates. Also contains homidium, and is therefore to be considered as potentially carcinogenic |

METHODS OF ADMINISTRATION

Anticoccidials used for controlling enteric coccidia principally belonging to the genus *Eimeria* are mainly administered in feed. In the poultry industry, it is usual to employ anticoccidials in broiler birds continuously in feed until just before slaughter. In layer replacement stock, pullets are medicated continuously until commencement of egg-laying. Continuous use of anticoccidials may lead to ineffective treatment due to drug resistance; as a consequence, various rotational programmes have been developed by the poultry industry to reduce or avoid this problem.

Antiprotozoals are generally used in two ways: therapeutically, to treat existing infections or clinical outbreaks, or prophylactically, in which the timing of treatment is based on knowledge of the epidemiology. Clearly, prophylactic use is preferable where administration of a drug at selected intervals or continuously over a period can prevent the occurrence of disease.

Most other antiprotozoal agents, particularly those targeting haemoprotozoan infections, are given parenterally, either by subcutaneous or intramuscular injection (e.g see Table 5.2 Trypanocidal drugs).

Not all trypanocides are available in every country and there is also no guarantee that production of all or any of them will continue for economic reasons.

ECTOPARASITICIDES (INSECTICIDES/ACARICIDES)

The control of the ectoparasites found on animals, including fleas, lice, ticks, mange mites, warbles and nuisance flies, is largely based on the use of chemicals. There is a vast world market in these

chemicals with increasingly more spent on flea control products in companion animals.

ECTOPARASITICIDES AND THEIR MODE OF ACTION

Three main chemical groups have been used as the basis for the common ectoparasiticides: the organochlorines, the organophosphates and the synthetic pyrethroids. Other groups that are also used include the carbamates (primarily in poultry), the formamidines, the triazines, benzylbenzoate and natural plant products such as pyrethrin. The avermectins and milbemycins have also been shown to have high activity against a range of ectoparasites and these are increasingly used for ectoparasite control, for example mange in sheep, cattle and pigs. There are also compounds which affect the growth and development of insects. Based on their mode of action they can be divided into chitin inhibitors, chitin synthesis inhibitors and juvenile hormone analogues. Insect growth regulators (IGRs) are widely used for flea control in domestic pets and for blowfly control in sheep but have limited use in other host species. For example, lufenuron blocks the formation of larval chitin in fleas, and cyromazine disrupts growth regulation in blowfly larvae on sheep.

Organochlorines

Organochlorines are now banned in many countries on the grounds of both human and environmental safety. Organochlorines fall into three main groups.

- *Chlorinated ethane derivatives.* Includes DDT (dichlorodiphenyltrichloroethane), DDE (dichlorodiphenyldichloroethane) and DDD (dicofol, methoxychlor). Chlorinated ethanes cause inhibition of sodium conductance along sensory and motor nerve fibres by holding sodium channels open, resulting in delayed repolarisation of the axonal membrane. This state renders the nerve vulnerable to repetitive discharge from small stimuli that would normally cause an action potential in a fully repolarised neurone.
- *Cyclodienes.* The cyclodienes include chlordane, aldrin, dieldrin, heptachlor, endrin and tozaphene. They appear to have at least two component modes of action: inhibition of GABA-stimulated Cl^- flux and interference with calcium ion (Ca^{2+}) flux. The resultant inhibitory postsynaptic potential leads to a state of partial depolarisation of the postsynaptic membrane and vulnerability to repeated discharge.
- *Hexachlorocyclohexanes.* Includes benzene hexachloride (BHC) and its gamma-isomer lindane. The mode of action is similar to the cyclodienes, with the drug binding to the picrotoxin side of the GABA receptor resulting in inhibition of GABA-dependent Cl^- flux into the neurone.

DDT and BHC were used extensively for flystrike control but were subsequently replaced in many countries by the more effective cyclodiene compounds, dieldrin and aldrin. DDT and lindane (BHC) were widely used in dip formulations for the control of sheep scab but the organophosphates and synthetic pyrethroids have largely replaced them. They have the advantage that the effect of the drug persists for a longer time on the coat or fleece of the animal but the disadvantage, at least in food animals, is that they persist in animal tissues. If toxicity occurs the signs are those of

central nervous system (CNS) stimulation with hypersensitivity, followed by increasing muscular spasm progressing to convulsions.

Organophosphates

These include a vast number of compounds, of which chlorfenvinphos, coumaphos, crotoxyphos, crufomate, cythioate, diazinon, dichlofenthion, dichlorvos, fenthion, iodofenphos, malathion, phosmet, propetamphos, ronnel, tetrachlorvinphos and trichlorphon have been among the most commonly used. These can persist in the animal's coat or fleece for reasonable periods, but residues in animal tissues are short-lived. Some have the ability to act systemically, given parenterally, orally or as a pour-on, but the effective blood levels of these are maintained for only 24 hours. The organophosphates are cholinesterase inhibitors; if acute toxicity occurs, the signs are salivation, dyspnoea, incoordination, muscle tremors and sometimes diarrhoea. There is also concern over the chronic toxicity that may be associated with use of these compounds and which is thought to be the result of inhibition of the enzyme neurotoxic esterase.

Synthetic pyrethroids

The common synthetic pyrethroids in use include **deltamethrin**, **permethrin**, **cypermethrin**, **flumethrin** and **fenvalerate**. The main value of these compounds lies in their repellent effect and since they persist well on the coat or skin, but not in tissue, they are of particular value against parasites which feed on the skin surface, such as lice, some mites and nuisance flies. Pyrethroids act as neurotoxins on sensory and motor nerves of the neuroendocrine system and CNS of insects. All the pyrethroids are lipophilic and this property helps them to act as contact insecticides. Some have the ability to repel and to 'knock down', i.e. affect flight and balance without causing complete paralysis. Because the synthetic pyrethroids have a strong affinity for sebum, this property has been capitalised upon by incorporating them into ear tags or tail bands. The synthetic pyrethroids are fairly safe, but if toxicity does occur it is expressed in the peripheral nervous system as hypersensitivity and muscle tremors. Synthetic pyrethroids are also extremely toxic to fish and aquatic invertebrates and there are environmental concerns over their use.

Carbamates

Carbamate insecticides are closely related to the organophosphates and are anticholinesterases, but unlike organophosphates they appear to induce a spontaneously reversible block of the enzyme acetylcholinesterase without changing it. The two main carbamate compounds in use in veterinary medicine are **carbaryl** and **propoxur**, with **butocarb** and **carbanolate** also used in the control of poultry ectoparasites. Carbaryl has low mammalian toxicity but may be carcinogenic and is often combined with other active ingredients. **Fenoxycarb** is used for flea control and appears to have a mode of action closely related to the juvenile hormone analogues, preventing embryonic development in flea eggs, larval development and adult emergence (see section Insect growth regulators). It has been formulated with permethrin or chlorpyrifos for use on animals or in liquid concentrate form for environmental flea control.

Avermectins/milbemycins

These are effective at very low dose levels against certain ectoparasites when given parenterally and by pour-on applications. They are particularly effective against ectoparasites with tissue stages, such as warbles, bots and mites, and have good activity against blood-sucking parasites such as lice and one-host ticks. As in nematodes, they are thought to affect cell function by direct action on Cl^- channels. They have a very wide safety margin. Some avermectins have a marked residual effect and a single treatment given parenterally is still effective against lice or mites hatching from eggs 3–4 weeks later.

Selamectin has high activity against fleas of cats and dogs (*Ctenocephalides*) and prevents flea infestations on dogs and cats for a period of 30 days. It is safe and effective in controlling mite (*Otodectes*, *Sarcoptes*) and tick (*Rhipicephalus*) infestations.

Formamidines

The main member of this group is **amitraz**, which acts at octopamine receptor sites in ectoparasites resulting in neuronal hyperexcitability and death. It is available as a spray or dip for use against mites, lice and ticks in domestic livestock. In cattle, for example, it has been widely used in dips, sprays or pour-on formulations for the control of single-host and multi-host tick species. In dipping baths, it can be stabilised by the addition of calcium hydroxide, and maintained by standard replenishment methods for routine tick control. An alternative method has been the use of total replenishment formulations whereby the dip bath is replenished with the full concentration of amitraz at weekly intervals prior to use. Amitraz has also been shown to have expellent action against attached ticks. It has been shown to be effective in controlling lice and mange in pigs and psoroptic mange in sheep.

In small animals, amitraz is available for topical application for the treatment and control of ticks, and for canine demodicosis (*Demodex*) and sarcoptic mange (*Sarcoptes*). Amitraz is contraindicated in horses and in pregnant or nursing bitches and cats, although it has been used at a reduced concentration to treat feline demodicosis. Amitraz is also formulated in collars for tick control in dogs.

Phenylpyrazoles

Fipronil is a phenylpyrazole compound that blocks transmission of signals by the inhibitory neurotransmitter GABA present in insects. The compound binds within the Cl^- channel and consequently inhibits the flux of Cl^- ions into the nerve cell, resulting in hyperexcitation of the insect nervous system. Fipronil is used worldwide for the treatment and control of flea and tick infestations on dogs and cats and has reported activity against mange mites (*Sarcoptes*), ear mites (*Otodectes*), forage mites (*Trombicula*, *Cheyletiella*) and dog lice (*Trichodectes*). It is highly lipophilic and diffuses into the sebaceous glands of hair follicles that then act as a reservoir giving it a long residual activity. Sunlight, immersion in water and bathing do not significantly impact on the performance of products containing this compound. There is evidence that fipronil has an extremely rapid knock-down effect which occurs before the fleas have time to feed and hence it may be especially useful in cases of flea allergic dermatitis.

Nitroguanidines and spinosyns

Imidacloprid is a chloronicotinyln insecticide, a synthesised chlorinated derivative of nicotine. It specifically binds to nicotinic acetylcholine receptors in the insect's CNS, leading to inhibition of cholinergic transmission resulting in paralysis and death. This mode of action is the same as nicotine, which has been used as a natural insecticide for centuries. The favourable selective toxicity of imidacloprid appears to be due to the fact that it only seems to bind to the acetylcholine receptors of insects, having no effect on these receptors in mammals. Its activity appears to be mainly confined to insect parasites and it is available as a spot-on product in many countries for use in dogs and cats for the control of adult fleas, providing protection against reinfestation for up to 4–5 weeks.

Spinosad is a fermentation product of the soil actinomycete *Saccharopolyspora spinosa*, and has been developed in some countries for use on sheep in the control of blowfly strike and lice.

Oxadiazines

Indoxacarb is a pro-insecticide that requires biological, or metabolic, activation in the target insect host to an active insecticidal metabolite. The active metabolite induces irreversible hyperpolarisation of insect nerve cell membranes, by binding to voltage-gated Na^+ channels, leading to impaired insect nerve function, feeding cessation, paralysis and death of susceptible insects. Indoxacarb is used for the control of fleas in dogs and cats.

Isoxazolines

Afoxolaner and **fluralaner** are isoxazoles, a new class of insecticide, and act as non-competitive GABA receptor agonists, binding to Cl^- channels in nerve and muscle cells of the target parasites. Afoxolaner and fluralaner are given orally and used for the control of fleas and ticks in dogs.

Insect growth regulators

Several IGRs are used throughout the world, and represent a relatively new category of insect control agents. They constitute a group of chemical compounds that do not kill the target parasite directly, but interfere with growth and development. IGRs act mainly on immature stages of the parasite and as such are not usually suitable for the rapid control of established adult populations of parasites. Where parasites show a clear seasonal pattern, IGRs can be applied prior to any anticipated challenge as a preventive measure.

Based on their mode of action they can be divided into chitin synthesis inhibitors (benzoylphenyl ureas), chitin inhibitors (triazine/pyrimidine derivatives) and juvenile hormone analogues. IGRs are widely used for flea control in domestic pets and for blowfly control in sheep but have limited use in other host species.

Benzoylphenyl ureas

The benzoylphenyl ureas (**diflubenzuron**, **flufenoxuron**, **fluaxuron**, **lufenuron** and **triflumuron**) are chitin inhibitors, of which several have been introduced for the control of ectoparasites of

veterinary importance. Chitin is a complex aminopolysaccharide and a major component of the insect's cuticle. During each moult it has to be newly formed by polymerisation of individual sugar molecules. Chitin molecules, together with proteins, are assembled into chains, which in turn are assembled into microfibrils. The exact mode of action of the benzoylphenyl ureas is not fully understood. They inhibit chitin synthesis but have no effect on the enzyme chitin synthetase, and it has been suggested that they interfere with the assembly of the chitin chains into microfibrils. When immature insect stages are exposed to these compounds they are not able to complete ecdysis and as a consequence die during the moulting process. Benzoylphenyl ureas also appear to show a transovarial effect. Exposed adult female insects produce eggs in which the compound is incorporated into the egg nutrient. Egg development proceeds normally but the newly developed larvae are incapable of hatching. Benzoylphenyl ureas show a broad spectrum of activity against insects but have relatively low efficacy against ticks and mites. The exception to this is fluzuron, which has greater activity against ticks and some mite species.

Benzoylphenyl ureas are highly lipophilic molecules and, when administered to the host, build up in the body fat from where they are slowly released into the bloodstream and excreted largely unchanged.

Diflubenzuron and **flufenoxuron** are used for the prevention of blowfly strike in sheep. Diflubenzuron is available in some countries as an emulsifiable concentrate for use as a dip or shower. It is more efficient against first-stage larvae than second and third instars and is therefore recommended as a preventive, providing 12–14 weeks' protection. It may also have potential for the control of a number of major insect pests such as tsetse flies. Fluzuron is available in some countries for use in cattle as a tick development inhibitor. When applied as a pour-on it provides long-term protection against the one-host tick *Rhipicephalus (Boophilus) microplus*.

Lufenuron is administered orally and is used for the control of fleas of dogs and cats. The drug accumulates in fat tissue allowing subsequent slow release. Fleas take up the drug through the blood and transfer it to their eggs, which are non-viable within 24 hours of administration. The formation of larval chitin structures is blocked, thereby inhibiting the development of flea larvae and providing environmental control of the flea population. For oral administration, the drug must be administered in the food to allow sufficient time for absorption from the stomach. Injectable treatment is given at 6-monthly intervals while oral treatment is given once monthly during summer, commencing 2 months before fleas become active. As lufenuron has no activity against adult fleas, an insecticide treatment may be required if there is an initial heavy infestation or in cases of severe hypersensitivity.

Triflumuron is active against lice and fleas in dogs.

Triazine/pyrimidine derivatives

Triazine and pyrimidine derivatives are closely related compounds that are also chitin inhibitors. They differ from the benzoylphenyl ureas both in chemical structure and in mode of action, in that they appear to alter the deposition of chitin into the cuticle rather than its synthesis.

Cyromazine, a triazine derivative, is effective against blowfly larvae on sheep and lambs and also against other Diptera, such as house flies and mosquitoes. At recommended dose rates, cyromazine shows only limited activity against established strikes and

must therefore be used prophylactically before anticipated challenge. Blowflies lay eggs usually on the damp fleece of treated sheep. Although larvae are able to hatch out, the young larvae immediately come into contact with cyromazine, which prevents the moult to second instars. The use of a pour-on preparation of cyromazine has the advantage that efficacy is not dependent on factors such as weather, fleece length and whether the fleece is wet or dry. In addition, the persistence of the drug is such that control can be maintained for up to 13 weeks after a single pour-on application, or longer if applied by dip or shower.

Dicyclanil, a pyrimidine derivative, is highly active against dipteran larvae and is available as a pour-on formulation for blowfly control in sheep in some countries, providing up to 20 weeks' protection.

Juvenile hormone analogues

The juvenile hormone analogues mimic the activity of naturally occurring juvenile hormones and prevent metamorphosis to the adult stage. Once the larva is fully developed, enzymes within the insect's circulatory system destroy endogenous juvenile hormones, and final development occurs to the adult stage. The juvenile hormone analogues bind to juvenile hormone receptor sites, but because they are structurally different are not destroyed by insect esterases. As a consequence, metamorphosis and further development to the adult stage does not proceed.

Methoprene is a terpenoid compound with very low mammalian toxicity that mimics a juvenile insect hormone and is regularly used for flea control. It is sensitive to light and will not persist outdoors. It has been used extensively and successfully in indoor environments and on pets in the form of collars, shampoos, sprays and dips and also as a feed through larvicide for hornfly (*Haematobia*) control on cattle. The other member of this group used for the control of fleas in dogs and cats is **pyriproxyfen**.

Essential oils

There is a growing body of evidence indicating the potential value of essential oils as control agents against a range of arthropod ectoparasites, particularly lice, mites and ticks. Essential oils are blends of approximately 20–80 different plant metabolites that are usually extracted from plants through steam distillation. These metabolites are volatile molecules of low molecular weight. Essential oils usually contain two or three major terpene or terpenoid components, which constitute up to 30% of the oil. Their efficacy is often attributed to the oil's major component(s), although there is also evidence that the various oil components may work in synergy. This may be achieved because some oil components aid cellular accumulation and absorption of other toxic components. Nevertheless, the mode of action of many essential oils or components is largely unknown, although there is evidence of toxic effect on the insect nervous system. Toxicity has been demonstrated following immersion and physical contact with treated surfaces but also after exposure to the vapour of these oils, the latter implying that there is a neurotoxic rather than simply a mechanical pathway in their mode of action. However, because of the volatile nature of essential oils, their residual activity may be short-lived. Some ovicidal efficacy has been reported, although it is unclear whether this results from neurotoxicity or mechanical suffocation.

Miscellaneous compounds

Piperonyl butoxide (PBO) is a methylenedioxyphenyl compound that has been widely used as a synergistic additive in the control of arthropod pests. It is commonly used as a synergist with natural pyrethrins, the combination having a much greater insecticidal activity than the natural product alone. The degree of potentiation of insecticidal activity is related to the ratio of components in the mixture, such that as the proportion of PBO increases, so the amount of natural pyrethrins required to evoke the same level of kill decreases. The insecticidal activity of other pyrethroids, particularly of knockdown agents, can also be enhanced by the addition of PBO. The enhancement of activity of synthetic pyrethroids is normally less dramatic but PBO may be included in several formulations. PBO inhibits the microsomal enzyme system of some arthropods and has been shown to be effective against some mites. In addition to having low mammalian toxicity and a long record of safety, PBO rapidly degrades in the environment.

Various products from natural sources, as well as synthetic compounds, have been used as insect repellents. Such compounds include cinerins, pyrethrins and jasmolins (see pyrethroids), citronella, indalone, garlic oil, MGK-264, butoxypolypropylene glycol, DEET (*N,N*-diethyl-meta-toluamide) and DMP (dimethylphthalate). The use of repellents is advantageous as legislative and regulatory authorities become more restrictive towards the use of conventional pesticides.

METHODS OF PESTICIDE APPLICATION AND USES

Farm animals

Traditionally, ectoparasiticides have been applied topically as dusts, sprays, foggers, washes, dips and occasionally used in baits to trap insects. However, with the advent of pour-on and spot-on formulations with a systemic effect, the parenteral administration of drugs such as the avermectins and closantel and the use of impregnated ear tags, collars and tail-tags, the methodology of control applications to animals has changed.

Traditional methods

To be successful, the use of insecticides in dusts, sprays or washes usually requires two or more treatments, since even the most diligent applicant is unlikely to be successful in applying these formulations at the right concentration to all parts of the animal's body. The interval between treatments should be linked to the persistence of the chemical in the skin, hair or wool and to the life cycle of the parasite, further treatment being given prior to completion of another cycle.

Dip baths or spray races containing the necessary concentration of insecticide are used to control mites, lice and ticks and certain dipterans such as blowflies on sheep on a worldwide basis and on cattle in tropical areas. This technique is more successful in sheep where the persistence of insecticide is greater in the wool fleece than in the hair coat found in cattle. It is important to remember that the concentration of insecticide in a dip bath is preferentially 'stripped' or removed as sheep or cattle are dipped, and so must be replenished at a higher than initial concentration, sufficient to

maintain an adequate concentration of the active ingredient. Most dips are based on the organophosphate group and synthetic pyrethroids. Despite human and environmental safety concerns, some countries have reintroduced organochlorines because of developing resistance to organophosphates.

Insect control in dairies or stables may be aided by the use of various resin strips incorporating the insecticide; dichlorvos and trichlorphon are often used for this purpose. Sometimes baits, containing synthetic pheromones, sugars or hydrolysed yeasts, plus insecticide are spread around animal premises to attract and kill dipterans.

Pour-on, spot-on or spray-on

Those available at present contain organophosphates with a systemic action such as fenthion or phosmet, the avermectins/milbemycins or the synthetic pyrethroids. They are recommended for the control of warbles and lice in cattle and lice and keds in sheep. A valuable development is that of pour-on phosmet for the control of sarcoptic mange in pigs and cattle. A single treatment in pigs gives very good results and, if used in sows prior to farrowing, prevents transmission to the litter; two treatments at an interval of 14 days are necessary in cattle. The synthetic pyrethroids are also available as sprays, pour-ons or spot-ons for the treatment of lice and the control of biting and nuisance flies in cattle, sheep and goats.

Ear tags

These are based primarily on the synthetic pyrethroids and occasionally the organophosphates. They are recommended for the protection of cattle against nuisance flies. The tags are usually made of polyvinylchloride impregnated with the insecticide. When attached to an animal's ear the insecticide is released from the surface, dissolves in the sebum secreted by the skin and is then spread over the whole body by the normal grooming actions or ear flapping and tail swishing as well as by bodily contact between cattle. Because the insecticide is rapidly bonded to the sebum on the animal's coat, the treatment is rain-fast; also the tag or tail band continues to release a supply of chemical under all climatic conditions. Since the drugs are located in the sebum, they are not absorbed into the tissue so there is no need for a withdrawal period prior to slaughter nor is it necessary to discard milk. The common synthetic pyrethroids marketed for this purpose are cypermethrin and permethrin. Under conditions of heavy fly challenge a tag should be inserted in each ear, possibly augmented by a tail band.

Parenteral treatment

The avermectins/milbemycins and closantel may be given parenterally to control some ectoparasites. For example, the endectocides have good activity against warbles, lice, many mites and also the one-host tick *Boophilus*. Closantel is available in some tropical countries for use against one-host ticks and sucking lice.

Companion or pet animals

Ectoparasiticides are mainly used as dusting powders, aerosols, washes/shampoos, spot-on preparations and impregnated collars,

while some are available for oral use. They are mainly used for the control of fleas, lice and mange in dogs and cats and for lice, mange and nuisance flies in horses.

Dusting powders

The powders should be shaken well into the animal's fur or hair and, in the case of house pets, into the bedding. The powders commonly used contain pyrethroid-based insecticides with or without the synergist PBO. These are particularly useful for fleas and lice and repeat treatments are generally recommended every 2–3 weeks.

Aerosols

Although easy to use, some of the noisier sprays can upset pets. Overzealous spraying in confined spaces, such as in a cat basket, may produce toxic effects. Sprays available are generally based on pyrethroids and carbamates or a mixture of organophosphates such as dichlorvos plus fenitrothion, or a mixture of the synergist PBO with organophosphates or pyrethroids. Depending on the spray, the aerosol container should be held 15–30 cm from the animal and sprayed for up to 5 seconds for cats and a little longer for dogs. A repeat treatment is often recommended in 7–14 days; however, a single spray application with fipronil can give up to 3 months' protection against reinfestation with fleas in dogs and cats. The aerosol sprays are very effective for fleas and lice, but several treatments may be necessary for mange mites. The synthetic pyrethroids are also available as a wash or spot-on for horses for the control of flies including midges, which are responsible for 'sweet-itch'.

Aerosols containing the insect growth regulator methoprene are available for the control of larval populations of fleas in the environment.

Baths

These are available as shampoos, emulsifiable concentrates, wettable agents or creams for the control of fleas, lice and mange mites. Most preparations are for dogs and care is needed if they are used for cats. Common ingredients are carbaryl, propoxur and the organophosphate phosmet; amitraz is particularly useful for demodectic mange in dogs. The instructions for bathing should be carefully followed and, where necessary, care taken that the insecticide is properly rinsed from the coat. Organophosphate shampoos should not be used when dogs have insecticidal collars.

Insecticidal collars

These are used primarily for flea control and are based on the organophosphates, carbamates and synthetic pyrethroids. The period of protection is claimed to be 3–4 months, but the success of this method of application is variable. Occasional problems arise from contact dermatitis and care should be exercised that the animals do not receive other organophosphate treatments. Apart from collars, impregnated medallions are also available in some countries. Care should be taken with the use of collars in pedigree long-haired cats and greyhound dogs due to individual susceptibility to organophosphate poisoning.

Collars have also been introduced containing deltamethrin for the control of biting flies, including sandflies, as a means of preventing infection with transmissible diseases such as leishmaniosis.

Oral preparations

One organophosphate, cythioate, is marketed as an oral preparation. It is specifically for the treatment of demodectic mange and flea infestations in dogs and flea infestation in cats; the daily administration of tablets is recommended as a supplement to topical application.

Other preparations (spot-ons)

Spot-on preparations containing fenthion, deltamethrin, fipronil, imidocloprid, emodepside and selamectin are now available for the control of fleas, and in some cases ticks, on dogs and cats. In horses, lice and areas of mange mite infestation can be treated topically, but the problem of nuisance or pasture flies remains. It has been suggested that ear tags impregnated with cypermethrin be attached to the saddle or mane as a possible means of incorporating the synthetic pyrethroid into the sebum.

Poultry ectoparasites

The carbamates and the organophosphate malathion are the most widely used. Individual birds are dusted and the insecticide applied in the poultry house, nesting boxes and litter. Cypermethrin is available for the environmental treatment of poultry red mites (*Dermanyssus*).

PARASITICIDE RESISTANCE

ANTHELMINTIC RESISTANCE

Drug resistance is heritable and repeated dosing will therefore select for an increasing proportion of resistant individuals. The mechanisms involve either differences in drug metabolism within the parasite and/or mutations at the binding site of the drug. The prevalence and severity of anthelmintic resistance is increasing and leading to uncontrolled loss of production.

Anthelmintic resistance in small ruminants

Resistance to anthelmintics has been most frequently recorded in sheep and goats (mainly *Haemonchus* spp. and *Trichostrongylus* spp. in tropical and subtropical regions and *Teladorsagia* and occasionally *Cooperia* and *Nematodirus* spp. in temperate areas). This initially involved the benzimidazole group of compounds (1-BZ, benzimidazoles and pro-benzimidazoles) and then the levamisole group (2-LV, levamisole/morantel); more recently, macrocyclic lactone (3-ML, avermectins/milbemycins) resistance has emerged. This sequence of events reflects the period these drugs have been available. The severity and prevalence of resistance differs between different geographic locations and between different species of helminths and animal hosts. Resistance can be particularly significant

in goats. The highest levels of resistance occur in Australia, South America, South Africa, southern parts of the USA and New Zealand. Resistance to the benzimidazoles, levamisole and to some of the macrocyclic lactones is widespread and there are worms which are resistant to all three classes of anthelmintic and in some countries also to some narrow-spectrum drugs. Resistance has also been reported for some drug combination products. Where recent prevalence studies are available it has been shown that the level of resistance to some anthelmintics has increased. Of particular concern is that total anthelmintic failure is now prevalent in parts of Brazil. The situation in Europe differs in that although resistance to the benzimidazoles is high, that for levamisole and the macrocyclic lactones is still comparatively low. However, there are recent reports of isolates with concurrent resistance to 1-BZ, 2-LV and ivermectin (3-ML) but only a few reports of moxidectin resistance. The differences in the rate of emergence of anthelmintic resistance between these agroclimatic zones are considered to be due to the number of parasite generations and biotic potential of the parasite species involved and also to the proportion of the total population not exposed to the drug (i.e. left *in refugia*). Frequency of treatment and underdosing are considered to be the main cause of benzimidazole and levamisole resistance in *Haemonchus* and *Teladorsagia*. The timing of treatments and the presence of larvae *in refugia* may be particularly important in the development of macrocyclic lactone resistance. Trematode resistance to flukicides is currently at lower levels, although there have been increasing reports of triclabendazole resistance in liver fluke (*Fasciola*) in some countries.

Anthelmintic resistance in cattle nematodes

Although anthelmintic resistance is less of a problem in cattle than in sheep and goats, reports of resistance have increased over the last decade and the majority involve resistance to the macrocyclic (3-ML) compounds. There is little information to assess the global problem as very few studies have been conducted on the prevalence in cattle. The main species implicated in benzimidazole resistance are *Cooperia* spp., although in some cases *Ostertagia ostertagi*, *Trichostrongylus axei* and *Haemonchus* spp. have also been involved. Reports of macrocyclic lactone resistance mainly involve *Cooperia* spp., which is the dose-limiting species with this class of compounds. Levamisole resistance is not currently common in cattle. Trematode resistance to flukicides is considered to be at a low level and possibly has been selected in sheep and transmitted to cattle where mixed grazing occurs.

Anthelmintic resistance in horse nematodes

Most of the information originates from the USA and prevalence studies are limited. High levels of resistance to the benzimidazoles (1-BZ) and lower levels to pyrantel (2-LV) exist in horses and the parasites involved are mainly cyathostomins and *Parascaris equorum*. There is recent evidence that macrocyclic lactone (3-ML) resistance is developing in cyathostomins and is becoming more common and widespread in *P. equorum*.

Resistance management strategies

Studies have shown minimal reversion to susceptibility in highly selected homozygous isolates following withdrawal of the selecting

drug and, as a consequence, once resistant worms are present on a livestock enterprise they can be considered as permanent. Therefore, it is important to be able to detect the presence of emerging resistant isolates at an early stage. Unfortunately, the *in vivo* faecal egg count reduction test and the *in vitro* egg hatch assay, larval development assay and larval migration inhibition assay, used to detect the presence of resistant isolates, are time-consuming, insensitive and will only detect resistant parasites when these comprise around 25% of the total population. The use of a discriminating dose of anthelmintic may increase the sensitivity. There is a need for more convenient tests and robust guidelines for their interpretation to enable uptake by the end-user. New molecular-based probes are more sensitive but to date are only available for the benzimidazoles and are mainly used as research tools.

The increasing severity and prevalence of anthelmintic resistance has highlighted the importance of resistance management strategies for the control of nematode infections in livestock. There is an urgent need to change many of the drug treatment strategies, which are known to impose a high level of selection for resistance, and thus preserve the efficacy of current anthelmintics and, most importantly, the two new drugs for use in sheep, monepantel (4-AD) and derquantel (5-SI) (in combination with the 3-ML drug abamectin). Strategies to delay the development/transmission of anthelmintic resistance are discussed in the section Treatment, prevention and control of parasitic gastroenteritis in Chapters 8 and 9, but the concept of refugia is considered here.

Recently, the concept of leaving sufficient numbers of parasites in the environment that are not exposed to anthelmintic treatment (the principle of refugia) has been an area of increased focus. This principle is based on the concept that in order to lower the selection pressure for anthelmintic resistance any eggs from resistant worms that survive treatment must be diluted by a pool of non-resistant infective larvae. This strategy will reduce the relative contribution of resistant parasites to future worm populations. The application of the concept of refugia will require some alterations to existing management strategies for control of roundworms in livestock enterprises, and depending on individual circumstances will usually involve either treatment of all the animals in a group or targeted treatment of only a proportion of the stock. These treatment approaches aim to create a balance between allowing sufficient larvae to remain unexposed to drug treatment and the inevitable consequence on production performance of a higher worm burden in some animals.

Treatment of the whole flock/herd

In circumstances where treatment of the whole flock/herd is inevitable, then the dosing regimen needs to take into consideration those periods where there is minimal survival of larvae on pasture. Treatment of animals at this time will impose an increased selection for anthelmintic resistance. It may be possible to delay the strategic treatment to those periods in the grazing season when eggs from untreated animals are more likely to develop into infective larvae on pasture. It may also be possible to provide refugia within a flock/herd by turning animals out after treatment onto 'dirty' pasture for a period to allow any eggs from worms that survived treatment to be diluted. This can be achieved most effectively by moving the more resilient adult treated animals onto 'wormy' pastures rather than the more susceptible younger animals. Targeted treatments can also be effective. In this approach an indication of the level of parasitism

in the flock, such as the regular monitoring for worm eggs in faeces, is used and the whole flock is treated when these reach a predetermined level. A reduction in treatment frequency will lead to a refugia benefit, particularly in situations where animals are exposed to continual larval challenge from pasture. A further potential benefit of this regular monitoring is that additional information on the species of parasites present and their epidemiology will be recorded.

Treatment of a proportion of the flock/herd

One approach is to use indices of animal performance and parasitism to identify those animals in the flock/herd which would benefit from anthelmintic treatment (i.e. targeted selective treatment) rather than treating the whole group of animals. This approach should maximise the number of parasites which are not exposed to treatment and thus maintain a reservoir of 'susceptible' worms within the overall parasite population on pasture, thus slowing the rate of drug resistance. The indices used vary but include faecal egg counts, the FAMACHA system to assess anaemia in *Haemonchus* infections, serum pepsinogen levels in first-season grazing calves at housing, and production parameters such as liveweight gain, body condition scoring or milk yield. Recently, a model has been developed which predicts growth rate from the nutritional status of the pasture and size of the animal and highlights any underperforming animals which may benefit from treatment. Recent trials have supported the ability of the targeted selective treatment approach to lower the rate of development of resistance. The adoption of refugia-based strategies by livestock farmers to reduce the selection pressure for anthelmintic resistance is essential for long-term sustainable parasite control programmes.

It is unlikely that further new anthelmintic groups will be licensed for use in ruminants in the near future, partly due to cost and partly, for the sheep industry at least, the size of the global market. It was three decades between the launch of the two new anthelmintic groups (4-AD and 5-SI) and that of the previous class of anthelmintics (3-ML) onto the livestock market. It is therefore essential that the livestock industries adopt control strategies that conserve the efficacy of those compounds which are still effective and of the new 4-AD and 5-SI class of drugs used in sheep. It is encouraging that a recent modelling exercise indicates that in situations where the older anthelmintics still have a reasonably high level of efficacy, the introduction of a new class of anthelmintic may assist in delaying the development of resistance to these older drugs. Other strategies that are directed at increasing the natural effective immune response, such as vaccination, selection of more resistant livestock or the introduction of nutritional supplementation will reduce the overall reliance on anthelmintics.

Non-chemical control

Non-chemical approaches include the following, even though some are still at the research stage of application.

- 1 The breeding of animals which are able to resist or tolerate worm infections.
- 2 Feeding of nematophagous fungi which are able to trap larvae in the faeces and thus reduce pasture contamination.
- 3 Dietary supplementation with rumen bypass protein or forages rich in condensed tannins, which may increase the supply of protein to the small intestine and thus enhance the rate

of acquisition of immunity. Bioactive tanniferous plants also have direct anthelmintic activity against some gastrointestinal nematodes of small ruminants.

- 4 Periodic grazing of pastures that contain forage species with anthelmintic properties.
- 5 The administration of copper oxide wire particles.
- 6 The application of new molecular vaccines. These new approaches may initially need to be introduced in conjunction with limited chemotherapy to provide an integrated strategy for the control of parasitic gastroenteritis. Vaccines are considered in more detail in Chapter 7.
- 7 The use of physical approaches, often involving habitat modification, to reduce populations of insect pests and vectors (particularly the removal of breeding sites such as manure heaps, the use of barriers and the use of traps).

Use of genetic selection of animals which exhibit enhanced resilience and resistance to parasitic infection

An approach to complement other sustainable control measures for parasites in livestock is to select animals which exhibit significantly enhanced levels of resistance to parasites in comparison to the mean response of the population and include this trait into selection criteria. There is considerable evidence for extensive genetic variation, both between breeds and within populations of animals, for resistance to internal and external parasites. In sheep, between-flock variation in resistance is often small compared to within-flock variation. Resistance is inherited as a dominant trait, with heritability often exceeding 0.3. An increased resistance to gastrointestinal nematode infections is frequently associated with higher antibody responses, greater levels of T-cell proliferation and increased inflammatory responses.

There has been considerable progress in the last decade in the use of performance recording schemes and indices of selection that identify those high-producing animals which also exhibit enhanced resistance to internal parasites. Index selection combines production traits (e.g. growth rate, body condition score) under conditions of parasite challenge with markers of parasite burdens such as faecal egg count (FEC) (in some countries a worm FEC service is available) or the FAMACHA index (for those parasites, such as *Haemonchus*, that cause anaemia). In general, resistance is assessed in young male animals as they are the major contributors to genetic advancement, and genetic variation within a breed is usually recommended rather than breed substitution. Examples of small ruminants which have been selectively bred for resistance to gastrointestinal nematodes include a *Haemonchus*-resistant Merino sheep flock in New South Wales, Australia; the Rylington Merino, adapted for the winter-rainfall regions of western Australia; and a Romney line of sheep in New Zealand. The use of such resistant animals will reduce pasture contamination with worm eggs, and subsequently larval challenge and worm burdens will be lower for all grazing animals, and hence there will be benefits for the whole flock or herd. The outcome will be a reduced effect of parasitism on production, and a reduction in the number of drenches required for control.

Concern was initially raised as to whether the selection for enhanced resistance to parasites would reduce the genetic gains in other production traits. Evidence suggests that in most cases livestock which have been bred for resistance to gastrointestinal

nematodes are equally productive over a grazing season as the unselected animals in the flock. Furthermore, there is evidence that animals that are resistant to one species of nematode appear to demonstrate favourable responses to other nematode species and also that this resistance to nematodes has not been gained at the expense of resistance to other diseases.

It is important that breeding for resistance to parasites should be envisaged as a component of an ongoing sustainable parasite control programme and should not be considered in isolation.

Feeding of nematophagous fungi

A potential approach to integrated control strategies is biological control using the nematode-destroying microfungus *Duddingtonia flagrans*. This is a naturally occurring predacious nematode fungus found in soil and the abundant tough-walled spherical resistant spores (chlamydospores) are capable of surviving passage through the gastrointestinal tract of grazing livestock. Following excretion of fungal spores in faeces and manure, along with nematode eggs, the spores germinate and produce three-dimensional hyphal networks of sticky adhesive filaments during their development which trap the recently hatched free-living larval stages of parasitic nematodes within or around the faeces or faecal pats. The fungus gradually penetrates and digests the trapped nematodes. The advantage of *D. flagrans* is that viable spores are able to rapidly germinate and colonise the faeces and capture free-living larval stages before they have time to migrate out of the faecal mass onto herbage. Trials have demonstrated that when the spores (chlamydospores) of this fungus are administered daily to grazing livestock over several weeks or months, the pasture infectivity is significantly reduced and hence the intake of larvae is limited and worm burdens of the grazing animals are lowered. These effects have been demonstrated over a wide range of climatic regions and also with many livestock species, including cattle, sheep, goats, horses and pigs. Trials in which fungus was administered continuously showed a significant increase in live-weight gain and production benefits of treated animals compared to those not administered the fungus. The dosages of chlamydospores required to achieve adequate control of parasites vary with the species of livestock. Recently, there have been some encouraging results which demonstrated the potential for *D. flagrans* to entrap canine *Ancylostoma* spp. infective larvae in soil. Currently, investigations on biological control are being focused to ascertain the most effective mechanism for consistent delivery of the fungal spores, such as feed-blocks, slow-release devices and incorporation into sodium alginate pellets. There is growing evidence that this approach of feeding nematophagous fungi can provide a useful tool in combination with other non-chemical control systems (previously highlighted) to reduce the loss of productivity attributable to parasitic gastroenteritis, particularly in areas where the prevalence of nematodes resistant to anthelmintics is high. From an environmental aspect the administration of *D. flagrans* does not appear to have a detectable impact on other pasture and soil microorganisms, such as other soil free-living nematodes, microarthropods or earthworms. Importantly, the feeding of copper oxide wire particles (see later section) as a non-chemotherapeutic approach to worm control in ruminants does not appear to have any significant effect on the ability of *D. flagrans* to trap free-living larval stages and thus these two approaches would complement each other when used in a sustainable control strategy.

Control of parasitism through dietary supplementation

Gastrointestinal nematodes can cause severe pathophysiological effects, such as reduced appetite, lowered efficiency of nutrient utilisation and a change in nutrient metabolism. A framework has been developed which hypothesises that there is a priority for nutrient allocation in parasitised hosts and that supplementation with rumen bypass protein will have beneficial effects, particularly on host resilience to infection. The supplementation of ewes with protein around parturition can reduce or eliminate the phenomenon of the periparturient relaxation in immunity. Protein supplementation is an expensive option and trials in subtropical and tropical regions have shown beneficial effects on the production of livestock using urea–molasses feed-blocks as a source of non-protein nitrogen. This approach is of particular relevance for smallholders farming sheep and browsing goats. More extensive information on dietary supplementation is given in Chapter 6.

Administration of herbs/plants or extracts as dewormers

A wide range of plant/herbal dewormers (ethnoveterinary products or phytotherapeutic drugs) are used by smallholder farmers throughout many subtropical/tropical regions of the world. They are usually available locally and can be of low cost. However, in the majority of cases there is a lack of scientific validation of the reported anthelmintic attributes of these plants and extracts. Sources of material include lichens, ferns, shrubs and trees (*Salix* spp., *Azadirachta indica* the source of neem, *Celosia laxa*). Most of these have been used to treat parasitic infections in humans and there are more limited reports on their use in animals. In contrast, there is a wide variety of herbaceous plants or their extracts which have been used for deworming livestock. Some examples (with active ingredient in parentheses) are oil of chenopodium (ascari-dole), members of the Asteraceae such as *Artemisia* (santonin) and Fumariaceae such as *Fumaria parviflora*, common tansy *Tanacetum vulgare* (thujone), tobacco plant *Nicotiana tabacum* and *N. rustica* (nicotine), and cucumber seeds (cucurbitine). Also, fruits or latex from plants such as papaya, pineapple and fig contain cysteine proteinases which may adversely affect the nematode cuticle. Some of these potential anthelmintics are toxic in higher concentrations and in order to validate their usefulness it is essential to isolate, characterise and rigorously test the active molecules under controlled clinical efficacy and safety trials. Indeed where this approach has been applied many of these remedies have failed to live up to their earlier expectations. Future commercialisation of these non-synthetic anthelmintics may be limited by the problem of obtaining patents for extracts whose nature is widely available in the literature and also by the relatively small global market.

Grazing of livestock on pastures containing 'bioactive' forages or nutraceuticals

In recent years there has been increased interest in growing specialised crops for the control of nematode infections in grazing ruminants. Although the inclusion of herbs such as caraway, parsley, chicory, chervil, thyme, dill, tansy and wormwood into leys has mainly been of interest to smallholder farmers, there has been

wider interest in the use of tanniniferous forages for the control of parasitic nematode infections in small ruminants and more recently this has been extended to include cattle. These bioactive plants/forages or nutraceuticals contain secondary metabolites, particularly proanthocyanidins (condensed tannins) and flavanols, which have been shown to have a positive effect on host resilience and resistance and are considered likely to bestow their effects on parasite populations at various stages of their life cycle. Examples of those tanniniferous forages adapted to temperate and/or Mediterranean climates are the legumes (Fabaceae), sulla (*Hedysarum coronarium*), lotus major/great trefoil (*Lotus pedunculatus*), birdsfoot trefoil (*Lotus corniculatus*) and sainfoin (*Onobrychis viciifolia*). Chicory (*Cichorium intybus*) is not a tannin-rich plant but possesses sesquiterpene lactones which are considered to exhibit anthelmintic properties. Subtropical and tropical tanniniferous forages include Sericea lespedeza (*Lespedeza cuneata*), which is grown in the south-east of the USA; *Lysiloma latisiliquum* (wild tamarind); *Havardia albicans*; *Acacia gaumeri* in the Caribbean, Central and South America; and *Leucaena leucocephala* and *Zanthoxylum zanthoxyloides*, which have been naturalised in many parts of the tropics. Quebracho, a condensed tannin extracted from the bark of South American trees (*Schinopsis* spp.), has also been shown to exhibit anthelmintic properties and has been used as a model tannin in *in vitro* studies. These plants and their extracts have shown activity in either reducing FECs, worm burdens and/or the fecundity of female parasites in parasitised ruminants. Establishment of infective larvae has also been shown to be reduced in some trials in sheep and goats. Extracts from some of these plants can adversely affect larval feeding behaviour, motility or exsheathment or reduce egg hatching in *in vitro* assays. However, considerable variation in anthelmintic activity against ruminant nematodes has been demonstrated for these plants and extracts, partly as a result of difficulties encountered in standardisation of the tanniniferous polymers or active compounds in the plant material. In addition, the concentration of the active compounds can vary depending on how the plants are cultivated, the growing season and climatic conditions and also the prevailing conditions in the digestive tract.

Tanniniferous plants/extracts may affect parasites through several mechanisms.

- 1 Condensed tannins bind proteins and therefore may protect them from digestion in the rumen, thus increasing the supply and absorption of digestible protein. Such an additional release of protein can improve the resilience and resistance of the host to nematode infections.
- 2 It has been demonstrated that some tannins can have a direct anthelmintic effect on established nematode infections *in vivo*. This may be through their ability to form complexes with parasite proteins in the cuticle, digestive or reproductive tract and thus affect essential biological processes.
- 3 The presence of tannins and/or their breakdown products in faeces has been shown to adversely influence the developmental stages of parasites.

Further work is required to quantify these effects and also to isolate and characterise the active compounds and their mode of action on the integrity of the parasites.

Although these data on plants or plant extracts present potential alternative approaches to conventional chemotherapy for reducing the impact of parasitism on animal performance, there are many aspects which need to be addressed. Are some of these plants amenable to culture in a variety of differing environments? Can they withstand continuous grazing pressure by livestock and how do

they compete in mixed swards and forages? What is their palatability and potential toxicity (particularly those plants which contain alkaloids, glycosides and oxalates)? What is the most appropriate way to use these plants/extracts, curatively or preventively? Pure stands of bioactive forages could be used for short-term grazing as part of a rotational deworming strategy. They could also be harvested, dried and fed strategically to housed animals, either directly or incorporated into feedstuffs, but it would be important to assess the biodegradability of the active components during processing. These options would have a particular use in the niche market of organic farming.

Further development is necessary as although experimental trials have shown some encouraging results with forages, many of the effective plants will not withstand heavy grazing pressure or have a restricted agroclimatic requirement.

Administration of copper oxide wire particles

Capsules containing copper oxide wire particles (COWP) were initially developed as a feed supplement to treat copper deficiency in small ruminants but over the last couple of decades their anthelmintic properties against nematodes have been recognised and investigated as an additional control strategy where the prevalence of anthelmintic-resistant nematodes is high. Following administration to ruminants the COWP pass through the rumen and lodge in the folds of the abomasum where the low pH induces the release of high concentrations of soluble copper into the digesta that adversely affect the parasites. The effects on parasite populations vary but include reduced worm establishment, reduction of established burdens and/or reduced fecundity of the female worms and consequently lower FECs. These effects appear to be more pronounced against *Haemonchus contortus* than either *Teladorsagia circumcincta* or *Trichostrongylus colubriformis* and most trial data for sheep and goats have accumulated for the former parasite. The effects on worm establishment and fecundity can persist for around 6–8 weeks after administration of COWP. The data are variable, particularly in adult animals, and will be influenced by the changes in abomasal pH which often accompany heavy infections, especially under tropical grazing conditions.

Copper can potentially be toxic in small ruminants and the dose of COWP which induces anthelmintic effects, and which is also considered of low toxicity, is around 2–3 g. A higher dose of 4 g administered to late pregnant ewes may negatively impact multiple-born lambs. In addition, there are considerable differences between breeds in their susceptibility to copper supplementation. Therefore, if one is going to apply these capsules as an aid to nematode control in small ruminants, then it would be advisable to first assess the copper status of the flock and the pasture. It would also be sound practice to limit the number of treatments given within a year (probably one dose).

Physical approaches

Environmental modification Simple modification of the environment may reduce pest abundance significantly. For example, many of the fly pests of cattle and horses have larval stages which develop in animal dung or decaying organic refuse. Management of dung is therefore of prime importance in their control and considerable success can be achieved simply by removing dung

regularly from pastures or feedlots and dispersing it in such a way that it no longer attracts ovipositing flies. Biting and non-biting flies can also be effectively controlled through simple procedures such as the removal of moist bedding and straw, food wastes, heaps of grass cuttings and vegetable refuse in which they breed.

Similarly, changing the suitability of the on-host environment may help reduce the susceptibility of the host to pest attack. With sheep, for example, minimising pasture worm burdens to reduce diarrhoea, tail-docking (amputation of the tails) and crutching or dagging (the regular shearing of soiled wool from around the breech) all help to minimise the incidence of myiasis by blowflies. These procedures reduce wool soiling and lower the humidity of the on-host environment, thereby reducing the availability of oviposition sites and suitability of the fleece for maggot survival.

High pest abundance, in space or time, can be avoided by appropriate grazing practices which reduce contact with the pest. For example, avoiding low-lying pasture at particular times of the year or simply stabling horses during the morning and evening may prevent or reduce the effects of biting midges during periods of high midge abundance and activity.

Barriers Various types of physical barrier can be employed to protect stock from insect pests. These may be fine mesh screens on windows, plastic strips on milking parlour doors or brow tassels for protection and to help dislodge insects which have alighted on the host. Such techniques may often be used in conjunction with an insecticide.

Trapping Insects use a complex interaction of olfactory, visual and tactile cues to locate their hosts. If these cues can be identified and isolated, they can be selectively incorporated into trapping devices at levels that produce exaggerated responses from the pest species. Walk-through traps have been developed for the control of *Haematobia irritans*, stable flies and face flies. A screw-worm adult suppression system (SWASS) has been used to attract the New World screwworm fly *Cochliomyia hominivorax* in North America. This combined an insecticide (2% dichlorvos) with a synthetic odour cocktail known as 'Swormlure' to attract and kill adult flies. Field trials with the SWASS produced a 65–85% reduction in an isolated wild *C. hominivorax* population within 3 months. However, environmental concerns about the release of large quantities of dichlorvos resulted in the SWASS being largely abandoned as a control technique. The development of traps for the tsetse fly vectors of trypanosomiasis in Africa has been highly successful, identifying and exploiting appropriate visual shapes and colours in combination with host-mimicking chemical odours to attract and catch flies. Traps baited with synthetic chemicals are also commercially available for the control of sheep blowfly in Australia. Trapping techniques hold considerable promise for future development.

ANTIPROTOZOAL RESISTANCE

Continuous use of antiprotozoals has also led to ineffective treatment due to drug resistance in the target parasite populations. This is perhaps best exemplified by the situation with anticoccidial compounds.

The control of avian coccidiosis (see Chapter 13) has relied almost entirely on chemotherapy, as is evident from the fact that most intensively reared chickens are fed an anticoccidial agent in the diet throughout their period of growth. Feed medication is a

convenient and cost-effective method of enabling large numbers of chickens to be reared under intensive conditions. The practice of including drugs in the feed throughout the life of the bird has ensured that few parasites escape the effects of medication. In such an environment, parasites are exposed throughout their life cycle to agents designed for their removal and this has inevitably resulted in the development of resistance.

A succession of chemical compounds has been introduced and has been crucial in the successful control of coccidiosis in the rapidly expanding poultry industries throughout the world. However, the emergence of resistance has been rapid and has limited the useful life of many chemical anticoccidials, although the speed at which resistance develops varies greatly between compounds. With the ionophore antibiotics, which have dominated the scene for the last three decades, resistance has been considerably slower to develop. Nevertheless, resistance to this group has been reported in both Europe and the USA, with cross-resistance occurring notably among the monovalent cation group. Although ionophore-resistant strains may be present, it is possible that the numbers of oocysts are insufficient to cause clinical coccidiosis. Selection pressure is therefore probably lower than with many of the chemical anticoccidials. It has been suggested that this incomplete control of parasite development stimulates production of immunity in the host and this may be a major factor in the effectiveness of ionophores in the field.

Knowledge of the mode of action of anticoccidial compounds is necessary to understand the mechanisms of resistance. Although some information is available on the biochemical pathways inhibited by certain anticoccidial drugs, explanations for their selectivity are either circumstantial or unknown. As in other parasites, the most likely mechanism of resistance involves modification of the target receptor so that its sensitivity to inhibition is decreased. Compounds that share a similar mode of action may also share resistance (cross-resistance). This should be distinguished from multiple resistance in which resistance may be to several drugs with differing modes of action.

It has been shown that parasites resistant to the recommended levels of certain anticoccidial drugs may be suppressed if the concentration of drug is increased. Resistance to these higher concentrations, however, is likely to develop rapidly after further selection. Increasing the concentration of a drug may therefore only be of use in the short term and furthermore would not be practical because most anticoccidial drugs are used at levels close to those that are toxic to the chicken.

Resistant strains may emerge if anticoccidial drugs have been employed at concentrations lower than those normally recommended for control. It would therefore appear to be important to maintain adequate drug levels in the field in order to reduce the possibility of selecting resistant strains. A reduction in the use of drugs is desirable since it is generally accepted that the selection of genes for resistance will occur more rapidly as the frequency of treatment is increased. Control of coccidiosis may be achieved by giving drugs intermittently, the objective being to prevent the build-up of infection in a poultry house. However, such a policy would be unacceptable to the poultry industry because of, for example, the impairment of food conversion that would probably result.

The genetics of anticoccidial resistance in *Eimeria* are poorly understood. Most drugs inhibit the asexual stages of the life cycle. Many of the complexities involved in the selection of resistance in diploid organisms, such as the degree of dominance of resistance genes, are absent because these stages are haploid. Any resistant mutants will therefore be immediately selected at the expense of

sensitive forms. Asexual division will ensure their rapid multiplication and resistance will swiftly become the dominant phenotype. It has been shown that resistance to certain drugs (e.g. decoquinate, methylbenzoate) develops rapidly in a single step and may be due to a single mutation, whereas resistance to other drugs, such as amprolium and robenidine, develops more slowly, possibly as a result of a series of small discrete steps involving successive mutations. Information on the rate at which resistance develops may be helpful in selecting the most appropriate drugs for use in the field.

The control of coccidiosis is likely to continue to depend on chemotherapy although alternatives, such as immunoprophylaxis, are now established and offer a practical alternative. Until now, as resistance has developed to the older compounds, new ones have been discovered to replace them. It is doubtful whether this situation will continue. It is important therefore that strategies be devised to obtain the best use of existing drugs.

Alternation of drugs (rotation) with different modes of action has been widely advocated in the poultry industry, but this has been based on an empirical, rather than scientific, basis. It is not known for what duration (number of crops) a particular drug should be used before changing to another anticoccidial agent. Alternation of drugs within a single crop (shuttle programmes) has also been widely practised. It has been claimed that this may slow the development of resistance but no evidence to support this contention has been provided. The period of medication for the drugs in a shuttle may be too short to eliminate any resistant forms. Resistant parasites may survive in the litter for the life of the crop and the subsequent use of the same drugs would result in further selection pressure for resistance. A likely result of short periods of alternation between drugs is the development of strains resistant to several drugs (multiple resistance). Vaccines based on live attenuated parasites are now in use as an alternative to medication for the control of coccidiosis. Alternating cycles of planned immunisation and chemotherapy might result in the replacement of drug-resistant parasites by drug-sensitive strains with reduced pathogenicity.

Reversion to sensitivity with older chemical compounds can eventually occur leading to their reintroduction in control programmes. However, the time interval before a population recovers susceptibility to a drug is likely to be considerably longer than the time taken to acquire resistance. It is also probable that resistance will re-emerge more rapidly if older compounds are reintroduced. Various combinations of drugs have been employed to extend the spectrum of activity against different species of *Eimeria* rather than prevent the development of resistance (e.g. amprolium and ethopabate). Mixtures have also been used to reduce the risk of toxicity since, in some cases, adequate activity can be obtained with lower doses than if the drugs are used alone (e.g. naracin and nicarbazin). Even where these combination drug mixtures have been used, resistance has developed.

Another area in which resistance has become a problem is in the control of trypanosomiasis. Drug resistance was first noted in trypanosomes to the arsenicals and aromatic compounds. For example, diminazene resistance in *T. v. vivax* and *T. c. congolense* strains is now widespread. As a rule, diminazene-resistant strains are susceptible to isometamidium. Widespread use of homidium and quinapyridine in cattle resulted in the appearance of resistant *T. c. congolense* strains in East and West Africa. Homidium-resistant trypanosomes can be controlled by diminazene or isometamidium at increased dose rates. Quinapyrimine-resistant strains are usually controlled by isometamidium. Quinapyrimine is also active against suramin-resistant strains of *T. b. evansi* and *T. b. brucei*.

PESTICIDE RESISTANCE

At the recommended doses modern insecticides are highly effective at removing susceptible individuals, but they can impose strong selection pressure for the development of resistance. The development of resistance may reduce the effectiveness of the treatment applied and thereby increase the frequency of application and the dose required, in turn increasing the costs and adding to the environmental impact.

There are two major variables that determine the rate at which resistance is likely to spread throughout the population: its mechanism of inheritance and the severity of selective pressure (the percentage of susceptible individuals that survive each generation). In general, resistance will spread through a population most rapidly when it is inherited as a single dominant allele and selective pressure is high (meaning very few susceptible individuals escape and reproduce).

When an insect population develops resistance to one pesticide, it may also prove to be resistant to similar compounds that have the same mode of action. This phenomenon, known as class resistance, occurs frequently in pest populations that develop resistance to organophosphate, carbamate or pyrethroid insecticides. In some cases, a population may develop a form of resistance that protects it from compounds in more than one chemical class. This is known as cross-resistance, and may result in an ectoparasite population that can no longer be controlled with chemical insecticides. Overall, resistance in the majority of ectoparasite species is not as severe or widespread a problem as that seen in endoparasites (Table 5.3).

There are three general approaches that can be used to reduce the rate of resistance development.

- 1 Management by saturation** involves heavy or frequent use of a pesticide that is designed to leave absolutely no survivors. It is most effective when the resistant gene is dominant and the target population is small, isolated or living in a limited habitat.
- 2 Management by moderation** uses only the minimum control necessary to reduce a population below an acceptable level. This strategy tries to ensure that susceptible genes are never eliminated from the population. It works best when the susceptible trait is dominant over the resistant trait.
- 3 Management by multiple attack** involves the use of several control tactics that work in different ways. By rotating insecticides with different modes of action or by alternating chemical with non-chemical control tactics, a pest population is exposed to selective pressures that change from generation to generation.

Clearly, the approach adopted will also depend on the parasite in question, the epidemiology of transmission and the farming environment. Permanent ectoparasites, or highly host-specific species which spend long periods on the host and which have relatively low rates of transmission, such as bot and warble flies, can be susceptible to coordinated programmes of management by saturation because entire populations can be targeted and removed simultaneously. In general, however, for most ectoparasites, management by moderation and management by multiple attack are recommended. In addition, it is essential to ensure that manufacturer's recommendations are scrupulously followed and that all apparatus is calibrated correctly and working effectively.

For farmers wanting to reduce reliance on synthetic insecticides, a range of management practices and non-chemical methods may be utilised in an integrated manner to reduce ectoparasite prevalence. One or several techniques may be used, but importantly

Table 5.3 Insecticide resistance in the major ectoparasites of importance in cattle and sheep.

| Family | Species | Primary host | Known resistance |
|---|---|-----------------------------|--|
| Mites (Acari: Astigmata) | <i>Sarcoptes scabiei</i> | Pig | Ivermectin resistance in humans; not yet known in animal parasites |
| | <i>Psoroptes ovis</i> | Sheep (occasionally cattle) | Gamma-hexachlorohexane (OC), diazinon (OP), propetamphos (OP), flumethrin (SP), high- <i>cis</i> -cypermethrin (SP) |
| | <i>Chorioptes bovis</i> | Sheep | None recorded |
| Ticks (Acari: Ixodidae) | <i>Ixodes ricinus</i> | Sheep and cattle | None recorded |
| | <i>Ixodes persulcatus</i> | Sheep and cattle | None recorded |
| | <i>Rhipicephalus sanguineus</i> group, <i>R. bursa</i> , <i>R. turanicus</i> , <i>R. appendiculatus</i> | Sheep and cattle | Amitraz (formamidine), dichlorfenvinphos (OP), cypermethrin (SP) |
| | <i>Hyalomma marginatum</i> | Sheep and cattle | None recorded |
| | <i>Boophilus annulatus</i> | Sheep and cattle | None recorded |
| | <i>Dermacentor reticulatus</i> , <i>D. marginatus</i> | Sheep and cattle | None recorded |
| | <i>Haemaphysalis punctata</i> | Sheep and cattle | None recorded |
| Sucking lice (Phthiraptera: Anoplura) | <i>Linognathus vituli</i> | Cattle | None recorded |
| | <i>Linognathus pedalis</i> , <i>L. ovis</i> | Sheep | None recorded |
| | <i>Haematopinus eurysternus</i> | Cattle | None recorded |
| | <i>Haematopinus quadripertusus</i> | Cattle | None recorded |
| | <i>Solenopotes capillatus</i> | Cattle | None recorded |

IGR, insect growth regulator; OC, organochlorine; OP, organophosphate; SP, synthetic pyrethroid.

these should be integrated with each other to form components of a general livestock ectoparasite management programme. Such management is usually based on the use of control technologies which modify some aspect of the parasite's environment, on or off the host, in order to increase pest mortality, reduce fecundity or reduce contact between the pest and host.

There can be little doubt that resistance to existing chemicals is unlikely to be reversed and indeed will become more widespread, and that new compounds developed in the future will also select for resistance. Probably the most optimistic prognosis is that appropriate management will allow the rate of development of resistance to be reduced.

The epidemiology of parasitic diseases

Although the reasons for the occurrence of parasitic diseases are multiple and often interactive, the vast majority occur for one of four basic reasons.

- 1 An increase in the numbers of infective stages.
- 2 An alteration in host susceptibility.
- 3 The introduction of susceptible stock.
- 4 The introduction of infection into a clean environment.

Each of these will be discussed in turn, giving examples.

AN INCREASE IN THE NUMBERS OF INFECTIVE STAGES

This category involves parasitic diseases which occur seasonally. Although more distinct in zones with a wide climatic variation, parasitic diseases may also be observed in zones with minor variations in climate such as the humid tropics.

A multiplicity of causes is responsible for the seasonal fluctuations in the numbers and availability of infective stages, and these may be conveniently grouped as factors affecting contamination of the environment and those controlling the development and survival of the free-living stages of the parasites and, where applicable, their intermediate hosts.

CONTAMINATION OF THE ENVIRONMENT

The level of contamination is influenced by several factors.

Biotic potential

This may be defined as the capacity of an organism for biological success as measured by its fecundity. Thus, some nematodes, such as *Haemonchus contortus* and *Ascaris suum*, produce many thousands of eggs daily, while others, like *Trichostrongylus* and *Ostertagia*, produce only a few hundred. Egg production by some external parasites, such as the blowfly *Lucilia sericata* and the tick *Ixodes ricinus*, is also very high, whereas *Glossina* spp. produce relatively few offspring.

The biotic potential of parasites which multiply within either an intermediate or final host is also considerable. For example, the infection of *Galba* (*Lymnaea*) with one miracidium of the trematode *Fasciola hepatica* can give rise to several hundred cercariae. Within the final host, protozoal parasites such as *Eimeria*, because of merogony and gametogony, also give rise to a rapid increase in contamination of the environment.

Stock management

The density of stocking can influence the level of contamination and is particularly important in nematode and cestode infections in which no multiplication of the parasite takes place outside the final host. It has the greatest influence when climatic conditions are optimal for development of the contaminating eggs or larvae, such as in spring and summer in the northern hemisphere.

A high stocking density will also favour the spread of ectoparasitic conditions such as pediculosis and sarcoptic mange, where close contact between animals facilitates the spread of infection. This may occur under crowded conditions in cattle yards, or from mother to offspring where, for example, sows and their litters are in close contact.

In coccidiosis, where large numbers of oocysts are disseminated, management procedures which encourage the congregation of stock, such as the gathering of lambs around feeding troughs, may lead rapidly to heavy contamination.

In temperate countries, where livestock are stabled during the winter, the date of turning out to graze in spring will influence contamination of pasture with helminth eggs. Since many helminth infective stages which have survived the winter succumb during late spring, the withholding of stock until this time will minimise subsequent infection. Exceptions can occur, as in the case of the intestinal nematode *Nematodirus battus*. With this species eggs deposited on pasture during the previous grazing season require a period of chill followed by rising temperatures in the spring when a mass hatch of infective larvae occurs. This has evolved to coincide with the availability of young susceptible lambs on pasture.

Immune status of the host

Clearly, the influence of stocking density will be greatest if all the stock are fully susceptible, or if the ratio of susceptible to immune stock is high, as in sheep flocks with a large percentage of twins or in multiple suckled beef herds.

However, even where the ratio of adults to juveniles is low it must be remembered that ewes, sows, female goats and, to a lesser extent, cows become more susceptible to many helminths during late pregnancy and early lactation due to the periparturient relaxation in immunity. In most areas of the world, parturition in grazing animals, synchronised to occur with the climate most favourable to pasture growth, is also the time most suitable for development of the free-living stages of most helminths. Thus, the epidemiological significance of the periparturient relaxation of immunity is that it ensures increased contamination of the environment when the number of susceptible animals is increasing.

There is some evidence that resistance to intestinal protozoal infections such as coccidiosis and toxoplasmosis is also lowered during pregnancy and lactation, and so enhances spread of these important infections.

On the credit side, host immunity will limit the level of contamination by modifying the development of new infections either by their destruction or arrest at the larval stages, while existing adult worm burdens are either expelled or their egg production severely curtailed.

While immunity to ectoparasites is less well defined, in cattle it develops against most species of ticks, although in a herd this expression of resistance often inadvertently results in an overdispersed population of ticks with the susceptible young animals carrying most of the ticks.

In protozoal diseases, such as babesiosis or theileriosis, the presence of immune adults also limits the likelihood of ticks becoming infected; however, this effect is not absolute since such animals are often silent carriers of these protozoal infections.

Hypobiosis/diapause

These terms are used to describe an interruption in development of a parasite at a specific stage and for periods which may extend to several months.

Hypobiosis refers to the arrested development of nematode larvae within the host and occurs seasonally, usually at a time when conditions are adverse to the development and survival of the free-living stages. The epidemiological importance of hypobiosis is that the resumption of development of hypobiotic larvae usually occurs when conditions are optimal for free-living development and so results in increased contamination of the environment. There are many examples of seasonal hypobiosis in nematodes, including *Ostertagia/Teladorsagia* infections in ruminants, *Hyostromylus rubidus* in pigs and *cyathostomins* in horses.

Diapause in arthropods, like hypobiosis in nematodes, is also considered to be an adaptation whereby ectoparasites survive adverse conditions by cessation of growth and metabolism at a particular stage. It is most common in temporary arthropod parasites in temperate climates. In these, feeding activity is restricted to the warmer months of the year and winter survival is often accomplished by a period of diapause. Depending on the extremity of the northern or southern latitudes, this may occur after one or several generations. For example, the head fly *Hydrotoea irritans* in northern latitudes has only one annual cycle and overwinters as a mature larva in diapause. Other insects, such as *Stomoxys calcitrans* or blowflies in these latitudes, have several generation cycles before entering diapause. Diapause occurs less in parasites which continuously infect their hosts, such as mange mites or lice.

To date, similar phenomena have not been ascribed to protozoa, although there is one report of latent coccidiosis occurring in cattle for which a similar hypothesis has been proposed.

DEVELOPMENT AND SURVIVAL OF INFECTIVE STAGES

The factors that affect development and survival are mainly environmental, especially seasonal climatic change and certain management practices. Current changes in the global climate are anticipated to influence the infective stages of many parasites and/

or the prevalence of some intermediate hosts. For example, the trend towards warmer wetter seasons has been one factor attributed to the increase in prevalence of *Fasciola hepatica* infection in ruminants in some temperate regions.

The microhabitat

Several environmental factors which affect the microhabitats of free-living parasitic stages are vital for development and survival. Thus moderate temperatures and high humidity favour development of most parasites, while cool temperatures prolong survival. The microclimate humidity depends, of course, not only on rainfall and temperature, but on other elements such as soil structure, vegetation type and drainage. Soil type influences the growth and species composition of the herbage and this in turn determines the degree to which a layer of 'mat' is formed between the soil and the herbage. The mat is abundant in older pastures and holds a permanent store of moisture in which the relative humidity remains high even after weeks of drought. The presence of this moisture and pockets of air trapped in the mat limit the rate of temperature change and these factors favour the development and survival of helminth larvae, ticks, larval stages of insects and coccidial oocysts. In contrast, the use of rotational cropping of pastures reduces the influence of 'mat' and therefore parasite survival. In the arid tropics pasture growth is usually negligible, causing a similar effect. In the same way, a high water table is important for the development and survival of intermediate snail vectors of trematodes, such as liver and rumen flukes.

The development and survival of helminth eggs or larvae within faeces are also dependent on temperature and moisture. The host species may also influence this situation since normal cattle faeces remain in their original form for a longer time than, say, sheep or goat pellets. Thus the moisture content at the centre of a bovine faecal pat remains high for several weeks or even months and so provides shelter for developing larvae until the outside environment is suitable.

Dictyocaulus larvae may also be distributed with the spores of the fungus *Pilobolus* which grow in bovine faeces, while several species of nematode larvae, including *Oesophagostomum* spp. of pigs, are known to be spread mechanically by some dipteran flies.

Seasonal development

In temperate countries with distinct seasons of summer and winter there is a limited number of generations and the same is true of countries with distinct dry and wet seasons. In Britain, for example, there has generally only been one, or at the most two, parasitic generations of the common trichostrongyle infections of ruminants, since larval development on the pasture occurs only from late spring through to early autumn, the peak levels of infective larvae being present from July until September. This pattern of events has changed in recent years with climate changes to milder and longer seasons. In tropical climates there may be numerous generations per year, but even in this case there are times when conditions for the development and survival of the free-living stages are optimal.

The development of large numbers of infective stages of parasites within distinct seasons is usually followed by a high mortality rate within a few weeks. However, considerable numbers survive for much longer than is commonly realised. For example, in Britain,

significant numbers of metacercariae of *Fasciola hepatica* and infective larvae of trichostrongyles are capable of surviving for at least 9 months.

Dipteran fly populations also vary in the number of generations per year. Using the blowflies as an example, there are three or four generations, and therefore higher populations, in southern England, whereas in Scotland there are usually only two, temperature being the limiting factor. In the humid tropical or subtropical countries the development of trichostrongyle larvae or fly populations proceeds throughout most of the year and although this may be slower at certain times, there will be numerous generations per annum.

Although the permanent ectoparasites, such as lice or mange mites, live on or in the skin of animals and therefore in an apparently stable environment, this is not really the case as the hair or wool alters in length due to seasonal factors or human intervention. In the northern hemisphere development of these parasites is optimal in the winter when the coat is long and the microenvironment humid and temperate.

Apart from the free-living stages of coccidian parasites, which have seasonal requirements similar to those of the trichostrongyles, the prevalence of other protozoan infections is related to the feeding activity of their arthropod vectors. For example, in Britain, babesiosis in cattle occurs at peak times of tick activity in the spring and autumn, although again in recent years climate changes have affected the seasons such that tick activity has become less confined to these times of the year.

Stock management

The availability of helminth infective stages is also affected by certain management practices. Thus, a high density of stocking increases the level of contamination and, by lowering the sward height, enhances the availability of the larval stages largely concentrated in the lower part of the herbage. Also, the scarcity of grass may induce animals to graze closer to faeces than otherwise. However, against this, the microclimate in a short sward is more susceptible to changes in temperature and humidity and so the free-living stages may, on adverse occasions, be particularly vulnerable. This may explain why the helminth burdens of ruminants in close-cropped set-stocked pastures are often less than those in animals on rotated pastures.

Similarly, many pasture improvement schemes have direct or indirect effects on arthropod populations. Improved host nutrition results from pasture improvement and helps to maintain host resistance to parasitism. However, pasture improvement, particularly in the tropics, can increase the breeding success of ectoparasites such as ticks. Furthermore, the increased stocking rates on improved pastures may increase the chances of parasites finding a host.

The date of parturition in a flock or herd may also influence the likelihood of parasitic infection. Where livestock are born out of season, the numbers of trichostrongyle infective stages are usually lower and the chance of infection is postponed until the young animals are older and stronger.

AN ALTERATION IN HOST SUSCEPTIBILITY

This may refer to existing infections or to the acquisition of new infections.

ALTERED EFFECTS OF AN EXISTING INFECTION

This is observed principally in adolescent or adult stock which are harbouring parasite populations below the threshold usually associated with disease and may be explained by various dietary and host factors.

Diet

It has been shown that adequately fed animals are better able to tolerate parasitism than animals on a low plane of nutrition. Thus, ruminants affected with blood-sucking helminths, such as *Haemonchus contortus* or *Fasciola hepatica*, may be able to maintain their haemoglobin levels as long as their iron intake is adequate. However, if their iron reserves become low, their haemopoietic systems become exhausted and they may die. Similarly, cattle may grow at a reasonable rate with moderate trichostrongylid burdens even though some loss of protein is occurring through the alimentary mucosa. However, if there is a change in diet which reduces their protein intake, they are unable to compensate for the loss of protein and lose weight. These deleterious effects of parasitism, without any change in the level of infection, are not uncommon in outwintered stock or, in the tropics, in animals during a period of drought.

Incidentally, the same effect is produced when food intake is not increased during pregnancy and lactation. Good examples of this are the accumulation of lice on poorly fed animals during the winter and the fact that the anaemia caused by ticks is greater in animals on poor nutrition.

Apart from protein and iron, dietary deficiencies in trace elements are also significant. Thus, trichostrongylosis in ruminants is known to impair the absorption of both calcium and phosphorus and, where the dietary intake of these is suboptimal, osteoporosis can occur. Also, the deleterious effects of some abomasal parasites in sheep are greater where there is a cobalt deficiency and, in such animals, levels of parasitism generally considered to be non-pathogenic may be associated with severe diarrhoea and weight loss.

Impact of nutrition on parasite infections

When considering the host's response to parasite challenge it is convenient to discuss the effects under the headings 'resilience' and 'resistance', although in practice both are interrelated. Resilience refers to the ability of the host to maintain an acceptable level of productivity when subjected to larval challenge or when carrying a significant parasite burden. Resistance describes the ability of the host to limit the establishment, size or fecundity and/or persistence of its parasite population. An animal which is parasitised has the problem of allocating scarce dietary nutrients between essential body functions such as maintenance, growth and reproduction and functions induced by parasitic invasion such as repair of damaged mucosal/tissue barriers, replacement of endogenous protein losses and mounting of an effective immune response in an attempt to limit the parasite population. A **nutrient partitioning framework** has been developed to take account of the differing nutritional requirements of the host during its life and to predict the likely responses to the provision of additional nutrient supplementation during parasite challenge.

Young growing animals

Resilience Animals on a good plane of nutrition are usually better able to maintain their productivity when subjected to parasitic challenge. Resilience of growing ruminants has been shown to be markedly improved by the addition of rumen-undegradable protein when they are subjected to challenge with gastrointestinal nematodes. The increased supply of metabolisable protein (MP) partly alleviates the pathophysiological consequences of infection. These effects are usually more dramatic in infections of young naive animals where parasitism often results in severe pathophysiological changes and extensive tissue damage. Other studies have investigated the use of non-protein nitrogen sources. Supplementation with urea–molasses feed-blocks alone will often not completely overcome the adverse effects of parasitism, whereas protein supplementation plus these feed-blocks can increase the resilience of the host.

Macrominerals can also influence the resilience of sheep to parasitism. Infection with intestinal nematodes induces phosphorus deficiency and the growth rate of infected lambs can be markedly improved when they are offered diets high in phosphorus.

Resistance

- 1 Acquisition phase.** This occurs when the host first encounters parasites and its immune system is recognising the invasion before it can mount an effective immune response. The duration will vary from a few days in the case of some protozoa to several weeks or even months with helminth infections. In the young naive animal the priority for a scarce nutrient resource will be directed towards the maintenance of body protein (including the maintenance and repair of the gastrointestinal tract and the regulation of blood and plasma proteins and to the acquisition of immunity), as these functions have high priority and will ensure that the susceptible animal survives. There is now a body of evidence to indicate that the provision of additional dietary protein to young growing parasitised ruminants has little effect on the early rate of establishment of gastrointestinal nematode infections, although the pathophysiological consequences are usually more severe in animals on lower planes of protein intake.
- 2 Expression phase.** This occurs when the host's immune system is responding to limit the existing parasite population and/or the establishment of further infection. During the expression phase of acquired immunity to parasites it is predicted by the partitioning framework that maintenance of body protein and the requirement for body protein gain (in growing animals) and maintenance of body protein and reproductive effort (in pregnant/lactating animals) will both have a higher priority for scarce nutrient resources. This being the case, it is anticipated that the benefits of additional MP supplementation on the immune response would be most apparent during the expression phase. Indeed, the main effect of protein supplementation is to increase the rate of acquisition of immunity and increase resistance to reinfection and this has been associated with an enhanced cellular immune response in the gastrointestinal mucosa. It is clear that the provision of additional MP can reduce the establishment of incoming larvae and reduce the fecundity and/or survival of a worm population in young susceptible ruminants. There is evidence that the magnitude of the effect on host resistance is influenced by the level of MP supply and, as predicted from the partitioning framework, is greater in

young growing livestock where the demand for protein is higher than that for metabolisable energy.

Details of how an increased supply of MP affects the host's immune response to a parasitic infection are poorly understood. However, supplementation with rumen-undegradable protein can enhance the numbers of peripheral/mucosal effector cells involved in the immune response of young sheep infected with gastrointestinal nematodes.

Both macronutrients (phosphorus) and micronutrients (molybdenum, copper, cobalt, selenium) can also influence the resistance of livestock to gastrointestinal nematode infection.

Mature reproducing and/or lactating animals

By the time livestock are yearlings they generally exhibit a protective level of immunity. However, in sheep, and to a lesser extent in cattle, this immunity is reduced in late pregnancy and during lactation (periparturient relaxation of immunity, PPRI) but is restored by the time lambs are weaned.

Resistance Around the periparturient period the ewe has a high requirement for protein relative to energy and the partitioning framework would suggest that there could be benefits on immune status through the provision of additional rumen-undegradable protein. There is evidence that either direct or indirect manipulation of nutrition can influence the ewe's response to nematode infection at this time. The supply of MP has been shown to be more important than the availability of energy in influencing the response of the periparturient ewe to nematode infection. Removal of lambs at birth or during lactation, which reduces protein demands, has been shown to partially restore the expression of immunity against abomasal parasitism. The addition of rumen-undegradable protein in late pregnancy or early lactation to ewes parasitised with gastrointestinal nematodes can reduce worm fecundity and/or worm populations and enhance local immune responsiveness, the effects being more pronounced in twin-bearing and twin-rearing ewes where the protein demands are higher than for singles. As predicted the body composition of the ewe has been shown to influence these relationships. There is now considerable evidence to support the view that under conditions where there is a scarcity of MP the PPRI in the ewe to abomasal nematode infection can be partly alleviated by the provision of an increased supply of MP or by a reduction in the demand for MP. Competition for nutrients, particularly protein, between reproductive processes and the expression of immunity are considered to be a major factor in the phenomenon of PPRI in parasitised ewes.

Influence of nutrition on expression of genotype

Ruminants on similar planes of nutrition show considerable variation in susceptibility to parasitism as a result of genetic variation. Studies with abomasal parasite infections in sheep have shown that the expression of genetic superiority in terms of host resistance (usually measured as reductions in the level of faecal egg count) to infection is not compromised by poor nutrition. It is in situations where the availability of nutrients is low that differences between genotypes are frequently at their greatest and both susceptible and resistant genotypes will usually respond to protein supplementation

by showing evidence of increased levels of resistance to infection. The ability of additional protein supplementation to reduce the pathophysiological consequences of parasite infection in animals on a moderate to high nutritional intake is higher in genetically susceptible than in genetically resistant livestock. Studies in Australia with sheep lines selected for resistance to *H. contortus* have suggested that those lines which exhibit resistance are likely to be directing more of their supply of protein into the immune responses against infection at the expense of channelling of protein into production processes such as liveweight gain and wool growth. These genotype-dependent effects will influence the approach to nutrient supplementation.

Pregnancy and lactation

The period of gestation in grazing livestock often coincides with that of inadequate nutrition and is geared to completion at a time when freshly growing pasture becomes available for their newborn progeny. In housed or overwintered livestock the cost of maintaining an adequate nutritional intake during pregnancy is often high and as a result the nutritional levels are often suboptimal. If this occurs, quite low worm burdens can have a detrimental effect on the food conversion of the dam, which in turn influences fetal growth and subsequently that of the neonate through poor milk production by the dam. This has been clearly illustrated in sows infected with moderate burdens of *Oesophagostomum dentatum* and in ewes infected with helminths such as *Haemonchus* or *Fasciola*.

Steroid therapy

Steroids are widely used in therapy of both humans and animals and it is known that they may alter the susceptibility to parasitism. A good example of this is in the cat infected with *Toxoplasma gondii*; excretion of oocysts usually occurs for only about 2 weeks, but may reappear and be prolonged following the administration of steroids. Egg production by nematodes is also known to increase following steroid treatment and so pasture contamination is increased.

ALTERED SUSCEPTIBILITY TO THE ACQUISITION OF NEW INFECTIONS

Role of intercurrent infections

The interaction of various parasites or a parasite with another pathogen, resulting in exaggerated clinical disease, has been reported on several occasions. For example, in lambs, the nematode *Nematodirus battus* and the protozoan *Eimeria*; in cattle, the trematode *Fasciola hepatica* and the bacterium *Salmonella dublin*, and also *Fasciola hepatica* and the mange mite *Sarcoptes*; in pigs, the nematode *Trichuris suis* and the spirochaete *Serpula (Treponema) hyodysenteriae*.

Effect of chemotherapy

In certain instances, immunity to parasites appears to be dependent on the continuing presence of low-threshold infections, commonly called premunity. If the balance between the host and the immunising infection is disturbed by therapy, then reinfection of

the host may occur or, in the case of helminths, an arrested larval population may develop to maturity from the reservoir of infection within the host. Thus the use of anthelmintics, known to be effective against adult parasites but not arrested nematode larvae, may precipitate development of the latter once the adults are removed; this is known to occur in infections with *Hyostrongylus rubidus* in the pig. Sometimes, also, the overzealous application of anthelmintics in grazing animals will result in the eventual establishment of higher numbers of trichostrongyles than were present prior to treatment. Excessive application of acaricides to control ticks may also lower herd immunity to babesial and theilerial infections, so-called 'enzootic instability'.

Hypersensitivity

In many instances, at least part of the immune response to parasites is associated with a marked IgE response and a hypersensitivity reaction. Where this occurs in the gut, as in intestinal nematode infections, the reaction is associated with increased permeability of the gut to macromolecules such as protein, and this may be a significant factor in immune animals under heavy larval challenge. In sheep, for example, relatively poor growth rates and poor wool production may result.

A stunting effect has also been observed in tick-resistant animals which are under constant challenge, while pet animals repeatedly exposed to mite infestations may have severely thickened, hyperaemic and sensitive skin, although only negligible numbers of mites are present.

THE INTRODUCTION OF SUSCEPTIBLE STOCK

Parasitism may result from the movement of susceptible stock into an infected environment due to the following factors.

ABSENCE OF ACQUIRED IMMUNITY

The common nematode diseases of ruminants provide the best examples of outbreaks of parasitic disease following the movement of calves into infected areas. For example, in western Europe the cattle lungworm, *Dictyocaulus viviparus*, is endemic; the most severe outbreaks are seen in calves born in early spring and turned out in late summer to graze alongside older batches of calves which have grazed from early spring. Overwintered larval populations have cycled in these older calves and when the fresh populations of infective larvae, which develop from these infections, accrue on pasture, the younger calves, with no previous experience of infection, are extremely susceptible.

The occurrence of 'cysticercosis storms' in adult cattle, grazed on fields contaminated with eggs of the human tapeworm, *Taenia saginata*, or handled by infected stockmen, are occasionally reported in Europe and the USA. This high degree of susceptibility is due to lack of previous exposure to infection. In contrast, in areas where cysticercosis is endemic, cattle are repeatedly infected and soon acquire solid resistance to reinfection, only the cysts acquired in early life persisting in the muscles.

With protozoal diseases, such as babesiosis, theileriosis, coccidiosis and toxoplasmosis, caution has to be exercised in introducing

naive animals into infected areas. In the case of toxoplasmosis, the introduction of female sheep into a flock in which the disease is endemic has to be carefully controlled and these animals should be non-pregnant when purchased and allowed to graze with the flock for some months prior to mating.

ABSENCE OF AGE IMMUNITY

A significant age immunity develops against relatively few parasites, and adult stock not previously exposed to many helminth and protozoal infections are at risk if moved into an endemic area. This may be exacerbated if livestock are in poor body condition or on a low plane of nutrition.

LONGEVITY OF INFECTIVE STAGES

Especially in temperate zones and in parts of the subtropics, the free-living stages of most parasites will survive in the environment or in intermediate hosts for periods sufficiently long to reinfect successive batches of young animals and may cause disease in these animals within a few weeks of exposure.

INFLUENCE OF GENETIC FACTORS

Between host species

Most parasites are host-specific and this specificity has been utilised in integrated programmes to control gastrointestinal nematodes, such as mixed grazing of sheep and cattle. However, some economically important parasites are capable of infecting a wide range of hosts that vary in their susceptibility to the effects of the parasite. For example, cattle seem able to cope with liver fluke infestations which would cause death in sheep, and goats appear to be very much more susceptible than cattle or sheep to their common gastrointestinal trichostrongyles.

Between breeds

Evidence is accumulating that the susceptibility of various breeds of animals to parasites varies and is genetically determined. For example, some breeds of sheep are more susceptible to the abomasal nematode *Haemonchus contortus* than others; *Bos indicus* breeds of cattle are more resistant to ticks and other haematophagous insects than *Bos taurus* breeds. In Denmark, the Black Pied cattle are genetically deficient in their cellular immune responses and have proved more susceptible to liver fluke, while the N'dama breed of cattle in West Africa is known to be tolerant to trypanosomosis.

Even within flocks or herds, individual responders and non-responders, in terms of their ability to develop resistance to internal and external parasites, are usually present and it is recommended by some experts that culling of the poorest responders should take place.

Sex

There is some evidence that entire male animals are more susceptible than females to some helminth infections. This could be of

importance in countries where castration is not routinely practised, or where androgens are used to fatten castrates or cull cows.

STRAIN OF PARASITE

Although this aspect has received scant attention, except in protozoal infections, there is now evidence that there are strains of helminths and some ectoparasites, such as *Psoroptes* mites, which vary in infectivity and pathogenicity. In some cases this may be due to the presence of more host-adapted populations. The increasing prevalence of drug-resistant isolates of many parasites is another point which should be considered when disease outbreaks occur in herds, flocks or studs where control measures are routinely applied.

INTRODUCTION OF INFECTION INTO A CLEAN ENVIRONMENT

There are several ways in which a parasite may be introduced into an environment from which it has been eradicated or where it has never been found.

INTRODUCTION OF NEW STOCK

One of the current trends in the international livestock arena is the movement of breeding stock from country to country. Quarantine restrictions and vaccination requirements are stringent in relation to epidemic diseases, but limited or non-existent for parasitic diseases. When infected animals are moved into an area previously free from any given parasite the infection may cycle, provided suitable conditions exist, and the consequences for the indigenous stock can be extremely serious. Examples of this category include the introduction of *Toxocara vitulorum* into Britain and Ireland, the source of infection being Charolais heifers from mainland Europe with transmission occurring via the dam's milk, and the spread of *Parafilaria bovicola* in Sweden, presumably introduced with cattle or by the inadvertent transportation of muscid intermediate hosts from southern Europe. In the USA, Australia and Britain the increased movement of human populations and their pets has seen the spread of a number of diseases of dogs including heartworm, canine babesiosis and ehrlichiosis, infections previously limited to more tropical areas. In some of these situations, competent arthropod vectors suitable for transmission may have already been present in some areas. Psoroptic mange in cattle, originally confined to southern Europe, is now endemic in Belgium and Germany due to trade in breeds of cattle. Protozoal diseases, such as toxoplasmosis, have been introduced into sheep flocks in countries where it was previously absent, by the importation of infected sheep. Babesiosis has also spread where animals carrying infected ticks have moved into non-endemic areas where the ticks were able to become established.

ROLE OF EFFLUENT

The transfer of infection from one farm to another via manure has also been reported. Thus outbreaks of ostertagiosis have occurred on farms following the application of cattle slurry as a fertiliser, while cysticercosis 'storms' due to *Cysticercus bovis* have occurred in cattle following the application of human sewage to pastures.

Finally, the application of pig slurry containing ascarid eggs to pastures subsequently grazed by sheep has resulted in pneumonia due to migrating ascarid larvae.

ROLE OF INFECTED VECTORS

Winged insects transmit a number of helminth and protozoal infections, and these can serve to introduce infection into areas

previously free of infection. Migratory birds are known to carry larval or nymphal stages of potentially infected ticks. Occasionally, birds may also mechanically transport infective stages of parasites to a new environment. This has occurred in the Netherlands where the ditches and dykes surrounding reclaimed land have become colonised by *Galba (Lymnaea)* snails transported by wild birds. The introduction of livestock lightly infected with *Fasciola hepatica* resulted in the snails becoming infected and, subsequently, outbreaks of clinical fasciolosis.

Host resistance to parasitic diseases

Broadly speaking, resistance to parasitic infections falls into two categories. The first of these, often termed innate resistance, includes species resistance, age resistance and in some cases breed resistance, which, by and large, are not immunological in origin. The second category, acquired immunity, is dependent on antigenic stimulation and subsequent humoral and cellular responses. Although, for reasons explained in this chapter, there are few vaccines available against parasitic diseases, natural expression of acquired immunity plays a highly significant role in protecting animals against infections and in modulating the epidemiology of many parasitic diseases.

SPECIES RESISTANCE

For a variety of parasitological, physiological and biochemical reasons, many parasites do not develop at all in other than their natural hosts; this is typified by, for example, the remarkable host specificity of the various species of *Eimeria*. In many instances, however, a limited degree of development occurs, although this is not usually associated with clinical signs; for example, some larvae of the cattle parasite *Ostertagia ostertagi* undergo development in sheep, but very few reach the adult stage. However, in these unnatural or aberrant hosts, and especially with parasites which undergo tissue migration, there are occasionally serious consequences, particularly if the migratory route becomes erratic. An example of this is visceral larva migrans in children due to *Toxocara canis*, which is associated with hepatomegaly and occasionally ocular and cerebral involvement.

Some parasites, of course, have a very wide host range, *Trichinella spiralis*, *Fasciola hepatica*, *Cryptosporidium parvum* and the asexual stages of *Toxoplasma* being four examples.

AGE RESISTANCE

Many animals become more resistant to primary infections with some parasites as they reach maturity. For example, ascarid infections of animals are most likely to develop to patency if the hosts are a few months old. If hosts are infected at an older age, the parasites either fail to develop or are arrested as larval stages in the tissues; likewise, patent *Strongyloides* infections of ruminants and horses are most commonly seen in very young animals. Sheep of more than 3 months of age are relatively resistant to *Nematodirus battus*, and in a similar fashion dogs gradually develop resistance to infection with *Ancylostoma* over their first year of life.

The reasons underlying age resistance are unknown, although it has been suggested that the phenomenon is an indication that the host-parasite relationship has not yet fully evolved. Thus, while the parasite can develop in immature animals, it has not yet completely adapted to the adult.

On the other hand, where age resistance is encountered, most parasitic species seem to have developed an effective counter-mechanism. Thus, *Ancylostoma caninum*, *Toxocara canis*, *Toxocara mystax*, *Toxocara vitulorum* and *Strongyloides* spp. all survive as larval stages in the tissues of the host, only becoming activated during late pregnancy to infect the young *in utero* or by the transmammary route. In the case of *Nematodirus battus*, the critical hatching requirements for the egg, i.e. prolonged chill followed by a temperature in excess of 10°C, ensure the parasites' survival as a lamb-to-lamb infection from one season to the next.

Oddly enough, with *Babesia* and *Anaplasma* infection of cattle, there is generally thought to be an inverse age resistance, in that young animals are more resistant than older naive animals.

BREED RESISTANCE

In recent years, there has been considerable practical interest in the fact that some breeds of domestic ruminants are more resistant to certain parasitic infections, such as coccidian protozoa, nematodes, ticks and flies, than other breeds.

Probably the best example of this is the phenomenon of trypanotolerance displayed by West African humpless cattle such as the N'dama and the West African Shorthorn cattle, which survive in areas of heavy trypanosome challenge. The mechanism whereby these cattle control their parasitaemias is still not fully known, although it is thought that immunological responses may play a role.

In helminth infections, it has been shown that Red Masai sheep, indigenous to East Africa, are more resistant to *Haemonchus contortus* infection than some imported breeds studied in that area, while in South Africa it has been reported that the Merino is less susceptible to trichostrongylosis than certain other breeds. In the USA, the Florida Native (Gulf Coast), Barbados Blackbelly and the St Croix breeds of sheep are considerably more resistant to *H. contortus* than the Merino or the European breeds.

Within breeds, haemoglobin genotypes have been shown to reflect differences in susceptibility to *H. contortus* infection in that Merino, Scottish Blackface and Finn Dorset sheep, which are all homozygous for haemoglobin A, develop smaller worm burdens after infection than their haemoglobin B homozygous

or heterozygous counterparts. Unfortunately, these genotypic differences in susceptibility often break down under heavy challenge.

Studies within a single breed have shown in Australia that individual Merino lambs may be divided into responders and non-responders on the basis of their immunological response to infection with *Trichostrongylus colubriformis* and that these differences are genetically transferred to the next generation.

The selection of resistant animals could be of great importance, especially in many developing areas of the world, but in practice would be most easily based on some easily recognisable feature such as coat colour rather than be dependent on laboratory tests.

In Australia resistance to ticks, particularly *Rhipicephalus (Boophilus)*, has been shown to be influenced by genetics, being high in the humped, *Bos indicus*, Zebu breeds and low in the European, *Bos taurus*, breeds. However, where cattle are 50% Zebu, or greater, in genetic constitution, a high degree of resistance is still possible allowing a limited use of acaricides.

ACQUIRED IMMUNITY TO HELMINTH INFECTIONS

Multicellular parasites such as helminths are very complex genetic organisms and because of their physical size they are unable to be consumed by phagocytic cells or destroyed by classic cytotoxic T cells. The host's immune system has had to devise new approaches to combat invasion by these parasites. These are generally referred to as type 2 immune responses (T-helper 2 or Th2) or the allergy-type immune responses. They are frequently characterised by increases in the concentrations of interleukin (IL)-4 and other Th2-type cytokines, such as IL-5, IL-9, IL-13 and IL-21. These responses are usually characterised by the recruitment and activation of effector cells, such as eosinophils, basophils and mast cells which can produce various type 2 cytokines. There is continual communication between the innate and adaptive components of an active immune response to parasite invasion, with the T cells evoking signals that increase and modify the function of innate effector cells. The specific effector cells and antibody classes that mediate protection in the host immune responses vary considerably between different parasites. Individual effector-cell types may also have multiple functions. Frequently, parasite infestation causes chronic infections and the immune response that develops over a prolonged period can induce pathological changes in tissues. For example, in schistosome infections antigens shed from eggs can induce a marked Th2-type response that stimulates the development of granulomatous lesions in the liver parenchyma. Immune responses to helminths are complex, possibly depending on antigenic stimulation by secretory or excretory products released during the development of the L₃ to the adult. For this reason it has only been possible to develop one or two practical methods of artificial immunisation, of which the radiation-attenuated vaccine against *Dictyocaulus viviparus* is perhaps the best example.

Despite this, there is no doubt that the success of many systems of grazing management depend on the gradual development by cattle and sheep of a naturally acquired degree of immunity to gastrointestinal nematodes. For example, experimental observations have shown that an immune adult sheep may ingest around 50,000 *Teladorsagia (Ostertagia)* L₃ daily without showing any clinical signs of parasitic gastritis.

EFFECT OF THE IMMUNE RESPONSE

Dealing first with gastrointestinal and pulmonary nematodes, the effects of the immune response may be grouped under three headings, the sequence reflecting the usual progression of acquired immunity.

- 1 Initially, the host can attempt to limit reinfection by preventing the migration and establishment of larvae and penetration of the mucosal barrier or, sometimes, by arresting their development at a larval stage. This type of inhibition of development should not be confused with the more common hypobiosis triggered by environmental effects on infective larvae on pasture or, in the present state of knowledge, with the arrested larval development associated with age resistance in, for example, the ascarids.
- 2 Adults that do develop may be stunted in size or their fecundity may be reduced. The important practical aspect of this mechanism is perhaps not so much the reduced pathogenicity of such worms as the great reduction in pasture contamination with eggs and larvae, which in turn reduces the chance of subsequent reinfection.
- 3 The development of immunity after a primary infection may be associated with an ability to kill or expel the adult nematodes.

Each of these mechanisms is exemplified in infections of the rat with the trichostrongyloid nematode *Nippostrongylus brasiliensis*, a much-studied laboratory model, which has contributed greatly to our understanding of the mechanisms of host immunity in helminth infection. The infective stage of this parasite is normally a skin penetrator, but in the laboratory is usually injected subcutaneously for convenience. The larvae travel via the bloodstream to the lungs where, having moulted, they pass up the trachea and are swallowed. On reaching the small intestine they undergo a further moult and become adult, the time elapsing between infection and development to egg-laying adults being 5–6 days. The adult population remains static for about another 5 days. After this time the faecal worm egg output drops quickly, and the majority of the worms are rapidly expelled from the gut. This expulsion of adult worms, originally known as the 'self-cure' phenomenon, has been shown to be due to an immune response.

If the rats are reinfected, a smaller proportion of the larval dose arrives in the intestine, i.e. their migration is stopped. The few adult worms which do develop in the gut remain stunted and are relatively infertile, and worm expulsion starts earlier and proceeds at a faster rate.

Under natural grazing conditions larval infections of cattle and sheep are acquired over a period, but an approximately similar series of events occurs. For example, calves exposed to *Dictyocaulus viviparus* quite rapidly acquire patent infections, readily recognisable by the clinical signs. After a period of a few weeks, immunity develops and the adult worm burdens are expelled. On subsequent exposure in succeeding years such animals are highly resistant to challenge, although if this is heavy, clinical signs associated with the reinfection syndrome (i.e. immunological destruction of the invading larvae in the lungs) may be seen. With *Ostertagia* and *Trichostrongylus* infections, the pattern is the same, with the build-up of an infestation of adult worms being followed by their expulsion and subsequent immunity; in later life only small, short-lived, adult infections are established and eventually the infective larvae are expelled without any development at all. However, with gastrointestinal infections in ruminants, the ability to develop good immune

responses is often delayed for some months because of immunological unresponsiveness.

The mechanism of immunity to luminal parasites is still not fully understood despite considerable research. This response includes both innate and adaptive components. However, it is generally agreed that such infections stimulate a Th2-type response and produce a state of gut hypersensitivity associated with an increase in mucosal mast cells in the lamina propria and the production of worm-specific IgE, much of which becomes bound to the surface of the mast cells. The reaction of worm antigen, from an existing infection or from a subsequent challenge, with these sensitised mast cells releases vasoactive amines, which cause an increase in capillary and epithelial permeability and hyperproduction of mucus. Some workers have concluded that these physiological changes simply affect the well-being of the worms by, for example, lowering the oxygen tension of their environment so that they become detached from the mucosa and subsequently expelled. Others have postulated that, in addition, the permeable mucosa allows the 'leakage' of IgG anti-worm antibody from the plasma into the gut lumen, where it has access to the parasites. Although the majority of helminths induce marked mast-cell responses, their role in mediating resistance to infection varies considerably between parasite infections. For example, in rodent models, the presence of mast cells is required for the expulsion of *Trichinella spiralis*, whereas mast cells are not essential for the rejection of *Nippostrongylus brasiliensis*.

Additional factors, such as the secretion of specific anti-worm IgA on the mucosal surface and the significance of sensitised T cells, which are known to promote the differentiation of mast cells, eosinophils and mucus-secreting cells, are also currently under study.

With regard to tissue-invading helminths, the most closely studied have been the schistosomes. Schistosomulae of *Schistosoma mansoni* may be attacked by both eosinophils and macrophages, which attach to the antibody-coated parasite. Eosinophils, especially, attach closely to the parasites where their secretions damage the underlying parasite membrane. Eosinophils release a secondary granule protein and can also produce cytokines (IL-4, IL-13) which can have a regulatory role. Attempts to find if a similar mechanism exists against *Fasciola hepatica* have indicated that although eosinophils do attach to parts of the tegument of the young fluke, the latter seems able to shed its surface layer to evade damage.

In *Schistosoma* infections, there is an initial Th1-type response to the acute infection that is directed against adult parasites, but following patency and egg deposition in tissues the response changes to predominately a Th2-type response. In cases where an effective Th2-type response fails to develop after egg deposition, the outcome is often increased granulomatous inflammation in the tissues and liver parenchyma, induced by the underlying Th1-type response. Thus the protective Th2-type response minimises the pathological consequences of a Th1-type response and the outcome is often mild granulomas composed of macrophages, lymphocytes and eosinophils.

EVASION OF THE HOST'S IMMUNE RESPONSE

Despite the evidence that animals are able to develop vigorous immune responses to many helminth infections, it is now clear that parasites, in the course of evolution, have capitalised on certain defects in this armoury. This aspect of parasitology is still in its infancy, but four examples of immune evasion are described here.

Neonatal immunological unresponsiveness

This is the inability of young animals to develop a proper immune response to some parasitic infections. For example, calves and lambs fail to develop any useful degree of immunity to reinfection with *Ostertagia* spp. until they have been exposed to constant reinfection for an entire grazing season. Similarly, lambs remain susceptible to *H. contortus* infection until they are between 6 and 12 months old. The cause of this unresponsiveness is unknown. However, while calves and lambs ultimately do develop a good immune response to *Ostertagia* or *Teladorsagia* infection, in the sheep/*H. contortus* system the neonatal unresponsiveness is apparently often succeeded by a long period of acquired immunological unresponsiveness, for example Merino sheep reared from birth in a *Haemonchus*-endemic environment remain susceptible to reinfection throughout their entire lives.

Concomitant immunity

This term is used to describe an immunity which acts against invading larval stages, but not against an existing infection. Thus a host may be infected with adult parasites, but has a measure of immunity to further infection. Perhaps the best example is that found with schistosomes, which are covered by a cytoplasmic syncytium that, unlike the chitinous-like cuticle of nematodes, would at first seem to be vulnerable to the action of antibody or cells. However, it has been found that adult schistosomes have the property of being able to incorporate host antigens, such as blood group antigens or host immunoglobulin, on their surface membrane to mask their own foreign antigens.

Concomitant immunity does not appear to operate with *F. hepatica* in sheep, in that they remain susceptible to reinfection. On the other hand, cattle not only expel their primary adult burden of *F. hepatica*, but also develop marked resistance to reinfection. Concomitant immunity also includes the situation where established larval cestodes may survive for years in the tissues of the host, although the latter is completely immune to reinfection. The mechanism is unknown, but it is thought that the established cyst may be masked by host antigen or perhaps secrete an 'anti-complementary' substance which blocks the effect of an immune reaction.

Polyclonal stimulation of immunoglobulin

As well as stimulating the production of specific IgE antibody, helminths 'turn on' the production of large amounts of non-specific IgE. This may help the parasite in two ways. First, if mast cells are coated by non-specific IgE, they are less likely to attract parasite-specific IgE and so will not degranulate when exposed to parasite antigen. Secondly, the fact that the host is producing immunoglobulin in a non-specific fashion means that specific antibody to the helminth is less likely to be produced in adequate quantity.

Parasite immunomodulation

Despite the diversity of the helminth parasites, they show common ways of evading or manipulating the host immune response to their benefit. They suppress immunopathology by modulating the activity of immune effector cells (different B and T cell types) and the expression of a range of cytokines. Thus distantly related

parasites have independently evolved to exploit a range of host immunoregulatory mechanisms to their own advantage, and by invoking generic suppressive pathways can also suppress bystander responses to allergens and self-antigens. *Fasciola hepatica*, the liver fluke, is a common parasite of cattle in much of the world and suppresses interferon (IFN)- γ responsiveness in cattle infected with bovine tuberculosis. The determination of blood IFN- γ levels is an important element of tuberculosis testing programmes and it has been suggested that the presence of *F. hepatica* in infected animals could markedly interfere with tuberculosis eradication programmes where tuberculosis incidence and *F. hepatica* infection are both high.

COST OF THE IMMUNE RESPONSE

Sometimes, immune responses are associated with lesions that are damaging to the host. For example, the pathogenic effects of oesophagostomosis are frequently attributable to the intestinal nodules of *Oesophagostomum columbianum*; similarly, the pathogenic effects of schistosomosis are due to the egg granulomas, the result of cell-mediated reactions, in the liver and bladder.

There is evidence from some studies for a negative genetic interaction between production traits and resistance to parasitism. Sheep which have been selected for their resistance to gastrointestinal nematode infection show a higher incidence of scouring. This may be the result of an increased hypersensitivity to ingested larvae. Indeed, there is now a general consensus that the host's immune responses and immune pathology directly contribute to the impaired productivity observed in parasitised livestock.

Developing and implementing a strong effective immune response against parasite invasion, establishment or subsequent reinfection will utilise essential host resources, in particular protein, since antibodies, cytokines, leukotrienes and effector cellular responses are highly proteinaceous. These effects will be more deleterious in situations where nutrient supply is limited. Thus in high production animals on lower planes of nutrition it may not be desirable to induce a strong immune response. However, these consequences have to be weighed against the need to maintain protection against the potential pathogenic effects of the parasitic infection. One of the consistent features of many gastrointestinal infections of ruminants is a reduction in voluntary food intake (parasite-induced anorexia), although recent data have shown that the appetite of immunosuppressed parasitised lambs is similar to that of their uninfected controls. This observation might imply that the cascade of events involved in mounting an effective immune response against infection may be partly responsible for the parasite-induced reduction of food intake. Thus the cost of mounting an effective immune response may outweigh the benefits gained in some situations, although caution is required as these effects may vary between parasite species, host species and genotype. Longer-term studies would suggest that the lowering of production performance in younger livestock, which often occurs as they are initially acquiring a protective immune response to a gastrointestinal parasite infection, may be offset by the reduction in susceptibility to larval challenge observed in older animals and also the lower infectivity of pastures that results from reduced contamination with nematode eggs. Now that this complex relationship between the parasite, nutrition and the acquisition of immunity is better understood, it is hoped that in the future the trade-off between the nutrient cost of developing an effective immune response and the economic benefit

of maintaining an acceptable level of performance can be addressed in order to maintain the nutrient status of the parasitised animal, particularly in situations where nutrient supply is limited.

ACQUIRED IMMUNITY TO PROTOZOAL INFECTIONS

As might be anticipated from their microscopic size and unicellular state, immunological responses against protozoa are similar to those directed against bacteria. However, the subject is exceedingly complex and the following account is essentially a digest of current information on some of the more important pathogens. As with bacterial infections, immune responses are typically humoral or cell-mediated in type and occasionally both are involved. The cell-mediated responses are typically IFN- γ -dominant Th1-type responses which are associated with an increase in the number of cytotoxic CD8+ T cells, Th1 cells, macrophages and neutrophils.

Trypanosomosis is a good example of a protozoal disease to which immunity is primarily humoral. Thus, *in vitro*, both IgG and IgM can be shown to lyse or agglutinate trypanosomes and *in vivo* even a small amount of immune serum will clear trypanosomes from the circulation, apparently by facilitating their uptake, through opsonisation, by phagocytic cells. Unfortunately, the phenomenon of antigenic variation, another method of immune evasion, prevents these infections being completely eliminated and typically allows the disease to run a characteristic course of continuous remissions and exacerbations of parasitaemia. It is also likely that the generalised immunosuppression induced by this disease may, sooner or later, limit the responsiveness of the host.

It is also relevant to note that some of the important lesions of trypanosomosis, such as anaemia, myocarditis and lesions of skeletal muscle, are thought to be attributable to the deposition of trypanosome antigen or immune complexes on these cells and leading to their subsequent destruction by macrophages or lymphocytes, a possible debit effect of the immune response.

Acquired immunity to babesiosis also appears to be mediated by antibody, perhaps acting as an opsonin, and facilitating the uptake of infected red cells by splenic macrophages. Antibody is also transferred in the colostrum of the mother to the newborn animal and confers a period of protection against infection.

Finally, in trichomonosis, antibody, presumably produced by plasma cells in the lamina propria of the uterus and vagina, is present in the mucus secreted by these organs and to a lesser extent in the plasma. This, *in vitro*, kills or agglutinates the trichomonads and is probably the major factor responsible for the self-limiting infections that typically occur in cows.

Of those protozoal infections against which immunity is primarily cell-mediated, leishmaniosis is of particular interest in that the amastigotes invade and proliferate in macrophages whose function, paradoxically, is the phagocytosis and destruction of foreign organisms. How they survive in macrophages is unknown, although it has been suggested that they may release substances which inhibit the enzyme activity of lysosomes or that the amastigote surface coat is refractory to lysosomal enzymes. The immunity that develops seems to be cell-mediated, perhaps by cytotoxic T cells destroying infected macrophages or by the soluble products of sensitised T cells 'activating' macrophages to a point where they are able to destroy their intracellular parasites. Unfortunately, in many cases the efficacy of the immune response and the consequent recovery

is delayed or prevented by a variable degree of immunosuppression of uncertain aetiology.

As noted in the preceding paragraphs, sometimes both humoral and cell-mediated reactions are involved in immunity, and this seems to be the situation with coccidiosis, theileriosis and toxoplasmosis.

In coccidiosis, the protective antigens are associated with the developing asexual stages and the expression of immunity is dependent on T-cell activity. It is thought that these function in two ways: first, as helper cells for the production of neutralising antibody against the extracellular sporozoites and merozoites and, secondly, in a cell-mediated fashion by releasing substances such as lymphokines which inhibit the multiplication of the intracellular stages. The net effect of these two immunological responses is manifested by a reduction in clinical signs, and a decrease in oocyst production.

As described earlier, the proliferative stages of theilerial infections are the merogonous stages, which develop in lymphoblasts and divide synchronously with these cells to produce two infected daughter cells. During the course of infection, and provided it is not rapidly fatal, cell-mediated responses are stimulated in the form of cytotoxic T cells that target the infected lymphoblasts by recognising two antigens on the host surface. One of these is derived from the *Theileria* parasite and the other is a histocompatibility antigen of the host cell. The role of antibodies in protection is less clear, although it has been recently demonstrated, using an *in vitro* test, that an antibody against the sporozoites inoculated by the tick may be highly effective in protection.

In toxoplasmosis also, both humoral and cell-mediated components appear to be involved in the immune response. However, the relative importance of their roles remains to be ascertained, although it is generally believed that antibody formation by the host leads to cessation in the production of tachyzoites and to the development of the latent bradyzoite cyst. It is also believed that recrudescence of tachyzoite activity may occur if the host becomes immunosuppressed as a consequence of therapy or some other disease.

ACQUIRED IMMUNITY TO ARTHROPOD INFECTIONS

It is known that animals exposed to repeated attacks by some insects gradually develop a degree of acquired immunity. For example, at least in humans, over a period of time the skin reactions to the bites of *Culicoides* and mosquitoes usually decrease in severity. Likewise, after several repeated infestations by blowfly larvae, sheep have been known to develop a degree of resistance to further attack, although this response is short-lived.

A similar sequence of events has been observed with many tick and mite infestations. The immune reaction to ticks, dependent on humoral and cell-mediated components to the oral secretions of the ticks, prevents proper engorgement of the parasites and has serious consequences on their subsequent fertility; dogs that have recovered from sarcoptic mange are usually immune to further infection. Some sheep infected with psoroptic mange (sheep scab) and which recover may demonstrate a degree of protective immunity to subsequent reinfection.

Although these immune responses may moderate the clinical significance of some ectoparasitic infections, the immune response to infestation may result in the unfortunate consequences which often occur when an animal becomes sensitised to arthropod antigens.

Examples of this are flea dermatitis in dogs and cats, the pruritus and erythema associated with sarcoptic mange in the dog and pig and with psoroptic mange in sheep and cattle, and 'sweet itch' of horses due to skin hypersensitivity to *Culicoides* bites.

THE FUTURE OF PARASITE VACCINES

Early approaches that investigated the use of live radiation-attenuated parasite vaccines, which induced a high level of protection against larval challenge, resulted in commercially available vaccines for the bovine lungworm, *Dictyocaulus viviparus*, and also for *Eimeria* infections in poultry. Apart from *D. viviparus* there are no commercially produced vaccines for the control of helminth infections in ruminants. These encouraging results were experimentally applied to other economically important nematodes of ruminants (notably *T. colubriformis* and *H. contortus*); however, although partially effective in older animals, the vaccines provided an insufficient level of protection or the response was too variable in young animals under field conditions. An irradiated larval vaccine was developed against the dog hookworm *Ancylostoma caninum* that gave a high level of protection in the field but the vaccine was withdrawn from use over concerns with efficacy and storage viability. Early studies to develop a vaccine against liver fluke was hampered by the observation that these parasites do not appear to induce significant immunity in the natural ruminant host, even after repeated exposure to infection. The increased prevalence of parasites resistant to chemotherapy has led to further investment in vaccine development, particularly those based on recombinant parasite components, and considerable progress has been made over the past two decades in identifying candidate antigens for several important parasite species.

Experimental vaccines have already been developed, for example against *Taenia ovis* infection in sheep, *Babesia canis* in dogs, and *Babesia bovis* and *Rhipicephalus (Boophilus) microplus* in cattle. The commercial success of current experimental recombinant vaccines will depend not only on their efficacy under field challenge but also on factors such as effective low-cost delivery systems that will confer long-acting protection.

Two main approaches have been adopted for vaccine development: those based on 'natural antigens' on the surface of the parasite or excreted/secreted by the parasite which are recognised by the host during the course of infection, and those based on 'hidden' or 'covert' antigens. The latter strategy ignores the mechanisms of natural immunity and directs responses towards molecules located or secreted internally. There have been encouraging advances towards the aim of producing vaccines for the control of several parasitic diseases in the last decade. Recent research has identified protective antigen fractions which have then been enriched and characterised and the genes encoding the active components of many of these have been cloned.

HELMINTHS

Natural antigens

Natural antigens are those which are recognised by the host immune system following infection. The following information is not intended to represent a comprehensive list but to mainly

highlight some successful natural antigens derived from parasites of veterinary interest.

Surface and somatic antigens

A high level of protective immunity has been demonstrated in sheep vaccinated with fractions derived from the infective larval stage contained within the oncospheres of the cestodes *Taenia* and *Echinococcus* and identification of these protective proteins led initially to effective recombinant antigens for *T. ovis* and *E. granulosus*. Highly effective recombinant vaccines were subsequently available for vaccination of the intermediate hosts against infections with *Echinococcus multilocularis*, *Taenia solium* and *Taenia saginata*. However, the commercial development of vaccines for *T. ovis* and *T. saginata* was not entirely viable as these tapeworm infections are primarily a zoonotic problem in poor developing countries and are generally of minor economic significance. The economic return and sources of funding need further evaluation.

Excretory/secretory antigens

Parasitic helminths produce and secrete a range of proteins that have a variety of functions. Some enable the parasite to penetrate the host's tissue, while others are involved with the digestion of nutrients or in evasion of the host's immune response. It has been demonstrated that the immune response of the host can impair the function of these proteins and thus lead to worm expulsion and so they have received considerable attention as vaccine antigens. Highly protective effects have been reported against *H. contortus* using adult worm excretory/secretory (ES) products comprising two proteins of 15 and 24 kDa. However, recombinant versions of these proteins have not been protective. Research conducted over the last two decades has shown that the ES proteases, particularly cysteine proteases, associated with the intestinal surface of ovine nematodes such as *H. contortus* or bovine *Ostertagia ostertagi* are most effective vaccine components. Other proteases which can mediate vaccine-induced protective immunity in ruminants are the aspartic proteases, metalloproteases, dipeptidylpeptidases and aminopeptidases and thiol-binding fractions. The mode of action is mainly via induction of antibodies which block enzyme activity resulting in worm expulsion or impaired fecundity. However, expression of these promising native protease candidates as recombinant vaccines has been unsuccessful, probably as a result of incorrect folding and or glycosylation of the proteins.

Recently, protective antigens from *Teladorsagia circumcincta*, the major pathogen causing parasitic gastroenteritis in small ruminants in temperate regions, have been identified by studying IgA responses directed at proteins specific to post-infective larvae and also on the basis of their potential immunomodulatory role at the host-parasite interface. Recombinant versions of eight molecules identified by immunoproteomics, homology with vaccine candidates in other nematodes and/or with potential immunoregulatory activities were administered to sheep in a single vaccine formulation with an adjuvant and the animals subsequently subjected to a repeated challenge infection designed to mimic field conditions. The trial was performed on two occasions. In both trials, vaccinates had much lower mean faecal worm egg outputs and adult worm burdens were reduced by as much as 75% compared to the controls at postmortem. These levels of protection indicate that control of

parasitic helminths via vaccination with recombinant subunit vaccine cocktails could indeed be an alternative option in the face of multidrug resistance.

Promising vaccines against *F. hepatica* have mostly been based on antigens such as cysteine proteases, leucine aminopeptidase and glutathione *S*-transferase. Cathepsin L cysteine proteases are secretion products from liver flukes that are released throughout the life cycle in the host and facilitate penetration of the parasites through the tissues of the host and are targets for vaccination. High levels of protection (reduced fluke burdens and fewer flukes developing to maturity) have been attained in sheep and cattle against *F. hepatica* using these natural cysteine protease enzymes in vaccine trials. Efficacy was further improved in cattle trials when cathepsin L2 was used in combination with fluke haemoglobin compared with either antigen alone. Recently, field trials of a recombinant cathepsin L1 (rFhCL1) against *F. hepatica* in cattle showed a 48% reduction in fluke burden compared with non-vaccinated controls. Cathepsin B proteases of *Fasciola*, which are predominantly released in the juvenile stage of the life cycle, have also been shown to be promising vaccine targets. A further potential vaccine candidate for fluke are the fatty acid binding proteins (FABPs), which are thought to play an important role in the uptake of fatty acids from the bloodstream of the mammalian host. FABPs from *F. hepatica* exhibit cross-protection and cross-reaction against *Schistosoma mansoni*. A recombinant version of a FABP (Sm14) from *S. mansoni* reduced the number of liver flukes and limited the histopathological damage to the liver in vaccination trials in sheep against a challenge with *F. hepatica*.

Leucine aminopeptidase, a gut-associated protease isolated from detergent soluble-extract of adult flukes, was successfully used as a vaccine against *F. hepatica* in sheep. Given alone with adjuvant, or in combination with the adult stage-specific secreted cathepsin L proteases, it induced high levels of protection in recipient sheep, with vaccinated animals showing an 89% reduction in fluke burden compared with the controls. This success has been duplicated with a bacterially produced recombinant protein version of the vaccine.

Considerable progress has been achieved in the area of defining antigenic targets of potential hookworm vaccines. A recombinant haemoglobinase protein, aspartic protease (Ac-APR-1), from the hookworm *Ancylostoma caninum* induces protection in dogs via antibodies that neutralise enzymic activity and thus disrupt blood-feeding activity, resulting in reduced parasite burdens and blood loss. A recombinant glutathione *S*-transferase (Ac-GT-1) also shows efficacy as a vaccine candidate. A further recombinant product, *Ancylostoma* secreted protein (Ac-ASP-2), gave good protection in dogs. The mechanism of protection appears to be directed against the larval stages of the hookworm. The future approach may be to incorporate several potential vaccine antigens, including the promising candidates discussed here, in order to target both the larval and adults stages of hookworms.

Hidden antigens

This approach primarily uses gut membrane proteins from parasites and these are not normally exposed to the host's natural immune system. Injection of these proteins into a host induces high titres of circulating antibody. When a haematophagous parasite ingests blood these antibodies bind to the surface of the parasite's gut and impair the digestion/absorption of nutrients and the weakened parasite is expelled from the host. This gut membrane

approach formed the basis of the recombinant vaccine against *Rhipicephalus (Boophilus) microplus*, the Australian cattle tick (see details in the section Ectoparasites). Early experimental studies with *H. contortus* in sheep, using natural fractions of these gut proteins, have shown that the reduction in the number of eggs passed in faeces can be greater than 80% and worm burdens can be lowered by more than 50% in vaccinated animals when compared to unvaccinated controls. Fractionation of these proteins from adult *H. contortus* showed that two main components are involved: H11 (also known as aminopeptidase N), which contains microsomal aminopeptidases, and H-gal-GP, a gut membrane-associated protein complex containing metalloproteases and aspartyl proteases. Numerous trials conducted over the last two decades with penned sheep have confirmed the efficacy of this approach using native gut membrane proteins. There has been partial success in applying this 'hidden' antigen approach to non-haematophagous parasites such as *Ostertagia ostertagi* and *Teladorsagia circumcincta*. Despite these encouraging results using natural proteins and the characterisation of the protective antigens, the testing of recombinant versions of these gut membrane proteins have been unsuccessful in vaccine trials, indicating that conformational epitopes are likely to be important in conferring protection. The situation is similar with liver fluke vaccine trials. A natural gut membrane fraction enriched for glutathione *S*-transferases has been shown to lower fluke egg output in faeces and also reduce fluke burdens in both sheep and cattle, although with variable efficiency. However, attempts to vaccinate animals with recombinant versions of these proteins have been unsuccessful. An important advantage of using 'covert' or hidden antigens in vaccine strategies is that they should be effective in those infections where natural immunity is poorly developed or is ineffective. A possible disadvantage is that immunity is not boosted by infection. However, it has been shown in *H. contortus* infection in lambs that vaccination with hidden gut membrane antigens, which are predominantly proteases and which are not normally recognised by the host during infection, will provide protection and by the time this wanes sufficient natural immunity will have been acquired. Although considerable progress has been made towards the experimental production of some monovalent vaccines, it is likely to be several years before commercially produced recombinant vaccines are available.

In the light of the problems encountered in expressing the natural proteins in a recombinant form that is immunologically active and protective, attention has focused back on the possibility of using the natural proteins as vaccines. One of the perceived problems with this approach was that large amounts of fresh parasite material were required to produce sufficient quantities of the active fractions. However, once it had been established that the dose of natural antigen required to produce a significant level of protection was actually very small (as low as 5 µg), it became feasible, and a commercial possibility, to extract the relevant integral gut membrane proteins from adult worms collected from animals given booster infections. One example was a field trial where weaner sheep were grazed on pastures contaminated with *H. contortus* and were then vaccinated on three occasions at 3-week intervals with the native gut membrane glycoproteins H11 and H-gal-GP in combination. The vaccinated animals showed a significant reduction in their faecal egg counts and also in the severity of anaemia in comparison to that observed in the unvaccinated controls. An experimental vaccine, comprising native integral gut membrane proteins from *H. contortus*, has been shown to confer significant cross-protection in calves against a challenge infection

with *H. placei*. Recently, the technique for the rapid mass recovery of worms from booster-infected sheep has been markedly improved and this approach has formed the basis for a commercial vaccine, which uses small amounts of native *H. contortus* proteins, purified from the lining of worm intestines. Barbevax was registered for use in Australia in 2014. This is the first vaccine in the world for a nematode parasite for sheep and it presents a new approach for control of haemonchosis. Currently, trials are being extended into other countries to confirm the commercial potential of this *Haemonchus* vaccine.

It is important to consider that this vaccine strategy will not induce a sterile protection but will lower worm burdens and the faecal egg output sufficiently to be a very useful means of reducing and maintaining a low level of pasture contamination. Mathematical modelling of vaccines that use the hidden antigen approach predict that a level of protection of around 80% efficacy in 80% of the flock or herd would give a higher level of control than that achieved through an anthelmintic approach.

In conclusion to this whole area of vaccination against helminth parasites it is considered that the apparent inefficiency of many vaccines, experimentally tested against helminth infections, may be partly due to the focus on only one or two antigens and this invariably produces a fairly narrow antibody response. The most efficient vaccines will undoubtedly need to induce broad Th2-type responses that include strong humoral and cell-mediated constituents.

PROTOZOA

A number of vaccines have been on the market for several years or decades to ameliorate the impact of protozoal diseases to the livestock and poultry sectors. The majority of these products are based on live organisms, although more recently there has been increased focus on the development of killed and subunit vaccines. Live organism vaccines are more likely to induce T cell-mediated immune responses and induce a more potent and longer-lived protective immunity against a challenge infection. Their disadvantage is that many have a fairly short shelf-life and there can be safety issues using live vaccines. They also often require a cold facility for storage and administration.

Live vaccines

Several approaches have been used to produce a protective immune response, including using the native protozoa, attenuated strains, truncated life cycles and chemically abbreviated infections.

Unattenuated vaccines which involve complete life-cycle infections

An example is the control of coccidiosis in poultry using small doses of *Eimeria* species that are sufficiently low as to cause minimal clinical symptoms yet still able to induce a significant level of protection. The first commercial vaccine (CocciVac) comprised wild-type strains of *Eimeria tenella* oocysts, and over several decades other species of *Eimeria* were introduced to broaden the effectiveness of the vaccine. One disadvantage of this approach was the differences in the levels of pathogenicity induced in inoculated hosts by the live parasites.

Vaccines using virulence-attenuated strains

The safety of the unattenuated approach has been improved through the inclusion of oocysts from natural 'precocious' *Eimeria* strains that exhibit a smaller number of merogonic cycles and hence offer a lower risk of inducing disease. 'Precocious' parasites complete their life cycle more rapidly and exhibit reduced virulence with high immunogenicity and have been developed for the seven species of *Eimeria* in poultry (e.g. Paracox to protect breeding and laying hens and more recently Eimeriavax 4m for egg-laying hens and broilers). These vaccines should be administered simultaneously to all individuals and comprise the major type of live attenuated vaccines in use for the control of coccidiosis in poultry.

A further example is the inoculation of cattle with an attenuated strain of *Theileria annulata* for the control of tropical theileriosis. Repeated *in vitro* passaging of the intracellular macroschizont stage of *T. annulata* in tissue culture cell lines resulted in a live attenuated vaccine that has been used in many countries (China, India, North Africa and the Middle East). Continuous passage attenuates the schizont-infected cells so that their pathogenicity is reduced but their infectivity is retained. Cell-line immunisation has not been as successful with *Theileria parva* due to histo-incompatibility between the cell line and the recipient animal and the fact that *T. parva* and *T. annulata* infect distinct bovine leucocyte populations. Similarly, passage of *Babesia bigemina* and *Babesia bovis* piroplasms in splenectomised calves resulted in an attenuated strain which is used as a frozen vaccine to reduce the pathogenicity of infection in inoculated cattle.

Vaccines using drug-abbreviated infections

This approach (initiated in the 1970s) has been adopted to limit the losses in cattle arising from East Coast fever in East and Central Africa. Cattle are vaccinated with a defined dose of a cryopreserved wild-type *Theileria parva* sporozoite stabilate and concurrently given a long-acting tetracycline treatment. The antibiotic slows the rate of schizogony and allows the immune response time to develop. The immunity induced is very strain-specific. The main disadvantage is that this approach is expensive for resource-poor farmers. However, a recent collaboration between a small private company and Maasai cattle herders in Tanzania has seen the successful vaccination and treatment of around 500,000 cattle against East Coast fever that lowered the mortality in the herds by up to 95% in some cases. Success was partly due to improved quality control of the vaccine stabilate and the production processes.

Vaccines using parasites which produce a truncated life cycle

This approach is particularly relevant to those parasites that produce cysts within the intermediate hosts. One example is *Toxoplasma gondii* in sheep and goats. The live vaccine comprises tachyzoites attenuated by repeated passage in mice. This attenuated strain (S48) does not form tissue cysts (which contain the bradyzoites) in the intermediate host and is not able to establish a persistent infection. It has also lost the potential to form oocysts in the definitive host, the cat. Thus the S48 strain is incomplete and undergoes

limited multiplication within the intermediate host but is still able to stimulate protective immune responses. This live vaccine confers long-acting immunity (effective protection even at 18 months after inoculation in the absence of further *T. gondii* challenge) against abortion induced by *Toxoplasma* infection in breeding ewes and is available commercially as Toxovax. This is currently the only commercial vaccine available to help prevent toxoplasmosis.

Killed and subunit vaccines

These vaccines are generally less effective than those using live organisms as they rely mainly on the induction of neutralising antibodies but they can reduce transmission of disease and often can also lower the pathogenic effects of natural infection. The major challenge is to be able to identify and then present relevant parasite antigens to the host's immune system in such a way that they can be processed to induce protective immune responses.

Vaccines using inactivated parasites

Bovilis Neoguard® was a commercial vaccine developed to reduce abortion in pregnant cattle resulting from infection with *Neospora caninum* and was available in the USA, New Zealand and some other countries. This vaccine comprised inactivated whole tachyzoites and inoculation aimed to reduce the transmission of the parasite to the developing fetus. The vaccine has recently been withdrawn from the market by the manufacturer. Although progress has been achieved towards reducing the impact of bovine neosporosis in cattle, a fully effective vaccine needs to prevent disease on primary exposure, reduce vertical transmission and abrogate the clinical signs of infection.

A vaccine is available commercially (GiardiaVax®) to reduce the clinical signs and pathogenesis of *Giardia intestinalis* (syn. *G. duodenalis*) infection in dogs and cats. It also lowers the faecal output of oocysts in young vaccinated animals and the period of diarrhoea is of reduced duration. This vaccine is based on disrupting axenically cultured trophozoites from an ovine isolate.

A vaccine has been developed to reduce the pathogenesis of equine protozoal myeloencephalitis in horses caused primarily by infection with *Sarcocystis neurona*. The vaccine is based on chemically inactivated cultured merozoites and has shown to be promising in ameliorating the neurological effects of infection.

Subunit vaccines

A subunit transmission-blocking vaccine which targets the sexual macrogametocyte stages and thus reduces oocyst output has been developed for the control of coccidial infections in poultry. The vaccine (CoxAbic®) comprises affinity-purified antigens from the gametocyte stages of *Eimeria maxima*. It provides a good level of protection across three species of *Eimeria* (*E. maxima*, *E. tenella*, *E. acervulina*) and is administered to laying hens where protection is passed, via the yolk, to their broiler offspring. Unfortunately, it is an expensive vaccine to manufacture and work is ongoing to test whether recombinant forms of the gametocyte proteins are as effective at producing antigenicity as the natural proteins.

A subunit vaccine is available to reduce the severity of clinical disease resulting from canine babesiosis. It contains soluble surface proteins expressed by cultures of *Babesia canis canis*. The strain-specific immunity has been broadened in a similar vaccine by the inclusion of *Babesia canis rossi* antigens.

A subunit vaccine has been developed in South America for the control of visceral leishmaniasis in dogs caused by *Leishmania donovani infantum*. This vaccine is based on a surface fucose-mannose- ligand antigen complex. CaniLeish® is a parasite lyophilisate vaccine, commercially available in Europe, containing ES proteins of *Leishmania infantum* for the immunisation of dogs.

ECTOPARASITES

Using the hidden antigen approach, the first recombinant vaccine was developed in 1994 against the cattle tick *Rhipicephalus (Boophilus) microplus*, and introduced commercially in Australia. The vaccine was later available in Cuba and in parts of South America. The active antigen is a membrane-bound protein (BM86) from the gut of the tick. In controlled field trials in Cuba, Brazil, Argentina and Mexico, this vaccine showed 55–100% efficacy in the control of *B. microplus* infestations in grazing cattle 12–36 weeks after the first vaccination. However, in order to maintain high levels of circulating antibody cattle have to be inoculated repeatedly.

Parasites of cattle

ENDOPARASITES

Parasites of the digestive system

OESOPHAGUS

Gongylonema pulchrum

Synonym: *G. scutatum*

Common name: Gullet worm

Predilection site: Oesophagus, rumen

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: A long, slender, whitish worm, the males being about 5.0 cm and the females up to about 14.0 cm in length.

Description, microscopic: Worms are easily distinguished microscopically by the presence of longitudinal rows of cuticular bosses in the anterior region of the body. Asymmetrical cervical alae are prominent. The egg is thick-shelled and possesses two opercula. It measures 50–70 by 25–37 µm and contains an L₁ when passed in faeces.

Final hosts: Sheep, goat, cattle, pig, buffalo, horse, donkey, deer, camel, human

Intermediate host: Coprophagous beetles, cockroaches

Geographical distribution: Probably worldwide

For more details see Chapter 9 (Sheep and goats).

Hypoderma bovis

For more details see Parasites of the integument.

Hypoderma lineatum

For more details see Parasites of the integument.

RUMEN AND RETICULUM

Gongylonema verrucosum

Common name: Rumen gullet worm

Predilection site: Rumen, reticulum, omasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Long slender worms, reddish when fresh. The males are about 3.5 cm and the females 7.0–9.5 cm in length.

Description, microscopic: The adult parasites have a festooned cervical ala and cuticular bosses only on the left side of the body. The males' spicules are unequal in length, with the left spicule longer than the right.

Final hosts: Cattle, sheep, goat, deer, zebu

Intermediate hosts: Coprophagous beetles and cockroaches

Geographical distribution: India, South Africa, USA

Pathogenesis: Usually regarded as non-pathogenic.

Clinical signs: Infection is usually asymptomatic.

Diagnosis: Usually an incidental finding on postmortem.

Pathology: Adult worms bury in the epithelium of the forestomachs producing white or red, blood-filled zig-zag tracts in the mucosa.

Epidemiology: Infection is very much dependent on the presence and abundance of the intermediate hosts, principally coprophagous beetles of the genera *Aphodius*, *Onthophagus*, *Blaps* and *Caccobius*.

Treatment: Not reported

Control: Control is neither practical nor necessary.

Paramphistomum and other rumen fluke

Rumen fluke, as their name implies, are mainly parasitic in the forestomachs of ruminants. Their shape is not typical of the trema-

todes, being conical and thick and fleshy rather than flat. All require a water snail as an intermediate host. There are several genera: *Paramphistomum*, *Cotylophoron*, *Bothriophoron*, *Orthocoelium* and *Giganocotyle*, of which *Paramphistomum* is the most common and widespread in ruminants.

The taxonomy of the paramphistomes is complex and unresolved and many of the species described may be synonymous, being differentiated mainly on size and shape of the suckers.

Pathogenesis: The adult parasites in the forestomachs are generally well tolerated, even when many thousands are present and feeding on the wall of the rumen or reticulum (Fig. 8.1). Any pathogenic effect is mainly associated with the intestinal phase of the infection, although the presence of adults in the rumen has been reported to cause effects on rumination leading to weight loss and ill-thrift.

Clinical signs: In heavy duodenal infections, the most obvious sign is diarrhoea accompanied by anorexia and intense thirst. Sometimes in cattle there is rectal haemorrhage following a period of prolonged straining. Mortality in acute outbreaks can be as high as 90%.

Diagnosis: This is based on the clinical signs usually involving young animals in the herd and a history of grazing around snail habitats during a period of dry weather. Faecal examination is of limited value since the acute disease occurs during the prepatent period. However, large numbers of paramphistome eggs can sometimes be present in faeces during acute disease as the intestinal phase may also be accompanied by large numbers of adult flukes in the forestomach. Confirmation can be obtained by postmortem examination and recovery of the small pink-coloured immature flukes from the duodenal mucosa and ileal contents.

Pathology: The immature flukes are embedded in the mucosa of the upper ileum and duodenum and are plug feeders, and this can result in severe erosion of the duodenal mucosa. In heavy infections these cause enteritis characterised by oedema, haemorrhage, ulceration and associated anaemia and hypoproteinaemia. At necropsy, the young flukes can be seen as clusters of brownish-pink parasites attached to the duodenal mucosa and occasionally also in the jejunum and abomasum.

Epidemiology: Paramphistomosis often depends for its continuous endemicity on permanent water masses, such as lakes and ponds,

Figure 8.1 Adult paramphistomes in the rumen.

from which snails are dispersed into previously dry areas by flooding during heavy rains. Paramphistome eggs deposited by animals grazing these areas hatch and infect snails. Subsequent production of cercariae often coincides with receding water levels, making them accessible to grazing ruminants. In other areas, the situation is complicated by the ability of the snails to aestivate on dry pastures and become reactivated on the return of rainfall. A good immunity develops in cattle, and outbreaks are usually confined to youngstock. However, adults continue to harbour low burdens of adult parasites and are important reservoirs of infection for snails. In contrast, sheep and goats are relatively susceptible throughout their lives.

Treatment: Resorantel and oxclozanide are considered the anthelmintics of choice against adult rumen flukes in both cattle and sheep. Recent studies have shown that closantel is also effective in cattle at 10 mg/kg.

Control: As in *Fasciola gigantica*, the best control is achieved by providing a piped water supply to troughs and preventing access of animals to natural water. Even then snails may gain access to watering troughs and regular application of a molluscicide at source or manual removal of snails may be necessary.

Paramphistomum cervi

Synonym: *Paramphistomum explanatum*

Common name: Rumen fluke

Predilection site: Rumen

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Description, gross: The adults are small, conical (pear-shaped), maggot-like flukes about 1.0 cm long and light red in colour when fresh (Fig. 8.2).

Description, microscopic: One sucker is visible at the tip of the cone and the other well-developed sucker is at the base. The tegument has no spines. The larval stages are less than 5.0 mm, fresh specimens having a pink colour. The egg resembles that of *Fasciola hepatica*, being large (about 115–175 by 75–100 μm) and operculate,

Figure 8.2 Adult flukes of *Paramphistomum*.

but is transparent or slightly greenish rather than yellowish-brown and slightly smaller than eggs of *F. hepatica* (see Fig. 9.1). In the early stages of segmentation the egg contains four to eight blastomeres surrounded by yolk cells.

Final hosts: Cattle, sheep, goat, deer, buffalo, antelope

Intermediate hosts: Water snails, principally *Planorbis* and *Bulinus*

Geographical distribution: Worldwide. They are of little veterinary significance in Europe and America, but are occasionally the cause of disease in the tropics and subtropics.

Paramphistomum microbothrium

Common name: Rumens fluke

Predilection site: Rumen

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Final hosts: Cattle, sheep, goat, deer, buffalo, antelope

Intermediate hosts: Freshwater snails (*Fossaria* spp., *Bulinus* spp.)

Geographical distribution: Africa

Paramphistomum ichikawa

Common name: Rumens fluke

Predilection site: Rumen

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Final hosts: Sheep, cattle

Intermediate hosts: Planorbid snails (*Gyraulus*, *Helicorbis*, *Segmentilia*)

Geographical distribution: Southeast Asia

Paraphistomum streptocoelium

Synonyms: *Ceylonocotyle streptocoelium*, *Orthocoelium streptocoelium*

Common name: Rumens fluke

Predilection site: Rumen

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Final hosts: Cattle, sheep, goat and wild ruminants

Intermediate hosts: Freshwater snails (*Glyptanissus* spp.)

Geographical distribution: Africa

Calicophoron daubneyi

Synonyms: *Paramphistomum daubnei*, *Paramphistomum daubneyi*

Common name: Rumens fluke

Predilection site: Rumen

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Description: Resembles *P. cervi*, but there is a genital sucker surrounding the genital pore.

Final hosts: Cattle, goat

Intermediate hosts: Freshwater snails (*Omphiscola* spp.), *Galba truncatula*

Geographical distribution: Europe (mainly Mediterranean areas but also recorded in the UK and Ireland), parts of Asia

Cotylophoron cotylophorum

Synonym: *Paramphistomum cotylophorum*

Common name: Rumens fluke

Predilection site: Rumen, reticulum

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Description, microscopic: The fluke is very similar to *Paramphistomum cervi* but the genital pore is surrounded by a genital sucker. The egg measures 125–135 by 60–68 μm .

Final hosts: Cattle, sheep and many other ruminants

Intermediate hosts: Freshwater snails (*Bulinus* spp.)

Geographical distribution: Indian subcontinent, Australia and many other countries except northern temperate regions

Calicophoron calicophorum

Synonym: *Paramphistomum calicophorum*

Common name: Rumens fluke

Predilection site: Rumen, reticulum

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Description, microscopic: The body measures 7.5–14.8 by 3–4 mm, and the genital pore is post-bifurcal. Eggs are 110–150 by 60–90 μm .

Final hosts: Cattle, sheep and many other ruminants

Intermediate hosts: Freshwater snails

Geographical distribution: Indian subcontinent, Southeast Asia, Australasia and South Africa

Carmyerius spatiosus

Common name: Rumens fluke

Synonym: *Gastrothylax spatiosus*

Predilection site: Rumens

Phylum: Platyhelminthes

Class: Trematoda

Family: Gastrothylacidae

Description, gross: The flukes measure 8.5–12 by 2.5–3.0 mm.

Description, microscopic: The posterior sucker is quite small and is spherical. The intestinal caeca extend down into the last quarter of the body. The ventral pouch is either circular or slightly triangular with blunt angles and the terminal genitalium lies within the pouch. The testes lie horizontally, one on each side of the median line, which differs from the position in *Fischoederius*. Eggs measure 115–125 by 60–65 µm.

Final hosts: Cattle, zebu, antelope

Intermediate hosts: Water snails

Geographical distribution: Southeast Asia, India, Africa and America

Carmyerius gregarius

Common name: Rumens fluke

Predilection site: Rumens

Phylum: Platyhelminthes

Class: Trematoda

Family: Gastrothylacidae

Description, gross: The flukes are 7–10 mm in length.

Description, microscopic: The intestinal caeca extend only a short distance below the middle of the body.

Final hosts: Cattle, buffalo

Intermediate hosts: Water snails

Geographical distribution: India, Africa

Gastrothylax crumenifer

Common name: Rumens fluke

Predilection site: Rumens, reticulum

Phylum: Platyhelminthes

Class: Trematoda

Family: Gastrothylacidae

Description, gross: This is an elongated fluke, being circular in transverse section and reddish in colour when fresh. The body measures 10–16 by 5–8 mm.

Description, microscopic: These flukes differ in having an extremely large ventral pouch that opens anteriorly and which covers the ventral surface of the fluke as far as the large ventral sucker. The ventral pouch is normally triangular in cross-section with a dorsally directed apex. The terminal genitalium opens into

the ventral pouch about halfway between the intestinal bifurcation and the pharynx. The terminal oval sucker is small. Eggs are 115–135 by 66–70 µm.

Final hosts: Cattle, buffalo, zebu, sheep and many other ruminants

Geographical distribution: Indian subcontinent, China, Middle East, Africa and parts of Asiatic Russia and Europe

Pathogenesis: The fluke mainly causes anaemia.

Fischoederius elongatus

Predilection site: Rumens, duodenum or anterior small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Gastrothylacidae

Description, gross: The flukes are reddish when fresh. The body measures 10–20 by 3–5 mm.

Description, microscopic: The terminal genitalium is within the ventral pouch. The uterus is situated along the midline. The testes are lobed and one is sited dorsally to the other. Eggs measure 125–150 by 65–75 µm.

Final hosts: Cattle, buffalo, zebu, sheep and many other ruminants. It can accidentally infect humans.

Geographical distribution: Asia

Pathogenesis: Flukes in the rumens usually cause only mild congestion but flukes attached to the duodenum can result in thickening of the mucosa.

Fischoederius cobboldi

Predilection site: Rumens, duodenum or anterior small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Gastrothylacidae

Description, gross: The flukes are reddish in colour when fresh. The body measures 8–10 mm in length.

Description, microscopic: Eggs measure 110–120 by 60–75 µm.

Final hosts: Cattle, buffalo, zebu, sheep and many other ruminants

Geographical distribution: Asia

Pathogenesis: Similar to *F. elongatus*

Monocercomonas ruminantium

Synonyms: *Trichomonas ruminantium*, *Tritrichomonas ruminantium*

Predilection site: Rumens

Phylum: Preaxostyla

Class: Tritrichomonadea

Family: Monocercomonadidae

Description: The trophozoite is subspherical, 3–8 by 3–7 μm , with a rounded anterior end. The axostyle is curved and may or may not extend beyond the body. Both a pelta and parabasal body are present. The cytostome and anterior nucleus are anterior. There are three anterior flagella and a trailing one (see Fig. 2.18).

Hosts: Cattle, sheep

Life cycle: The life cycle is simple with trophozoites dividing by binary fission. No sexual stages are known and there are no cysts.

Geographical distribution: Worldwide

Pathogenesis: Not considered pathogenic

Diagnosis: Identification of trophozoites based on morphological examination.

Epidemiology: Transmission presumably occurs by ingestion of trophozoites from faeces or rumen contents.

Treatment and control: Not required

Entamoeba bovis

Predilection site: Rumen

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites are 5–20 μm in diameter. The smoothly granular cytoplasm is filled with vacuoles of various sizes. The nucleus is large with a large central endosome made up of compact granules, with a row of chromatin granules of varying sizes around its periphery. The cysts are 4–14 μm in diameter and contain a single nucleus when mature with irregular clumps of chromatin granules. A large glycogen granule may or may not be present.

Hosts: Cattle

Distribution: Worldwide

Pathogenicity: Non-pathogenic

Diagnosis: Identification of trophozoites, or cysts in large intestinal contents or faeces.

Treatment and control: Not required

ABOMASUM

Cattle can be parasitised by over 18 species of gastrointestinal nematodes, infection causing parasitic gastroenteritis. The most economically important gastrointestinal nematode in cattle is *Ostertagia ostertagi* and while the diagnosis, epidemiology, treatment and control are described in detail for this parasite, details are similar for other gastrointestinal nematodes. Although treatment for gastrointestinal nematodes is mainly targeted at susceptible first-year grazing animals, more recently there has been a trend to also treat cattle in their second grazing season and in some circumstances even adult animals, particularly where other helminths such as liver fluke and lungworm are present.

Ostertagia ostertagi

Synonyms: *Ostertagia lyrata*, *Skrjabinagia lyrata*

Common name: Brown stomach worm

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Descriptor, gross: Adults are small, slender, reddish-brown worms with a short buccal cavity which is not very pronounced. Males measure 6–8 mm and females 8–11 mm in length (Fig. 8.3).

Description, microscopic: The cuticle in the anterior region is striated transversely whereas the rest of the body is unstriated and bears around 30 longitudinal ridges. A pair of very tiny cervical papillae is present in both sexes. The spicules are divided in the posterior region, where two thin lateral branches arise from the main stem (see Table 1.4a). The bursa is small and the accessory bursal membrane is supported by two divergent rays (Fig. 8.4; see also Fig. 1.18). In the female, the vulva is sited about 1.5 mm from the posterior and is covered with a flap. Female worms have double ovejectors. The tail tapers gradually and ends in a slender rounded tip which often bears several refractile cuticular annulations. The medium-sized eggs measure about 75–90 by 38–45 μm . They are elliptical and symmetrical with slightly barrel-shaped walls and the thin chitinous shell has a smooth surface. The egg is filled with many blastomeres which are hard to distinguish.

In the morph species, *Ostertagia lyrata*, the spicules are stout and divided into three branches posteriorly. The main branch is solid and ends in a shoe-like expansion. One lateral branch is thick and massive, terminating in a hat-like expansion; the other is small and pointed. The gubernaculum is spindle-shaped.

Hosts: Cattle, deer and very occasionally goats

Geographical distribution: Worldwide. *Ostertagia* is especially important in temperate climates and in subtropical regions with winter rainfall.

Pathogenesis: Large populations of *O. ostertagi* can induce extensive pathological and biochemical changes and these are maximal

Figure 8.3 Adult *Ostertagia ostertagi*.

Figure 8.4 Bursa of adult male *Ostertagia ostertagi*.

when the parasites are emerging from the gastric glands (about 18 days after infection) but may be delayed for several months when arrested larval development occurs.

In heavy infections of 40,000 or more adult worms, the principal effects of these changes are as follows.

- 1 A reduction in the acidity of the abomasal fluid, the pH increasing from 2.0 to 7.0. This results in a failure to activate pepsinogen to pepsin. There is also a loss of bacteriostatic effect in the abomasum.
- 2 There is enhanced permeability of the abomasal epithelium to macromolecules.

The results of these changes are a leakage of pepsinogen into the circulation, leading to elevated plasma concentrations, and the loss of plasma proteins into the gut lumen, eventually leading to hypoalbuminaemia. In addition, in response to the presence of the adult parasites, the zymogen cells secrete increased amounts of pepsin directly into the circulation.

Although reduced feed consumption and diarrhoea affect live-weight gain, they do not wholly account for the loss in production. Current evidence suggests that this is primarily because of substantial leakage of endogenous protein into the gastrointestinal tract. Despite some reabsorption, this leads to a disturbance in post-absorptive nitrogen and energy metabolism due to the increased demands for the synthesis of vital proteins, such as albumin and the immunoglobulins, which occurs at the expense of muscle protein and fat deposition.

Clinical signs: Bovine ostertagiosis occurs in two clinical forms. In temperate climates with cold winters the seasonal occurrence of these is as follows.

- Type I disease is usually seen in calves grazed intensively during their first grazing season, as the result of larvae ingested 3–4 weeks previously; in the northern hemisphere this normally occurs from mid-July onwards. In type I disease, the morbidity is

usually high, often exceeding 75%, but mortality is rare provided treatment is instituted early.

- Type II disease occurs in yearlings, usually in late winter or spring following their first grazing season and results from the maturation of larvae ingested during the previous autumn and which subsequently become arrested in their development at the EL₄ stage. Hypoalbuminaemia is more marked, often leading to sub-mandibular oedema. In type II the prevalence of clinical disease is comparatively low and often only a proportion of animals in the group are affected; mortality in such animals can be high unless early treatment with an anthelmintic effective against both arrested and developing larval stages is instituted.

The main clinical sign in both type I and type II disease is a profuse watery diarrhoea; in type I disease, where calves are at grass, this is usually persistent and has a characteristic bright green colour. In contrast, in the majority of animals with type II disease, the diarrhoea is often intermittent and anorexia and thirst are usually present. In both forms of the disease, the loss of body weight is considerable during the clinical phase and may reach 20% in 7–10 days.

Diagnosis: In young animals this is based on the following.

- 1 The clinical signs of inappetence, weight loss and diarrhoea.
- 2 The season, for example in Europe type I occurs from July until September and type II from March to May.
- 3 The grazing history. In type I disease, the calves have usually been set-stocked in one area for several months; in contrast, type II disease often has a typical history of calves being grazed on a field from spring to midsummer, then moved and brought back to the original field in the autumn. Affected farms usually also have a history of ostertagiosis in previous years.
- 4 Faecal egg counts. In type I disease these are usually more than 1000 eggs per gram (epg) and are a useful aid to diagnosis; in type II the count is highly variable, may even be negative and is of limited value.
- 5 Plasma pepsinogen levels. In clinically affected animals up to 2 years old these are usually in excess of 3.0 iu tyrosine (normal levels are 1.0 iu in non-parasitised calves). The test is less reliable in older cattle where high values are not necessarily correlated with large adult worm burdens but, instead, may reflect plasma leakage from a hypersensitive mucosa under heavy larval challenge.
- 6 Postmortem examination. Adult worms can be seen on close inspection of the abomasal surface. Adult worm burdens are typically in excess of 40,000, although lower numbers are often found in animals which have been diarrhoeic for several days prior to necropsy. Species differentiation is based on the structure of the male spicules (see Table 1.4).

In older animals, laboratory diagnosis is more difficult since faecal egg counts and plasma pepsinogen levels are less reliable.

A serum *Ostertagia* enzyme-linked immunosorbent assay (ELISA) has been developed that can detect worm infections in adult milking cattle and this may have a potential effect on milk production. However, the assay can suffer from the disadvantage of cross-reactions with other helminths such as *Dictyocaulus viviparus* and *Fasciola hepatica* where these infections coexist. A milk ELISA has also been developed to monitor *Ostertagia* antibody levels in adult cattle from individual or from bulk-tank milk samples, with a good level of repeatability. However, milk antibody levels can be influenced by factors such as the age of the cow, stage of lactation and milk yield. Evaluation in the field is currently underway in some countries.

Figure 8.5 *Ostertagia ostertagi* emerging from a gastric gland.

Figure 8.7 Necrosis of mucosa in severe ostertagiosis.

Figure 8.6 Abomasum showing the characteristic nodules produced by the development of *O. ostertagi* larvae in the gastric glands.

Pathology: The developing parasites cause a reduction in the functional gastric gland mass; in particular the parietal cells, which produce hydrochloric acid, are replaced by rapidly dividing, undifferentiated, non-acid-secreting cells. Initially, these cellular changes occur in the parasitised gland (Fig. 8.5), but as it becomes distended by the growing worm these changes spread to the surrounding non-parasitised glands, the end result being a thickened hyperplastic gastric mucosa.

Macroscopically, the lesion is a raised nodule with a visible central orifice; in heavy infections these nodules coalesce to produce an effect reminiscent of morocco leather (Fig. 8.6). The abomasal folds are often very oedematous and hyperaemic and sometimes necrosis and sloughing of the mucosal surface occurs (Fig. 8.7); the regional lymph nodes are enlarged and reactive.

Epidemiology of ostertagiosis in temperate countries of the northern hemisphere

Dairy herds

- 1 A considerable number of L₃ can survive the winter on pasture and in soil. Sometimes the numbers are sufficient to precipitate type I disease in calves 3–4 weeks after they are turned out to

graze in the spring. However, this is unusual and the role of the surviving L₃ is rather to infect calves at a level which produces patent subclinical infection and ensures contamination of the pasture for the rest of the grazing season.

- 2 A high mortality of overwintered L₃ on the pasture occurs in spring and only negligible numbers can usually be detected by June. This mortality, combined with the dilution effect of the rapidly growing herbage, renders most pastures, not grazed in the spring, safe for grazing after midsummer. However, some L₃ may survive in the soil for at least another year and can subsequently migrate on to the herbage.
- 3 Eggs deposited in the spring develop slowly to L₃; this rate of development becomes more rapid towards midsummer as temperatures increase and, as a result, the majority of eggs deposited during April to June all reach the infective stage from around mid-July onwards. If sufficient numbers of these L₃ are ingested, the type I disease occurs any time from July until October. Development from egg to L₃ slows during the autumn.
- 4 As autumn progresses and temperatures decline, an increasing proportion (up to 80%) of the L₃ ingested become inhibited at the early fourth larval stage (EL₄). In late autumn, calves can therefore harbour many thousands of these EL₄ but few developing forms or adults. These infections are generally asymptomatic until maturation of the EL₄ takes place during winter and early spring when type II disease may materialise. Where maturation is not synchronous, clinical signs may not occur but the adult worm burdens which develop can play a significant epidemiological role by contributing to pasture contamination in the spring.

Two factors, one management and one climatic, appear to increase the prevalence of type II ostertagiosis.

- 1 The practice of grazing calves from May until late July on permanent pasture, then moving these to hay or silage aftermath before returning them to the original grazing in late autumn. Such pasture will still contain many L₃ and when ingested they will become arrested.
- 2 In dry summers the L₃ are retained within the crusted faecal pat and cannot migrate on to the pasture until sufficient rainfall occurs. If rainfall is delayed until late autumn, many larvae liberated on to pasture will become arrested following ingestion and so increase the chance of type II disease.

Although primarily a disease of young dairy cattle, ostertagiosis can nevertheless affect groups of older cattle in the herd, particularly if these have had little previous exposure to the parasite.

Acquired immunity is slow to develop and calves do not achieve a significant level of immunity until the end of their first grazing season. Housing over the winter allows the immunity to wane by the following spring and yearlings turned out at that time are partially susceptible to reinfection and so contaminate the pasture with small numbers of eggs. However, immunity is rapidly re-established and any clinical signs which occur are usually of a transient nature. By the second and third year of grazing, adult stock in endemic areas are usually highly immune to reinfection and of little significance in the epidemiology. However, around the periparturient period when immunity wanes, particularly in heifers, there are reports of clinical disease following calving. Burdens of adult *Ostertagia* spp. in dairy cows are usually low and routine treatment of herds at calving should not be required.

Beef herds Although the basic epidemiology in beef herds is similar to that in dairy herds, the influence of immune adult animals grazing alongside susceptible calves has to be considered. Thus, in beef herds where calving takes place in the spring, ostertagiosis is uncommon since egg production by immune adults is low, and the spring mortality of the overwintered L₃ occurs prior to the suckling calves ingesting significant quantities of grass. Consequently, only low numbers of L₃ become available on the pasture later in the year. However, where calving takes place in the autumn or winter, ostertagiosis can be a problem in calves during the following grazing season once they are weaned, the epidemiology then being similar to that for dairy calves.

Epidemiology of ostertagiosis in subtropical and temperate countries in the southern hemisphere

In countries with temperate climates, such as New Zealand, the seasonal pattern is similar to that reported for Europe with type I disease occurring in the summer and burdens of arrested larvae accumulating in the autumn. In those countries with subtropical climates and winter rainfall, such as parts of southern Australia, southwest Africa and some regions of Argentina, Chile and Brazil, the increase in L₃ population occurs during the winter and outbreaks of type I disease are seen towards the end of the winter period. Arrested larvae accumulate during the spring and where type II disease has been reported it has occurred in late summer or early autumn. A basically similar pattern of infection is seen in some southern parts of the USA with non-seasonal rainfall, such as Louisiana and Texas. There, larvae accumulate on pasture during winter and arrested development occurs in late winter and early spring with outbreaks of type II disease occurring in late summer or early autumn.

The environmental factors which produce arrested larvae in subtropical zones are not yet fully known.

Treatment: Type I disease responds well to treatment at the standard dosage rates with any of the modern benzimidazoles, the pro-benzimidazoles (febantel, netobimin and thiophanate), levamisole, or the avermectins/milbemycins. All these drugs are effective against developing larvae and adult stages. Following treatment, calves should be moved to pasture which has not been grazed by cattle in the same year.

For the successful treatment of type II disease it is necessary to use drugs which are effective against arrested (hypobiotic) larvae as well as developing larvae and adult stages. Only the modern benzimidazoles (such as albendazole, fenbendazole or oxfendazole) or the avermectins/milbemycins are effective in the treatment of type II disease when used at standard dosage levels, although the pro-benzimidazoles are also effective at higher dose rates.

The field where the outbreak originated may be grazed by sheep or rested until the following June.

In lactating dairy cattle, topical eprinomectin has the advantage that there is no milk withholding period.

Control: Traditionally, ostertagiosis has been prevented by routinely treating young cattle with anthelmintics over the period when pasture larval levels are increasing. However, it has the disadvantage that since the calves are under continuous larval challenge their performance may be impaired. With this system, effective anthelmintic treatment at housing is also necessary using a drug effective against hypobiotic larvae in order to prevent type II disease.

The prevention of ostertagiosis by limiting exposure to infection is a more efficient method of control. This may be achieved by allowing young cattle sufficient exposure to larval infection to stimulate immunity but not sufficient to cause a loss in production. The provision of this 'safe pasture' may be achieved in two ways.

- 1 Using anthelmintics to limit pasture contamination with eggs during periods when the climate is optimal for development of the free-living larval stages, i.e. spring and summer in temperate climates, or autumn and winter in the subtropics.
- 2 Alternatively, by resting pasture or grazing it with another host, such as sheep, which are not susceptible to *O. ostertagi*, until most of the existing L₃ on the pasture have died out.

Sometimes a combination of these methods is employed. The timing of events in the systems described in Table 8.1 is applicable to the calendar of the northern hemisphere.

Prophylactic anthelmintic medication Since the crucial period of pasture contamination with *O. ostertagi* eggs is the period up to mid-July, one of the efficient modern anthelmintics may be given on two or three occasions between turnout in the spring and July to minimise the numbers of eggs deposited on the pasture. For calves going to pasture in early May two treatments, 3 and 6 weeks later, are used, whereas calves turned out in April require three treatments at intervals of 3 weeks. Where parenteral or pour-on macrocyclic lactones are used the interval after first

Table 8.1 Risk management of pastures.

| | High | Medium | Low |
|---------------|--|---|--|
| Spring | Grazed by first-year calves in the previous year | Grazed only by adult or yearling cattle the previous year Grazed by beef cows (with or without calves at foot) the previous year | New leys/seeds or forage crops Sheep or conservation only in the previous year |
| From mid July | Grazed by first-year calves in the spring | Adult cattle or conservation in the spring Pasture clean at the start of the year and grazed by parasite-naive calves | Grazed by sheep or conservation only in the first half of the grazing season Forage crops or arable by-products |

treatment may be extended to 5 or 8 weeks (the interval depends on the anthelmintic used) due to residual activity against ingested larvae. A long-acting injectable formulation of moxidectin is available in some countries with persistent activity against *O. ostertagi* for around 120 days.

Several rumen boluses are available which provide either the sustained release of anthelmintic drugs, at a constant level, over periods of 3–5 months or the pulse release of therapeutic doses of an anthelmintic at intervals of 3 weeks throughout the grazing season. These are administered to first-season grazing calves at turnout, although some can be administered later in the season, and effectively prevent pasture contamination and the subsequent accumulation of infective larvae. Although offering a high degree of control of gastrointestinal nematodes, there is evidence to suggest that young cattle protected by these boluses, or other highly effective prophylactic drug regimens, are more susceptible to infection in their second year at grass. Boluses can also be used in the second grazing season. One advantage of using boluses is a reduction in handling and hence labour costs.

Anthelmintic prophylaxis has the advantage that animals can be grazed throughout the year on the same pasture and is particularly advantageous for the small heavily stocked farm where grazing is limited.

Anthelmintic treatment and move to safe pasture in mid-July This system, usually referred to as ‘dose and move’, is based on the knowledge that the annual increase of L₃ occurs after mid-July. Therefore if calves grazed from early spring are given an anthelmintic treatment in early July and moved immediately to a second pasture such as silage or hay aftermath, the level of infection which develops on the second pasture will be low. The one reservation with this technique is that in certain years the numbers of L₃ that overwinter are sufficient to cause heavy infections in the spring and clinical ostertagiosis can occur in calves in April and May. However, once the dose-and-move system has operated for a few years this problem is unlikely to arise. In some European countries the same effect has been obtained by delaying the turnout of calves until midsummer.

The dose-and-move strategy is considered to select heavily for resistance and the current recommendation, for sheep, is to delay the move after the dose. Practically, however, this is difficult with calves because of the variations in persistence in activity between macrocyclic lactone products and the timing between treatment intervals. The intention of delaying treatment is to allow any treated calves to become ‘lightly’ reinfected with susceptible worms before allowing them access to the ‘low-risk’ pasture. This will ensure that soon after the move, contamination of the ‘clean’ pasture with eggs from susceptible worms will recommence and reduce the reproductive advantage offered to any resistant parasites surviving treatment. However, it should be possible to plan the availability of aftermaths with turnout and the need for strategic early season worming plans as part of farm health planning initiatives.

Alternate grazing of cattle and sheep This system ideally utilises a 3-year rotation of cattle, sheep and crops. Since the effective lifespan of most *O. ostertagi* L₃ is under 1 year and cross-infection between cattle and sheep in temperate areas is largely limited to *O. leptospicularis*, *Trichostrongylus axei* and occasionally *C. oncophora*, good control of bovine ostertagiosis should, in theory, be achieved. It is particularly applicable to farms with a high proportion of land suitable for cropping or grassland conservation. In marginal or

upland areas reasonable control has been reported using an annual rotation of beef cattle and sheep. The drawback of alternate grazing systems is that they impose a rigorous and inflexible regimen on the use of land. Furthermore, in warmer climates where *Haemonchus* spp. are prevalent, this system can prove dangerous since this very pathogenic genus establishes in both sheep and cattle.

Rotational grazing of adult and young stock This system involves a continuous rotation of paddocks in which the susceptible younger calves graze ahead of the immune adults and remain long enough in each paddock to remove only the leafy upper herbage. The incoming immune adults then graze the lower more fibrous echelons of the herbage, which contain the majority of the L₃. Since the faeces produced by the immune adults contain few if any *O. ostertagi* eggs, the pasture contamination is greatly reduced. The optimal utilisation of permanent grassland and the control of internal parasitism without resort to therapy make it an option for organic systems of production. In single-suckled beef production systems, the grazing of immune cows with their offspring will lower the pasture infectivity levels for the susceptible calves.

Influence of production systems In northern temperate regions beef cows normally calve in the spring or autumn. Dairy cows may follow a similar pattern of calving, although in many herds calving occurs all year round. Parasite control in dairy herds reflects the management of the calves, which are usually removed from the dam soon after birth and reared indoors until weaning as heifer replacements. Age and timing of turnout will therefore be influenced by month of birth and availability of pasture. Calving typically occurs in late winter/early spring in spring-calving herds and weaned calves may be turned out onto pasture as early as 2 months of age in April or May, acquiring infection from overwintering infective larvae and subsequent pasture contamination. With a longer calving period the calves may be housed until after weaning and then grazed on pasture from midsummer. If the pasture has been grazed by older calves, then they could be exposed to high levels of larval challenge. Calves that are born in the late summer or autumn may be housed and then enter their second year as mainly parasite-naïve livestock and be susceptible to infection after turnout.

Anthelmintic resistance There are sporadic reports of gastrointestinal nematodes in cattle showing some resistance to benzimidazoles in several countries and a few isolated reports of resistance to the macrocyclic lactones, particularly in *Cooperia* species. However, anthelmintic resistance is considered to be much less of a problem in cattle compared to the situation in sheep and goats. This may be due to less frequent treatment of cattle and also the persistence of faecal pats, which prolong the survival of the free-living larval stages. Despite the current low level of anthelmintic resistance in cattle nematodes, it is advisable to follow guidelines (such as those listed in Table 8.2) devised to limit the development of resistance in cattle.

Notes: *Ostertagia ostertagi* is perhaps the most common cause of parasitic gastritis in cattle. The disease, often simply known as ostertagiosis, typically affects young cattle during their first grazing season, although herd outbreaks and sporadic individual cases have also been reported in adult cattle. *Ostertagia ostertagi* is considered to be a polymorphic species with *Ostertagia lyrata* (syn. *Skrjabinaia*).

Table 8.2 Guidelines for the control of gastrointestinal nematodes and use of anthelmintics in cattle (UK COWS recommendations).

| Guideline | Comment |
|--|--|
| 1 Work out a control strategy with your veterinarian or adviser | Specialist consultation as part of herd health planning is an increasing requirement on farms. Worm control programmes for cattle will require ongoing consultations |
| 2 Use effective quarantine strategies to prevent the importation of resistant worms in introduced cattle | Bought-in cattle can be a potential route of introducing resistance alleles into a non-closed herd |
| 3 Test for anthelmintic efficacy on your farm | While resistance is still rare in cattle nematodes, treatment failures do occur. It is important to monitor continued efficacy as underdosing can select for anthelmintic resistance |
| 4 Administer anthelmintics effectively | Administer the right dose in the correct way by following the manufacturer's instructions |
| 5 Use anthelmintics only when necessary | Understand the trade-off between tolerating some level of parasitism and minimising selection for anthelmintic resistance. FEC monitoring has an important role |
| 6 Select the appropriate anthelmintic for the task | Target treatment according to parasites (and their stages) present, based on time of year |
| 7 Adopt strategies to preserve susceptible worms on the farm | Aim to reduce selection for anthelmintic resistance when treating adult cattle, immune older animals or when dosing on low contamination pastures |
| 8 Reduce dependence on anthelmintics | Alternative control measures include grazing management using sheep or older immune animals |

Ostertagia leptospicularis

Synonyms: *Ostertagia crimensis*, *Skrjabinagia kolchida*, *Grosspiculagia podjapolskyi*

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: Adults are slender reddish-brown worms with a short buccal cavity. Males measure 6–8 mm and females 8–9 mm in length.

Description, microscopic: Distinguished from other ostertagian species by the length of the oesophagus, which is longer than in other species (0.7 mm compared with approximately 0.6 mm). In cattle, the worms are thinner than *Ostertagia ostertagi* and male worms are differentiated on spicule morphology (see Table 1.4).

Hosts: Deer (roe deer), cattle, sheep, goat

Geographical distribution: Many parts of the world, particularly Europe and New Zealand

Notes: Considered to be a polymorphic species with two male morphs, *Ostertagia leptospicularis* and *Skrjabinagia kolchida* (*Grosspiculagia podjapolskyi*).

Details of the pathogenesis, clinical signs, diagnosis, pathology, epidemiology, treatment and control are as for *O. ostertagi*.

Spiculoptera spiculoptera

Synonyms: *Apteragia spiculoptera*, *Rinadia spiculoptera*, *Mazamostrongylus spiculoptera*

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, microscopic: The spicules are of equal length, bifurcating distally where it contains a cavity and ending distally in a fan-shaped expansion (see Table 1.4g). The gubernaculum is absent.

Hosts: Deer (red deer, fallow deer, roe deer), cattle, sheep, goat

Haemonchus contortus

Synonym: *Haemonchus placei* (see Notes)

Common name: Barber's pole worm

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Notes: Until recently the sheep species was called *H. contortus* and the cattle species *H. placei*. However, there is now increasing evidence that these are the single species *H. contortus* with only strain adaptations for cattle and sheep.

For more details see Chapter 9.

Haemonchus similis

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are 2.0–3.0 cm long and reddish in colour.

Description, microscopic: The male has an asymmetrical dorsal lobe and barbed spicules differing from *H. contortus* in that the terminal processes of the dorsal ray are longer and the spicules shorter.

Hosts: Cattle, deer

Geographical distribution: North America, Europe

Pathogenesis: As for *H. contortus*

Trichostrongylus axei

Synonym: *Trichostrongylus extenuatus*

Predilection site: Abomasum or stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

For more details, see Chapter 9.

Mecistocirrus digitatus

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: To the naked eye, the worm is indistinguishable from *Haemonchus contortus*, although it is closely related to *Nematodirus*. The white ovary is wrapped around the red blood-filled intestine giving it a ‘barber’s pole’ appearance. The males measure up to around 30 mm and the females 42 mm in length.

Description, microscopic: The male is distinguishable from *Haemonchus* by the presence of long narrow spicules that are fused together for the majority of their length and the tips are enclosed in a spindle-shaped appendage (in *Haemonchus* the spicules are thicker, separate and barbed at the tips). The dorsal ray is symmetrically located in the bursa, whereas in *Haemonchus* the dorsal ray is asymmetrical. The female differs from *Haemonchus* in that the slit-shaped vulva is positioned nearer to the tip of the tail and there is no vulval flap. The cuticle contains many longitudinal ridges and the cervical papillae are readily apparent. The small buccal capsule is armed with a lancet. The eggs are large and, unlike *Nematodirus*, typically strongylate and measure around 100 µm in length.

Hosts: Cattle, buffalo, zebu, sheep and goat; occasionally the stomach of the pig and rarely human

Geographical distribution: Tropical and subtropical regions, particularly Central America and parts of Asia

Pathogenesis: In endemic areas, the pathogenesis of this haematophagous parasite is similar to that of *H. contortus* and it is of similar economic importance.

Clinical signs: Similar to *H. contortus*, inducing anaemia, weight loss and emaciation.

Diagnosis: See the description of the parasite.

Treatment and control: See *H. contortus* for details.

Parabronema skrjabini

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Geographical distribution: Central and East Africa, Asia, and some Mediterranean countries, notably Cyprus

For more details see Chapter 9.

Capillaria bilobata

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description: Male worms measure 10–16 mm and females 14–21 mm in length. The lemon-shaped eggs measure 33–53 by 14–21 µm and have two slightly protruding polar plugs.

Host: Zebu

Geographical distribution: Indian subcontinent

Cryptosporidium andersoni

Synonym: *Cryptosporidium muris*

Predilection site: Abomasum

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Description: Oocysts, passed fully sporulated, are ellipsoid, 6.0–8.1 by 5.0–6.5 µm (mean 7.4 × 5.5 µm), with a length/width ratio of 1.35.

Host: Cattle

Geographical distribution: Reported in USA, Brazil, UK, Czech Republic, Germany, France, Japan and Iran.

Pathogenesis: Generally considered to be non-pathogenic.

Clinical signs: Usually asymptomatic, although depressed weight gain in calves and milk yields in milking cows have been reported.

Diagnosis: Oocysts may be demonstrated using Ziehl–Neelsen stained faecal smears in which the sporozoites appear as bright red granules. Speciation of *Cryptosporidium* is difficult, if not impossible, using conventional techniques. A range of molecular and immunological techniques has been developed that includes the use of immunofluorescence or ELISA. More recently, DNA-based techniques have been used for the molecular characterisation of *Cryptosporidium* species.

Pathology: The presence of the endogenous stages of the parasite leads to destruction of the microvilli of peptic glands, leading to elevated concentrations of plasma pepsinogen.

Epidemiology: The epidemiology of infection has not been studied, although it is likely to be similar to that of *Cryptosporidium parvum* in cattle. Many calves are likely to become infected without showing clinical signs but become sources of infection for calves that follow. The primary route of infection is direct animal to animal via the faecal–oral route. Thus in calves, for example, overcrowding, stress of early weaning, transport and marketing, together with low levels of hygiene, will increase the risk of heavy infections.

Treatment and control: There is no reported treatment. Good hygiene and management are important in preventing disease from cryptosporidiosis. Feed and water containers should be high

enough to prevent faecal contamination. Young animals should be given colostrum within the first 24 hours of birth and overstocking and overcrowding should be avoided. Dairy calves should be either isolated in individual pens or kept in similar age groups and cleaned out daily.

Notes: Based on oocyst morphology, *C. muris*-like oocysts have been found in cattle in several countries around the world. Recent molecular characterisations have indicated that all bovine isolates are *C. andersoni*.

SMALL INTESTINE

Trichostrongylus colubriformis

Synonym: *Trichostrongylus instabilis*

Common name: Black scour or bankrupt worm

Predilection site: Duodenum and anterior small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

For more details see Chapter 9.

Trichostrongylus longispicularis

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are similar in size to *T. colubriformis*.

Description, microscopic: The spicules are stout, brown, unbranched, slightly unequal in length and terminate in a tapering blunt tip that has a small semi-transparent protrusion.

Hosts: Cattle, sheep, goat, deer, camel, llama

Geographical distribution: Ruminants in Australia; cattle in America and parts of Europe

Details of the pathogenesis, clinical signs, diagnosis, pathology, epidemiology, treatment and control are as for *T. colubriformis*.

Cooperia oncophora

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: In size *C. oncophora* is similar to *Ostertagia* but with a large bursa. Males measure around 5.5–9 mm and females 6–8 mm in length. When fresh the worms appear pinkish white.

Description, microscopic: The main generic features are the small cephalic vesicle and the transverse cuticular striations in the oesophageal region. The body possesses longitudinal ridges. The spicules have a distinct wing-like expansion in the middle region and often bear ridges (see Table 1.5a); there is no gubernaculum. The females have a long tapering tail. The medium-sized eggs are oval, thin-shelled with a smooth surface and measure 74–95 by 36–44 µm. The egg contains many blastomeres that are not easily distinguished. The small poles are very similar and the side walls are parallel. This feature allows the eggs to be differentiated from those of *Ostertagia* which have wider poles and more spherical walls.

Hosts: Cattle, sheep, goat, deer, camel

Geographical distribution: Worldwide

Pathogenesis: *Cooperia oncophora* is generally considered to be a mild pathogen in calves, although in some studies it has been associated with inappetence and poor weight gains. Immunity to reinfection develops after about 8–12 months of exposure to infective larvae.

Clinical signs: These include loss of appetite and poor weight gains. Occasionally a heavy infection can induce intermittent diarrhoea.

Diagnosis: Eggs of *Cooperia* spp. are all very similar morphologically. Faecal culture will allow identification of infective larvae.

Pathology: Moderate to heavy infections can induce a catarrhal enteritis with localised villous atrophy and oedema of the intestinal mucosa.

Epidemiology: In temperate areas, this is similar to that of *Ostertagia*. Arrested development (hypobiosis) at the EL₄ stage is a regular feature during late autumn and winter in the northern hemisphere, and in spring and summer in the southern hemisphere. Adult animals usually show few signs of infection but act as carriers, shedding low numbers of eggs in their faeces.

In the subtropics, the epidemiology is similar to that of *Haemonchus* though *Cooperia* does not have the same high biotic potential and the L₃ survive rather better under arid conditions. Hypobiosis is also a feature during prolonged dry seasons.

Treatment: The principles are similar to those applied in bovine ostertagiosis. *Cooperia* is one of the dose-limiting species and one should consult the manufacturer's data sheets for efficacy of anthelmintics against adult and L₄ stages.

Control: Similar to that described for *Ostertagia*.

Notes: In temperate areas, members of the genus *Cooperia* usually play a secondary role in the pathogenesis of parasitic gastroenteritis of ruminants, although they may be the most numerous trichostrongyle present. However, in some tropical and subtropical areas, some species are responsible for severe enteritis in calves.

Three further species of *Cooperia* are found in cattle. Details of the diagnosis, epidemiology, treatment and control are as for *C. oncophora*.

Cooperia punctata

Common name: Cattle bankrupt worm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: Similar to *C. oncophora*. Males measure around 4.5–6.0 mm, and females 6–8 mm in length.

Description, microscopic: See *C. oncophora* and Table 1.5(b) for further details. The medium-sized, thin-shelled oval eggs have a smooth surface and measure about 69–83 by 29–34 µm. The egg contains many blastomeres which are not easily distinguished.

Hosts: Cattle, deer

Geographical distribution: Worldwide

Pathogenesis: *Cooperia punctata* is a pathogenic parasite since it penetrates the epithelial surface of the small intestine and causes a disruption similar to that of other intestinal trichostrongylid species, which leads to villous atrophy and a reduction in the area available for absorption. In heavy infections, diarrhoea has been reported.

Clinical signs: There is loss of appetite, poor weight gain and diarrhoea and there may be submandibular oedema.

Cooperia pectinata

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: Similar to *C. oncophora*. Males measure around 7–8 mm and females 7.5–10 mm in length.

Description, microscopic: See *C. oncophora* and Table 1.5(e) for details.

Hosts: Cattle, deer

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Similar to *C. punctata*. A catarrhal enteritis is often present with loss of appetite, poor weight gain, diarrhoea and, in some cases, submandibular oedema.

Cooperia surnabada

Synonym: *Cooperia mcmasteri*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The males measure around 7 mm and the females 8 mm in length.

Description, microscopic: The appearance is very similar to *C. oncophora*, although the bursa is larger and the bursal rays tend to be thinner. The spicules are thinner with a posterior bifurcation and the tips possess a small conical appendage (see Table 1.5c).

Hosts: Cattle, sheep, camel

Geographical distribution: Parts of Europe, North America and Australia

Pathogenesis: Moderate pathogenicity as the worms penetrate the surface of the small intestine and can induce villous atrophy.

Clinical signs: See *C. punctata*

Diagnosis: See *C. oncophora*

Treatment and control: Refer to *C. oncophora*

Nematodirus helvetianus

Common name: Thread-necked worm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are slender, males measuring around 11–16 mm and females 17–24 mm in length.

Description, microscopic: A small but distinct cephalic vesicle is present. The male has two sets of parallel rays in each of the main bursal lobes and the long slender spicules end in a fused point with the surrounding membrane being lanceolate (see Table 1.6d). The female has a truncate tail with a small spine. The egg is large (160–233 by 87–121 µm), ovoid with slightly sharp poles and clear, and twice the size of the typical trichostrongyle egg. The chitinous egg-shell is thin with a smooth surface and contains two to eight large dark blastomeres, which are separated from the yolk membrane by quite a large fluid-filled cavity.

Hosts: Cattle, occasionally sheep, goat and other ruminants

Geographical distribution: Worldwide

Pathogenesis: Although this is similar to that of *Nematodirus battus*, there is some controversy over the extent of the pathogenic effect. *Nematodirus helvetianus* has been incriminated in outbreaks of bovine parasitic gastroenteritis but experimental attempts to reproduce the disease have been unsuccessful.

Clinical signs: Low to moderate infections may produce no obvious clinical manifestations. In severe infections, diarrhoea can occur during the prepatent period and young animals may become dehydrated.

Diagnosis: Examination of faeces will allow the large colourless eggs to be differentiated from those of *N. spathiger*. At necropsy, the tips of the male spicules will allow diagnosis from other *Nematodirus* species.

Pathology: Increased mucus production and focal compression and stunting of villi may occur in the small intestine.

Epidemiology: The eggs do not usually exhibit delayed hatching. The pattern of infection is similar to that of *Trichostrongylus* species.

Treatment: Several drugs are effective against *Nematodirus* infections: levamisole, an avermectin/milbemycin or one of the modern benzimidazoles. However, *Nematodirus* is one of the dose-limiting

species and manufacturer's data sheets should be consulted as there are differences in efficacy against adults and L₄ stages between oral and parenteral administration for some macrocyclic lactones. The response to treatment is usually rapid and if diarrhoea persists, coccidiosis should be considered as a complicating factor.

Control: Disease due to monospecific *Nematodirus* infections is rarely seen. They are usually part of the worm burden of trichostrongyloid species that are responsible for the syndrome of parasitic gastroenteritis in cattle and as such may be controlled by the measures outlined elsewhere.

Nematodirus battus

Common name: Thread-necked worm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Notes: *Nematodirus battus* has only rarely been recorded in cattle.

Nematodirus spathiger

Common name: Thread-necked worm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Notes: *Nematodirus spathiger* is only occasionally reported in cattle. The eggs are similar in appearance and may be confused with those of *N. helvetianus*.

For more details of both these species see Chapter 9.

Bunostomum phlebotomum

Synonym: *Monodontus phlebotomum*

Common name: Cattle hookworm

Predilection site: Small intestine, particularly the anterior jejunum and/or duodenum

Phylum: Nematoda

Class: Secernentea

Superfamily: Ancylostomatoidea

Description, gross: *Bunostomum* is one of the larger nematodes of the small intestine of ruminants (see Fig. 8.8), being 1–3 cm long, stout, greyish-white and characteristically hooked at the anterior end with the buccal capsule opening anterodorsally.

Description, microscopic: The large buccal capsule opens anterodorsally and bears on the ventral margin a pair of chitinous cutting plates and internally a large dorsal cone. Dorsal teeth are

Figure 8.8 Adult *Bunostomum phlebotomum*.

absent from the buccal capsule but there are two pairs of small subventral lancets at its base. In the male the bursa is well developed and has an asymmetrical dorsal lobe. The right externo-dorsal ray arises higher up on the dorsal stem and is longer than the left. It arises near the bifurcation of the dorsal ray, which divides into two tridigitate branches. The spicules are very long and slender. In the female the vulva opens a short distance in front of the middle of the body.

The infective larva is small with 16 gut cells and a short filamentous tail. The egg is a medium-sized (97–106 by 45–55 µm), thin-shelled, irregular broad ellipse with blunt ends and dissimilar side walls, one being flattened. It contains four to eight darkly pigmented blastomeres.

Hosts: Cattle

Geographical distribution: Worldwide

Pathogenesis: The adult worms are blood-suckers and infections of 100–500 worms can produce progressive anaemia, hypoalbuminaemia, loss of weight and occasionally diarrhoea. Worm burdens of around 2000 may lead to death in cattle. In stabled cattle, pruritus of the limbs, probably caused by skin penetration by the larvae, is seen.

Clinical signs: There may be inappetence, diarrhoea and emaciation, more frequently seen in young animals. Severe infection can also induce submandibular oedema ('bottle jaw'). Postmortem examination often reveals hydrothorax and fluid within the pericardium. Older livestock frequently develop sufficient immunity to limit reinfection and in many cases *Bunostomum* is present asymptotically. In calves, foot stamping and signs of itching may accompany skin penetration by the larvae.

Diagnosis: The clinical signs of anaemia and perhaps diarrhoea in calves are not in themselves pathognomonic of bunostomosis. However, in temperate areas, the epidemiological background may be useful in eliminating the possibility of *Fasciola hepatica* infection. In the tropics, haemonchosis must be considered, possibly originating from hypobiotic larvae. Faecal egg counts are useful in that these are lower than in *Haemonchus* infection while the eggs are more bluntly rounded, with relatively thick sticky shells to which debris is often adhered. For accurate differentiation, larval cultures should be prepared.

Figure 8.9 Inflamed and haemorrhagic intestinal mucosa due to the presence of feeding worms (*Bunostomum phlebotomum*).

Pathology: The carcass is anaemic and cachectic. Oedema and ascites are seen. The liver is light brown and shows fatty changes. The intestinal contents are haemorrhagic and the mucosa is usually swollen, covered with mucus, and shows numerous lesions resulting from the worms feeding (Fig. 8.9). The parasites may be seen still attached to the mucosa or free in the lumen.

Epidemiology: Pathogenic infections are more common in the tropics and subtropics and in some areas, such as Nigeria, the highest worm burdens are found at the end of the dry season, apparently due to the maturation of hypobiotic larvae. Young livestock are most susceptible. *Bunostomum phlebotomum* is often a serious pathogen in many regions, such as the southern and mid-western USA, Australia and parts of Africa. In temperate countries, high worm burdens are usually uncommon. The prophylactic dosing regimens, adopted for the control of trichostrongyles, have contributed to the low prevalence of *Bunostomum*.

Treatment: Anthelmintics listed for *O. ostertagi* are effective.

Control: A combination of strategic dosing with anthelmintics and pasture management is used in the control of larvae as they are susceptible to desiccation, and the infection is mainly found on permanently or occasionally moist pastures. Avoiding or draining such pastures is an effective control measure. The ground around water troughs should be kept hard and dry, or treated with liberal applications of salt. Stabled cattle should be protected by ensuring the floors and bedding are kept dry and that faeces are removed frequently, and are not allowed to contaminate food and water.

Agriostomum vryburgi

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ancylostomatoidea

Description, gross: Worms are stout and greyish-white in colour. Males are around 9–11 mm and females 13–16 mm in length. Spicules are equal in length and a gubernaculum is present.

Description, microscopic: The shallow buccal capsule contains four pairs of large teeth on its margin and has a rudimentary leaf-crown. The large oesophageal opening houses two small subventral lancets. Eggs measure about 130–190 by 60–90 μm .

Hosts: Cattle, buffalo, ox and zebu

Geographical distribution: Asia and South America

Pathogenesis: The hookworms attach to the mucosa of the anterior small intestine. The pathogenicity, although unknown, presumably depends on its haematophagic habits, inducing anaemia.

Notes: *Agriostomum vryburgi* is a common hookworm of the large intestine throughout its distribution range. Details on the diagnosis, treatment and control are likely to be similar to those for *B. phlebotomum*.

Strongyloides papillosus

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Rhabditoidea

Description, gross: Slender hair-like worms generally less than 1.0 cm long.

Description, microscopic: Only females are parasitic. The long oesophagus may occupy up to one-third of the body length and the uterus is intertwined with the intestine, giving the appearance of twisted thread. Unlike other intestinal parasites of similar size the tail has a blunt point. *Strongyloides* eggs are oval with blunt poles and slightly barrel-shaped side walls, thin-shelled and small, being half the size of typical strongyle eggs. These colourless eggs have a smooth shell and measure about 43–60 by 20–25 μm and contain an L₁ larva. Infective larvae measure about 600 μm .

Hosts: Cattle, sheep, goat and other ruminants, pig and rabbit

Geographical distribution: Worldwide

Pathogenesis: Skin penetration by infective larvae may cause an erythematous reaction. Passage of larvae through the lungs has been shown experimentally to result in multiple small haemorrhages visible over most of the lung surfaces. Mature parasites are found in the duodenum and proximal jejunum and if present in large numbers may cause inflammation with oedema and erosion of the epithelium. This results in a catarrhal enteritis with impairment of digestion and absorption.

Clinical signs: The common clinical signs, usually seen only in very young animals, are diarrhoea, dehydration, anorexia, dullness, loss of weight or reduced growth rate.

Diagnosis: The clinical signs in very young animals, usually within the first few weeks of life, together with the finding of large numbers of the characteristic eggs or larvae in the faeces, are suggestive of strongyloidosis. However, it should be emphasised that high faecal egg counts may be found in apparently healthy animals.

Pathology: Adult worms establish in tunnels in the epithelium at the base of the villi in the small intestine. In large numbers they may cause villous atrophy, with a mixed mononuclear inflammatory cell

infiltration of the lamina propria. Crypt epithelium is hyperplastic and there is villous clubbing.

Epidemiology: *Strongyloides* infective larvae are not ensheathed and are susceptible to extreme climatic conditions. However, warmth and moisture favour development and allow the accumulation of large numbers of infective stages. For this reason, it can be a major problem in housed calves up to 6 months of age in some Mediterranean countries. A second major source of infection for the very young animal is the reservoir of larvae in the tissues of their dams and this may lead to clinical strongyloidosis in the first few weeks of life. Successive progeny from the same dam often show heavy infections.

Treatment: Specific control measures for *Strongyloides* infection are rarely required. The benzimidazoles and the avermectins/milbemycins may be used for the treatment of clinical cases.

Control: Reduction in numbers of free-living larvae by removal of faeces and provision of dry bedding and areas may limit numbers and transmission. Suckling calves should be kept on clean dry areas to prevent infection by skin penetration.

Toxocara vitulorum

Synonym: *Neoascaris vitulorum*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: This is a very large whitish nematode. The adult male is up to 25 cm and the female 30 cm in length.

Description, microscopic: The cuticle is less thick than other ascarids and somewhat soft and translucent. There are three lips, broad at the base and narrowing anteriorly. The oesophagus is 3–4.5 mm long and has a posterior, granular ventriculus. The tail of the male usually forms a small spike-like appendage. There are about five pairs of post-cloacal papillae; the anterior pair is large and double. Pre-cloacal papillae are variable in number. The vulva is situated about one-eighth of the body length from the anterior end. The medium-sized egg of *T. vitulorum* is subglobular, with a thick finely pitted albuminous shell, and is almost colourless (75–95 by 60–74 µm) (see Fig. 4.3). The egg is unsegmented and the granular contents frequently only occupy part of the internal volume.

Hosts: Cattle, buffalo and zebu, rarely sheep and goat

Geographical distribution: Africa, India, Asia

Pathogenesis: The main effects of *T. vitulorum* infection appear to be caused by the adult worms in the intestines of calves up to 6 months old. Heavy infections are often associated with unthriftiness, catarrhal enteritis and intermittent diarrhoea, and in buffalo calves particularly fatalities may occur. Heavy burdens can be associated with intestinal obstruction and occasionally perforation may occur leading to peritonitis and death.

Clinical signs: Diarrhoea, poor condition

Diagnosis: In some instances heavily infected calves may exhale an acetone-like odour. The subglobular eggs, with thick pitted shells,

are characteristic in bovine faeces. Egg output in young calves can be very high (>50,000 epg) but patency is short and by around 4–6 months of age calves have expelled most of their adult worm population.

Pathology: The pathological effects of adult worms in the intestine are poorly defined. Heavy infections may obstruct the gut and lead to gut perforation. Migration up the bile or pancreatic duct may lead to biliary obstruction and cholangitis.

Epidemiology: The most important feature is the reservoir of larvae in the tissues of the cow, with subsequent milk-borne transmission ensuring that calves are exposed to infection from the first day of life. The majority of patent infections occur in calves of less than 6 months of age.

Treatment: The adult worms are susceptible to a wide range of anthelmintics, including piperazine, levamisole, macrocyclic lactones and the benzimidazoles. Many of these drugs are also effective against developing stages in the intestine.

Control: The prevalence of infection can be dramatically reduced by treatment of calves at 3 and 6 weeks of age, preventing developing worms reaching patency.

Capillaria bovis

Synonym: *Capillaria brevipes*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: These are very fine filamentous worms, the narrow stichosome oesophagus occupying about one-third to half the body length. Males measure around 8–9 mm and females up to 12 mm.

Description, microscopic: The males have a long thin single spicule about 0.9 mm long and often possess a primitive bursa-like structure. The small eggs are slightly lemon-shaped (similar to *Trichuris*) but the side walls are almost parallel. They measure 45–50 by 22–25 µm, are colourless and have thick shells that are slightly striated with two protruding transparent bipolar plugs. The contents are granular with no blastomeres.

Hosts: Cattle, sheep, goat

Geographical distribution: Worldwide

Pathogenesis: Considered to be of low pathogenicity and of little veterinary significance.

Clinical signs: No clinical signs have been attributed to infection with this parasite.

Diagnosis: Because of the non-specific nature of the clinical signs and the fact that, in heavy infections, these may appear before eggs are present in the faeces, diagnosis depends on necropsy and careful examination of the small intestine for the presence of the worms. This may be carried out by microscopic examination of mucosal scrapings squeezed between two glass slides; alternatively, the contents should be gently washed through a fine sieve and the retained

material resuspended in water and examined against a black background.

Pathology: No associated pathology

Epidemiology: Infection is by ingestion of the larvated eggs. Infection is common in sheep though not significant.

Treatment: Not usually required

Control: Not required

Moniezia benedeni

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, gross: These long tapeworms (2 m or more) are unarmed and possess prominent suckers.

Description, microscopic: Segments are broader than they are long (up to 2.5 cm wide) and contain two sets of genital organs grossly visible along the lateral margin of each segment. There is a row of inter-proglottid glands at the posterior border of each segment, which may be used in species differentiation; in *M. benedeni* they are confined to a short row close to the middle of the segment (see Table 1.10). The medium-sized irregularly quadrangular eggs have a well-defined pyriform apparatus and vary from 80 to 90 µm in diameter. The egg has a thick smooth shell and contains an embryo.

Final hosts: Cattle, buffalo

Intermediate hosts: Forage mites, mainly of the family Oribatidae

Geographical distribution: Worldwide

Pathogenesis: Generally regarded as of little pathogenic significance.

Clinical signs: No clinical signs have been associated with infection.

Diagnosis: This is based largely on the presence of mature proglottids in the faeces and the characteristic shape of *Moniezia* eggs (triangular, *M. expansa*; quadrangular, *M. benedeni*) that contain the oncosphere. The eggs of *M. benedeni* are slightly larger than those of *M. expansa* in sheep.

Pathology: No reported pathology

Epidemiology: Infection is common in calves during their first year of life and less common in older animals. A seasonal fluctuation in the incidence of *Moniezia* infection can apparently be related to active periods of the forage mite vectors during the summer in temperate areas. The cysticercoids can overwinter in the mites.

Treatment: In many countries a variety of drugs, including niclosamide, praziquantel, bunamidine and a number of broad-spectrum benzimidazole compounds, which have the advantage of also being active against gastrointestinal nematodes, are available for the treatment of *Moniezia* infection. If this is carried out in calves in late spring, in temperate areas, the numbers of newly infected mites on pasture will be reduced.

Control: Ploughing and reseeded, or avoiding the use of the same pastures for young animals in consecutive years, may prove beneficial.

Notes: This genus of cestodes is common in ruminants and resembles, in most respects, *Anoplocephala* of the horse. *Moniezia* spp. are the only tapeworms of ruminants in many countries of western Europe.

Thysaniezia ovilla

Synonyms: *Thysaniezia giardi*, *Helictometra giardi*

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, gross: Adults reach 200 cm in length, varying in width up to 12 mm.

Description, microscopic: The scolex is small, measuring up to 1 mm in diameter. Segments are short, bulge outwards giving the margin of the worm an irregular appearance, and contain a single set of genital organs, rarely two, with genital pores alternating irregularly (see Table 1.10). The oval eggs (measuring up to 27 by 19 µm) are devoid of a pyriform apparatus and have a thick grey shell and a protuberance at one end. They are found in groups of 10–15 in the numerous elongated paruterine organs (100 µm long) in each proglottid.

Final hosts: Cattle, sheep, goat, camel and wild ruminants

Intermediate hosts: Oribatid mites (*Galuma*, *Schelorbates*) and psocids (bark lice, dust lice)

Life cycle: Mature segments are passed in the faeces of the infected host onto pasture, where forage mites ingest the oncospheres. Cysticercoids develop within the oribatid intermediate hosts and infection of the final host is by ingestion of infected mites during grazing.

Geographical distribution: Southern Africa

Pathogenesis: Not considered pathogenic

Diagnosis: The mature segments found in the faeces are readily distinguishable from those of *Moniezia*.

Epidemiology: Infection is very commonly found in adult cattle in southern Africa.

Treatment and control: As for *Moniezia*

The following species have also been reported in cattle. For more details on these species see Chapter 9.

Moniezia expansa

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, gross: These long tapeworms (2 m or more) are unarmed and possess prominent suckers.

Description, microscopic: Segments are broader than they are long (up to 1.5 cm wide) and contain two sets of genital organs grossly visible along the lateral margin of each segment (see Table 1.10). There is a row of inter-proglottid glands at the posterior border of each segment, which may be used in species differentiation. In *M. expansa* they extend along the full breadth of the segment.

Final hosts: Sheep, goat, occasionally cattle

Intermediate hosts: Forage mites, mainly of the family Oribatidae

Avitellina centripunctata

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, gross: This tapeworm resembles *Moniezia* on gross inspection except that the segmentation is so poorly marked that it appears somewhat ribbon-like. It can reach 3 m in length by about 3–4 mm in width and the posterior end is almost cylindrical in appearance.

Description, microscopic: Single genitalia are present with the pores alternating irregularly (see Table 1.10). Proglottids are short. Eggs lack a pyriform apparatus and measure around 20–45 µm.

Final hosts: Sheep, goat, camel and other ruminants

Intermediate hosts: Thought to be oribatid mites or psocid lice

Geographical distribution: Europe, Africa and Asia

Pathogenesis: Of negligible pathogenicity, similar to that of *Moniezia* spp.

Clinical signs: Usually asymptomatic

Stilesia globipunctata

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, gross: Adults measure around 0.5 m in length by 3–4 mm wide.

Description, microscopic: A single set of genital organs is present.

Final hosts: Sheep, cattle and other ruminants

Intermediate hosts: As for *Avitellina centripunctata*

Thysanosoma actinoides

Common name: Fringed tapeworm

Predilection site: Small intestine, bile and pancreatic ducts

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, gross: Adult tapeworms measure 15–30 cm in length by around 8 mm wide.

Description, microscopic: The scolex is up to 1.5 mm; segments are short and fringed posteriorly. In the distal regions of the tapeworm the ‘fringes’ are as long as the proglottid (see Fig. 1.98 and Table 1.10). Each proglottid contains two sets of genital organs with the testes lying medially. Several paruterine organs are present in each proglottid and the eggs have no pyriform apparatus.

Final hosts: Sheep, cattle, deer

Intermediate hosts: As for *Thysaniezia ovilla*

Geographical distribution: North and South America

Cymbiforma indica

Predilection site: Gastrointestinal tract

Phylum: Platyhelminthes

Class: Trematoda

Family: Notocotylidae

Final hosts: Sheep, goat, cattle

Intermediate host: Snails

Description, gross: Adult fluke are pear-shaped, concave ventrally and measure 0.8–2.7 cm by 0.3–0.9 mm wide.

Description, microscopic: There is no ventral sucker and the cuticle is armed with fine spines ventrally and anteriorly. The ovary has four demarcated lobes. The fluke lacks a pharynx and the oesophagus is short.

Geographical distribution: India

Bovine coccidiosis At least 20 different species of *Eimeria* are known to infect cattle, of which 13 species are more commonly found. Clinical signs of diarrhoea are associated with the presence of *E. zuernii* or *E. bovis*, which occur in the lower small intestine, caecum and colon. *Eimeria alabamensis* has been reported to cause enteritis in yearling calves in some European countries. Affected animals develop watery diarrhoea, shortly after turnout in the spring on to heavily contaminated pastures previously grazed by calves.

The life cycles of the *Eimeria* species are typically coccidian and the general life cycle is described in detail in Chapter 2. Variations in sites of development of meront and gamont stages, and prepatent periods do occur, and where known are described under the respective species.

Prevalence: Most cattle are infected with coccidia during their lives and in the majority of animals the parasites coexist and cause minimal damage. Disease usually only occurs if animals are subjected to heavy infection or if their resistance is lowered through stress, poor nutrition or intercurrent disease. The presence of infection does not necessarily lead to the development of clinical signs of disease and in many situations low levels of challenge can actually be beneficial by stimulating protective immune responses in the host.

Table 8.3 Predilection sites and prepatent periods of *Eimeria* species in cattle.

| Species | Predilection site | Prepatent period (days) |
|-------------------------|---------------------------|-------------------------|
| <i>E. alabamensis</i> | Small and large intestine | 6–11 |
| <i>E. auburnensis</i> | Small intestine | 16–24 |
| <i>E. bovis</i> | Small and large intestine | 16–21 |
| <i>E. brasiliensis</i> | Unknown | ? |
| <i>E. bukidnonensis</i> | Unknown | ? |
| <i>E. canadensis</i> | Unknown | ? |
| <i>E. cylindrica</i> | Unknown | ? |
| <i>E. ellipsoidalis</i> | Small intestine | 8–13 |
| <i>E. pellita</i> | Unknown | ? |
| <i>E. subspherica</i> | Unknown | 7–18 |
| <i>E. wyomingensis</i> | Unknown | 13–15 |
| <i>E. zuernii</i> | Small and large intestine | 15–17 |

Pathogenesis: The most pathogenic species of coccidia are those that infect and destroy the crypt cells of the large intestinal mucosa (Table 8.3). This is because the ruminant small intestine is very long, providing a large number of host cells and the potential for enormous parasite replication with minimal damage. If the absorption of nutrients is impaired, the large intestine is, to some extent, capable of compensating. Those species that invade the large intestine are more likely to cause pathological changes, particularly if large numbers of oocysts are ingested over a short period of time. Here, the rate of cellular turnover is much lower and there is no compensation effect from other regions of the gut. In calves that become heavily infected, the mucosa becomes completely denuded, resulting in severe haemorrhage and impaired water resorption leading to diarrhoea, dehydration and death. In lighter infections, the effect on the intestinal mucosa is to impair local absorption. Species that develop more superficially in the small intestine cause a change in villous architecture with a reduction in epithelial cell height and a diminution of the brush border, giving the appearance of a ‘flat’ mucosa. These changes result in a reduction of the surface area available for absorption and consequently reduced feed efficiency.

Clinical and pathological signs: Clinical signs are associated with the presence of the pathogenic species, *E. zuernii* or *E. bovis*, which occur in the lower small intestine, caecum and colon. *Eimeria alabamensis* has been reported to cause enteritis in first-season grazing calves in the first week following turnout in some European countries. Some animals with coccidiosis develop concurrent nervous signs, including tremors, nystagmus, opisthotonus and convulsions. The cause of these symptoms is unknown, although the possibility of the neurological signs being induced by a toxin has been suggested.

Clinical signs of coccidiosis include weight loss, anorexia and diarrhoea, often bloody. On postmortem, there may be little to see beyond thickening and petechiation of the bowel but mucosal scrapings will reveal masses of gamonts and oocysts. Giant meronts may be seen in the mucosa of the small intestine as pin-point white spots, but unless they are present in vast numbers they cause little harm. The most pathogenic stages are the gamonts.

Host resistance: While animals of all ages are susceptible to infection, younger animals are generally more susceptible to disease. Occasionally, however, acute coccidiosis occurs in much older, even adult cattle with impaired cellular immunity or in those which have been subjected to stress, such as transportation, crowding in feedlot

areas, extremes of temperature and weather conditions, changes in environment or severe concurrent infection.

Epidemiology: Bovine coccidiosis is primarily a disease of young animals, normally occurring in calves between 3 weeks and 6 months of age but has been reported in cattle aged 1 year or more. The disease is usually associated with a previous stressful situation such as shipping, overcrowding, changes in feed, severe weather or concurrent infection with parvovirus.

Adult cattle, although possibly the original source of infective oocysts in the environment, are not usually responsible for the heavy levels of contamination encountered. The source is often young calves themselves, which following an initial infection often in the first few days of life may produce millions of oocysts within their own environment. Growing animals may then face potentially lethal doses of infective oocysts 3 weeks later when their natural resistance is at its lowest. Later-born calves introduced into the same environment are immediately exposed to heavy oocyst challenge. Under unhygienic overcrowded conditions, the young calves will be exposed to and ingest a large proportion of this infection and will develop severe disease and may even die from the infection. If conditions are less crowded and more hygienic, the infective dose ingested will be lower, they may show moderate, slight or no clinical signs and develop immunity to reinfection, but they will in turn have multiplied the infection a million-fold.

Stress factors, such as a poor milk supply, weaning, cold weather and transport, will reduce any acquired resistance and exacerbate the condition. A major problem in milking herds (cattle) is that in an attempt to ensure a constant year-round milk supply, births often take place over an extended period of time. If the same pens are used constantly for successive batches, or if young calves are added to a pen already housing older calves, then the later born are immediately exposed to heavy challenge and can show severe coccidiosis in the first few weeks of life.

Age is therefore one of the main risk factors. During their first weeks of life, young ruminants are normally protected by passive immunity derived from colostrum. Neonatal animals receiving insufficient intake of colostrum and milk or experiencing periods of stress may start to show clinical signs of disease from about 18 days of age onwards.

Adult cattle are usually highly resistant to disease, but not totally resistant to infection. As a result, small numbers of parasites manage to complete their life cycle and usually cause no detectable harm. In the wild or under more natural extensive systems of management, susceptible calves are exposed to only low numbers of oocysts and acquire a protective immunity. Extensive grazing, as occurs under natural conditions in the wild, limits the level of exposure to infective oocysts. Under modern production systems, however, young calves are born into a potentially heavily contaminated environment, and where the numbers of sporulated oocysts are high, disease often occurs. Traditionally, indoor housing is a high-risk period especially where young calves are heavily stocked and in conditions that favour rapid oocyst sporulation and high numbers of oocysts in the environment. Three management factors are associated with the development of high levels of infection and the development of disease: pens not cleaned on a regular basis, overcrowding in the pens, and pens used to house different age groups.

The season of the year can also play a role in the appearance of coccidiosis. Coccidiosis is common in spring when young calves are born and turned out onto permanent pastures close to the farm buildings. Inclement weather at this time may cause stress at this

stage, lowering immunity and precipitating disease. Cold winters favour survival of overwintering oocysts in large enough numbers to represent sufficient disease challenge at turnout in spring; conversely, mild wet springs favour sporulation and rapid accumulation of large numbers of infective oocysts. Autumn-born calves may be born into an already heavily contaminated environment.

The effects of coccidial infections may be exacerbated if different species that affect different parts of the gut are present at the same time. Similarly, concurrent infections with other disease-producing agents such as helminths, bacteria and viruses may affect the severity of disease. Interactions between coccidia and parvovirus infection is thought to aggravate coccidiosis in calves.

Diagnosis: Diagnosis should be based on history, clinical signs (severe diarrhoea in young calves), postmortem findings (inflammation, hyperaemia and thickening of caecum with masses of gamonts and oocysts in scrapings), supported by oocyst counts and speciation to identify pathogenic species. Counts of faecal oocysts identified to species can help to complete the picture, but oocyst numbers may be grossly misleading when considered in isolation. Healthy cattle may pass more than 1 million oocysts per gram of faeces, whereas in animals dying of coccidiosis the count may be less than 10,000 oocysts per gram. For instance, high counts of non-pathogenic species could mask significant numbers of the more pathogenic species and give the impression that the abundant species was the cause. A key to the identification of sporulated oocysts of cattle is provided in Chapter 4 (see Fig. 4.33 and Table 4.7).

Treatment: Outbreaks of clinical coccidiosis can appear suddenly and may prove troublesome to resolve as they often occur on heavily stocked farms, particularly where good husbandry and management are lacking. If deaths are occurring, early confirmation of the diagnosis is vital. Affected cattle should be medicated and moved to uncontaminated pens or pasture as soon as possible.

Normally all cattle in a group should be treated, as even those showing no symptoms are likely to be infected. For calves, this would normally be in the form of a single oral drench with either diclazuril or toltrazuril, in countries where these products are both available and licensed for use. Decoquinatate can be administered in feed, bearing in mind that not all animals may consume the feed, especially severely affected animals that may be off their feed and dehydrated. Where these products are not available or licensed, then treatment with a sulphonamide such as sulphadimidine or sulphamethoxy-pyridazine can be considered.

Severely infected animals that are diarrhoeic and dehydrated may require oral or intravenous rehydration. Coccidiosis-infected animals may also have concurrent bacterial or parasitic infections that need to be diagnosed and treated with either antibacterial or anthelmintic treatments.

Where non-specific symptoms of weight loss or ill-thrift are present, it is important to investigate all potential causes and seek laboratory confirmation. If coccidiosis is considered significant, much can be done through advice on management and instigation of preventive measures. Batch rearing of animals of similar ages limits the build-up and spread of oocysts and allows targeting of treatment to susceptible age groups during the danger periods.

Prevention and control: Coccidial infections can be reduced through avoidance of overcrowding and stress, and attention to hygiene. Raising of food and water troughs, for example, can help avoid contamination and thus reduce levels of infection. Young

animals should be kept off heavily contaminated pastures when they are most susceptible.

The control of outbreaks of coccidiosis is a balance between controlling the disease and allowing the development of protective immunity against subsequent oocyst challenge. It should also be remembered that not all species are pathogenic and that immunity is species-specific so that exposure to one coccidial species does not confer resistance to another species. Also, exposure to a single infective challenge may confer strong protective immunity with some species of coccidia, while with others repeated exposure may be required before full protective immunity is acquired.

The timing of any treatment intervention is therefore crucial in both preventing severe disease outbreaks and at the same time allowing protective immunity to develop through adequate parasite exposure. To achieve this it is important to understand the epidemiology of coccidial infections in relation to the different ruminant hosts and the differing systems of production around the world. Using this approach it is possible to identify within management and husbandry systems periods of stress that may precipitate outbreaks of disease. While appropriate disease prevention methods should always be considered and instigated wherever possible, a more strategic approach to anticoccidial treatment should be applied based on an assessment of disease risks.

Eimeria bovis

Predilection site: Small and large intestine

Eimeria zuernii

Predilection site: Small and large intestine

For more details see Parasites of the large intestine.

Eimeria alabamensis

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Cnoidasida

Family: Eimeriidae

Description: Oocysts are usually ovoid, 13–24 by 11–16 µm (mean 18.9 by 13.4 µm) with a smooth colourless wall with no micropyle, polar body or residuum. Sporocysts are ellipsoidal, 10–16 by 4–6 µm with a tiny Stieda body and a sporocyst residuum. The sporozoites lie lengthwise head to tail in the sporocysts and have one to three clear globules. First-generation meronts are usually ovoid, 7–9 by 5.5–8.0 µm, containing 8–16 merozoites. Second-generation meronts are 9–12 by 6–9 µm, ovoid or ellipsoidal in shape and contain 18–26 merozoites.

Life cycle: The life cycle is typically coccidian with the developmental stages occurring in the nucleus of epithelial cells. Sporozoites penetrate the intestinal cells as early as day 2 after infection, and meronts are visible in the nucleus 2–8 days post infection. Parasitised cells are usually those at the tips of the villi and multiple invasion of the nucleus may occur. Two generations of meronts have

been found: mature first-generation meronts are seen 2–7 days post infection, and mature second-generation meronts 4–7 days post infection. The gametocytes are found in the posterior third of the small intestine and may also occur in the mucous membrane of the caecum and colon in heavy infections. Oocysts may be seen in the cells of the lower ileum as early as 6 days post infection. The prepatent period is 6–11 days, with a patent period of 1–13 days. Sporulation takes 4–8 days.

Geographical distribution: Presumed worldwide, mainly Europe

Pathogenesis: Particularly pathogenic, attacking the epithelial cells of the jejunum, ileum and, in heavy infections, the caecum and colon.

Pathology: Infection causes catarrhal enteritis in the jejunum, ileum and caecum with petechial haemorrhages. Histologically, there is necrotic inflammation and destruction of epithelial cells. There is an inflammatory response consisting predominantly of mononuclear cells with a few eosinophils and neutrophils. Numerous meronts are seen in the nuclei of villous epithelial cells, with occasional meronts in the upper colon. The mesenteric lymph nodes are enlarged, and parasite stages have been observed in the lymph nodes.

Clinical signs: Diarrhoea in calves recently turned out on to permanent paddocks. The calves become depressed and reluctant to rise. From 8 days after turnout, 850,000 to several million oocysts per gram faeces are excreted. Growth rate of the calves is adversely affected. Morbidity ranges from 5 to 100% (average 64%) but mortality is generally low.

Treatment: Sulphonamides can be used to treat infection. Decoquinatone has a prophylactic action against the parasite.

Control: Where infection is suspected to be due to oocysts overwintering on the pasture, the grazing land should be rotated to ensure that calves are not turned out on to potentially heavily infected pasture.

Infection with the following species of coccidia present in the small intestine is not usually associated with clinical signs. Specific treatment and control measures are not usually indicated for these species, although they often present as mixed infections. Differentiation is based on oocyst morphology (see Tables 2.3 and 4.7 and Fig. 4.33).

Eimeria aubernensis

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are elongated, ovoid, 20–46 by 20–25 μm (mean $38.4 \times 23.1 \mu\text{m}$), yellowish-brown, with a smooth or heavily granulated wall with a micropyle and polar granule, but no oocyst residuum. Sporocysts are elongate ovoid, almost ellipsoidal, 15–23 by 6–11 μm with a Stieda body and a residuum. The sporozoites are elongate, almost comma-shaped, 15–18 by 3–5 μm , lie lengthwise head to tail in the sporocysts, and have a clear globule at the large end, and sometimes one to two small globules arranged randomly.

Life cycle: The first-generation meronts occur throughout the small intestine deep in the lamina propria near the muscularis mucosae. Second-generation meronts and gamonts occur in the subepithelium in the distal part of the villi, in the jejunum and ileum. The macrogamonts are about 18 μm in diameter when mature. The prepatent period is 16–24 days and the patent period is usually 2–8 days. The sporulation time is 2–3 days.

Geographical distribution: Worldwide

Eimeria brasiliensis

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal, yellowish-brown, 33–44 by 24–30 μm (mean $37 \times 27 \mu\text{m}$) with a micropyle covered by a distinct polar cap. Polar granules may also be present, but there is no oocyst residuum. Sporocysts are ellipsoidal, 16–22 by 7–10 μm , with a residuum and sometimes a small dark Stieda body. The sporozoites are elongate and lie lengthwise head to tail in the sporocysts and have a large posterior and a small anterior clear globule.

Life cycle: Details of the life cycle are unknown. The sporulation time is 12–14 days.

Geographical distribution: Worldwide

Eimeria bukidnonensis

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are pear-shaped or oval, tapering at one pole, 47–50 by 33–38 μm (mean $48.6 \times 35.4 \mu\text{m}$), yellowish-brown, with a thick radially striated wall and micropyle. A polar granule may be present but there is no oocyst residuum. Sporozoites are elongate and lie lengthwise head to tail in the sporocysts with a clear globule at each end.

Life cycle: Details of the life cycle are unknown. The sporulation time is 4–7 days.

Geographical distribution: Worldwide

Eimeria canadensis

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid or ellipsoidal, colourless, or pale yellow, 28–37 by 20–22 μm (mean $32.5 \times 23.4 \mu\text{m}$) with an inconspicuous micropyle, one or more polar granules and an oocyst residuum. Sporocysts are elongate ovoid, 15–22 by 6–10 μm , with an inconspicuous Stieda body and a residuum. The sporozoites are elongate, lie lengthwise head to tail in the sporocysts and have two to three clear globules each.

Life cycle: Details of the life cycle are unknown. The sporulation time is 3–4 days.

Geographical distribution: Worldwide

Eimeria cylindrica

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are elongated, cylindrical, 16–27 by 12–15 μm (mean $23.3 \times 12.3 \mu\text{m}$) with a colourless smooth wall, no micropyle and no oocyst residuum. Sporocysts are elongate ellipsoidal, 12–16 by 4–6 μm with an inconspicuous or absent Stieda body and a residuum. The sporozoites are elongate, lie lengthwise head to tail in the sporocysts and have one or more rather indistinct clear globules.

Life cycle: Details of the life cycle are unknown. Both the prepatent and patent periods are 10 days. The sporulation time is 2–3 days.

Geographical distribution: Worldwide

Eimeria ellipsoidalis

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal to slightly ovoid, colourless, 20–26 by 12–17 μm (mean $23.4 \times 15.9 \mu\text{m}$) with no discernible micropyle, polar granule or oocyst residuum. Sporocysts are ovoid, 11–17 by 5–7 μm and may have a conspicuous Stieda body, each with a residuum. The sporozoites are elongate, 11–14 by 2–3 μm , and lie head to tail in the sporocysts and have two clear globules.

Life cycle: Mature gamonts lie in the terminal section of the ileum, and are seen 10 days after infection in the epithelial cells near the bottom of the crypts. The prepatent period is 8–13 days. The sporulation time is 3 days.

Geographical distribution: Worldwide

Eimeria pellita

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are egg-shaped, with a very thick brown wall with evenly distributed protruberances, 36–41 by 26–30 μm (mean $40 \times 28 \mu\text{m}$), with a micropyle and polar granule consisting of several rod-like bodies but no oocyst residuum. Sporocysts are ellipsoidal, 17–20 by 7–9 μm (mean $18.5 \times 8 \mu\text{m}$), each with a small Stieda body and a small sporocyst residuum. The sporozoites are elongate and each has two clear globules.

Life cycle: Details of the life cycle are unknown. The sporulation time is 10–12 days.

Geographical distribution: Presumed worldwide

Eimeria subspherica

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are round or subspherical, colourless, 9–14 by 8–13 μm (mean $11 \times 10.4 \mu\text{m}$), with no micropyle, polar granule or oocyst residuum. Sporocysts are elongate ovoid, 6–10 by 2–5 μm , each with a small Stieda body, but usually lacking a sporocyst residuum. The sporozoites are elongate and lie lengthwise head to tail in the sporocysts and each has a clear globule at the large end.

Life cycle: Details of the life cycle are unknown. The prepatent period is 7–18 days and the patent period is 4–15 days. The sporulation time is 4–5 days.

Geographical distribution: Worldwide

Eimeria wyomingensis

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: The oocysts are ovoid, yellowish-brown, 37–45 by 26–31 μm (mean $40.3 \times 28.1 \mu\text{m}$), with a thick wall, a wide micropyle but no polar granule or oocyst residuum. Sporocysts are ellipsoidal with narrowed ends (18 \times 9 μm) and each has a tiny Stieda body and the residuum is generally small or absent. The sporozoites are elongate, about 7–8 by 5 μm , and lie lengthwise head to tail in the sporocysts, each with a large clear globule.

Life cycle: Details of the life cycle are unknown. The prepatent period is 13–15 days and the patent period 1–7 days. The sporulation time is 5–7 days.

Geographical distribution: Worldwide

Cryptosporidium parvum

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Description: Mature oocysts are ovoid or spheroid, 5.0 by 4.5 μm (range 4.6–5.4 \times 3.8–4.7 μm); length/width ratio 1.19.

Hosts: Cattle, sheep, goat, horse, deer, human

Geographical distribution: Worldwide

Pathogenesis: Cryptosporidiosis is common in young calves, although the pathogenesis of infection is not clear. It is remarkable in that, unlike other members of the Eimeriidae, *Cryptosporidium* does not enter the cells of the host and lacks host specificity so that cross-infection can occur between domestic animals and humans.

Clinical signs: Clinically the disease is characterised by anorexia and diarrhoea, often intermittent, which may result in poor growth rates.

Diagnosis: Oocysts may be demonstrated using Ziehl–Neelsen stained faecal smears in which the sporozoites appear as bright red granules (Fig. 8.10). Speciation of *Cryptosporidium* is difficult, if not impossible, using conventional techniques. A range of molecular and immunological techniques has been developed that includes the use of immunofluorescence (Fig. 8.11) or ELISA. More recently, DNA-based techniques have been used for the molecular characterisations of *Cryptosporidium* species.

Pathology: The meronts and gamonts develop in a parasitophorous envelope, apparently derived from the microvilli and so the cell disruption seen with other coccidia does not apparently occur. However, mucosal changes are obvious in the ileum where there is stunting, swelling and eventually fusion of the villi. This has a marked effect on the activity of some of the membrane-bound enzymes.

Epidemiology: A variety of mammals act as hosts to *C. parvum* but little is known of the importance of their involvement in transmitting infection to, or maintaining infection in, domestic livestock.

Figure 8.10 Oocysts of *Cryptosporidium parvum* (Ziehl–Neelsen stain).

Figure 8.11 Oocysts of *Cryptosporidium parvum* (immunofluorescent antibody test).

In young calves infection appears to be age related, with seasonal peaks of disease reported to coincide with birth peaks in spring and autumn. The first calves to be born often become infected without showing clinical signs but become sources of infection for calves that follow. Infection spreads rapidly, and later-born calves can become so heavily infected that clinical disease results. In many instances where *Cryptosporidium* is diagnosed in animals, it appears that infections usually originate from the same host species. The primary route of infection is mainly direct animal to animal via the faecal–oral route. Thus in calves, for example, overcrowding, stress of early weaning, transport and marketing, together with low levels of hygiene, will increase the risk of clinical infections. In lambs, chilling due to adverse weather conditions in the neonatal period, intercurrent infections or nutritional or mineral deficiencies could exacerbate or increase the likelihood of disease. Infection in these cases is likely to occur via grooming, nuzzling, coprophagy, or faecal soiling by direct contact with infected animals. Infection may also occur indirectly through consumption of contaminated foods or environmental sources, including pasture and water.

Treatment: There is no known treatment, although spiramycin may be of some value. The infection is difficult to control since the oocysts are highly resistant to most disinfectants except formol-saline and ammonia. Halofuginone is available for the prevention of cryptosporidiosis in calves at a dose rate of 1 mg per 10 kg. Symptomatic treatment may be given in the form of antidiarrhoeals and fluid replacement therapy.

Control: Good hygiene and management are important in preventing disease from cryptosporidiosis. Feed and water containers should be high enough to prevent faecal contamination. Young animals should be given colostrum within the first 24 hours of birth and overstocking and overcrowding should be avoided. Dairy calves should be either isolated in individual pens or kept in similar age groups and cleaned out daily. On calf-rearing farms with recurrent problems, the prophylactic use of halofuginone can be considered by treating for 7 days consecutively commencing at 24–48 hours after birth.

Notes: Recent molecular characterisations have shown that there is extensive host adaptation in *Cryptosporidium* evolution, and many mammals or groups of mammals have host-adapted *Cryptosporidium* genotypes, which differ from each other in both DNA sequences

and infectivity. These genotypes are now delineated as distinct species and include, in cattle, *C. parvum*, *C. bovis* (also termed the bovine genotype or genotype 2), *C. ryanae* and *C. ubiquitous*.

Giardia intestinalis

Synonyms: *Giardia duodenalis*, *Giardia lamblia*, *Lamblia lamblia*

Predilection site: Small intestine

Phylum: Fornicata

Class: Treponadea

Family: Giardiidae

Description: The trophozoite has a pyriform to ellipsoidal, bilaterally symmetrical body, 12–15 µm long by 5–9 µm wide (Fig. 8.12). The dorsal side is convex and there is a large sucking disc on the ventral side. There are two anterior nuclei, two slender axostyles, eight flagellae in four pairs and a pair of darkly staining median bodies. The median bodies are curved bars resembling the claws of a hammer. Cysts are ovoid, 8–12 by 7–10 µm and contain four nuclei (Fig. 8.13).

Hosts: Human, cattle, sheep, goat, pig, horse, alpaca, dog, cat, guinea pig, chinchilla

Geographical distribution: Worldwide

Pathogenesis: Infections in cattle are often asymptomatic but have been reported to cause diarrhoea in young calves.

Clinical signs: When disease does occur, the signs often include chronic pasty diarrhoea, weight loss, lethargy and failure to thrive. The diarrhoea may be continuous or intermittent.

Diagnosis: *Giardia* cysts can be detected in faeces by a number of methods. Traditional methods of identification involve direct examination of faecal smears, or faecal concentration by formalin-ethyl acetate or zinc sulphate methods and subsequent microscopic examination. It is generally recommended that three consecutive samples be examined as cysts are excreted intermittently.

Pathology: There may be villous atrophy, crypt hypertrophy and an increased number of intraepithelial lymphocytes. Trophozoites may be seen between villi, attached by their concave surface to the brush border of epithelial cells.

Figure 8.12 *Giardia intestinalis* trophozoite.

Figure 8.13 *Giardia* cysts.

Epidemiology: Molecular studies have revealed a substantial level of genetic diversity in *G. intestinalis* isolates. Human isolates fall into two major groups (assemblages A and B) with a wide host range in other mammals and some separate species names may be applicable. Other assemblages may also represent distinct species. Limited epidemiological studies suggest that in animal isolates direct animal-to-animal contact and faecal soiling is the most likely method of transmission, although water contamination can also be considered as a possible route. The incidence of these parasites varies but can be assumed to be higher in some species than has been reported. Studies in Canada and the USA indicate levels of infection in cattle of up to 20% in clinically normal animals and 100% infection rates in young diarrhoeic calves.

Treatment: There is no recommended treatment for infection in calves. Several benzimidazole anthelmintics (e.g. albendazole, fenbendazole) are effective and may prove to be of benefit.

Control: As infection is transmitted by the faecal–oral route, good hygiene and prevention of faecal contamination of feed and water is essential.

Notes: The parasite is important because of water-borne outbreaks that have occurred in human populations. Phylogenetic data suggest that *G. intestinalis* is a species complex composed of several species that are host-specific. There is still some controversy over the classification of *Giardia* spp. The current molecular classification places isolates into eight distinct assemblages. Some authors give separate specific names to *Giardia* organisms isolated from cattle, for example *Giardia enterica* (Assemblage B), *Giardia bovis* (Assemblage E), although species specificity of many isolates is unknown.

LARGE INTESTINE

Oesophagostomum radiatum

Common name: Nodular worm

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: Adults are slender whitish worms, 1–2 cm in size, with males 12–17 mm and females 16–22 mm long.

Description, microscopic: The cuticle forms a rounded mouth collar, and large cephalic vesicle, constricted around the middle by a shallow annular groove (see Fig. 1.43). External leaf crowns are missing and the internal ring consists of 38–40 small triangular denticles. Cervical papillae are present, just posterior to the cervical groove. The male bursa is well developed. The egg is a medium-sized (75–98 × 46–54 µm), regular, broad ellipse with barrel-shaped side walls and rounded poles, and contains 16–32 blastomeres when passed in the faeces. The colourless chitinous shell is thin with a smooth surface. Infective larvae (L₃) have long filamentous tails, 32 gut cells and a rounded head.

Hosts: Cattle, buffalo

Geographical distribution: Worldwide

Pathogenesis: In *O. radiatum* infections in cattle, the pathogenic effect is attributed to the nodules (up to 5.0 mm in diameter) in the intestine and it is one of the most damaging worms to cattle when present in high numbers, with >200 adult worms in calves and >1000 adults in adult cattle sufficient to produce clinical signs. In the later stages of the disease, anaemia and hypoalbuminaemia develop due to the combined effects of protein loss and leakage of blood through the damaged mucosa.

Clinical signs: In acute infections, there is anaemia, oedema and diarrhoea.

Diagnosis: This is based on clinical signs and postmortem examination. The presence of pea-shaped nodules in the intestinal wall on postmortem is indicative of nodular worm infection. In the chronic disease, eggs are present and L₃ can be identified following faecal culture.

Pathology: On postmortem examination, animals may be pale from anaemia, and oedematous from hypoproteinaemia. Colonic lymph nodes are enlarged and the mucosa of the colon is grossly thickened and folded by oedema and increased mixed inflammatory cell infiltrates in the lamina propria. Colonic submucosal lymphoid follicles are large and active. Effusion of tissue fluid and blood cells may be evident through small leaks between cells, or from erosions in glands or on the surface. Although repeated exposure to infective larvae may result in the accumulation of large numbers of fourth-stage worms in nodules, formation of nodules has little pathogenic significance in cattle.

Epidemiology: It is not yet known if hypobiosis occurs in *O. radiatum*. It is also capable of overwintering on pasture as L₃. In tropical and subtropical areas *O. radiatum* in cattle is especially important. Cattle develop a good immunity, partly due to age and partly to previous exposure so that it is primarily a problem in weaned calves.

Treatment: Anthelmintic therapy with broad-spectrum anthelmintics (benzimidazoles, levamisole and avermectins/milbemycins) is highly effective.

Control: While not generally considered highly pathogenic, a combination of strategic dosing with anthelmintics and pasture management, as used in the control of other nematodes, will also help to control *O. radiatum*.

Trichuris globulosa

Synonym: *Trichocephalus globulosa*

Common name: Whipworms

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: The adults are long white worms (about 4.0–7.0 cm) with a thick broad posterior end, tapering rapidly to a long filamentous anterior end that is characteristically embedded in the mucosa.

Description, microscopic: The male tail is coiled and possesses a single spicule in a protrusible sheath. The sheath is covered with minute spines and bears a spherical appendage; the female tail is merely curved. The characteristic medium-sized eggs are lemon-shaped, 70–80 by 30–40 µm, with a thick smooth shell and a conspicuous protruding transparent polar plug (operculum) at both ends. The content of the egg is granular, there being no blastomeres. In the faeces these eggs appear yellowish or brown in colour.

Hosts: Cattle, occasionally sheep, goat, camel and other ruminants

Geographical distribution: Worldwide

Pathogenesis: Most infections are light and asymptomatic. Occasionally, when large numbers of worms are present they cause a diphtheritic inflammation of the caecal mucosa.

Clinical signs: Despite the fact that ruminants have a high incidence of light infections, the clinical significance of this genus, especially in ruminants, is generally negligible, although isolated outbreaks have been recorded.

Diagnosis: Since the clinical signs are not pathognomonic, diagnosis may depend on finding numbers of lemon-shaped *Trichuris* eggs in the faeces. Egg output is often low in *Trichuris* infections.

Pathology: In severe cases, the mucosa of the large intestine is inflamed and haemorrhagic with ulceration and formation of diphtheritic membranes.

Epidemiology: The most important feature is the longevity of the eggs, which may survive for 3 or 4 years. On pasture this is less likely since the eggs tend to be washed into the soil.

Treatment: In ruminants the benzimidazoles, the avermectins/milbemycins or levamisole by injection are very effective against adult *Trichuris*, but less so against larval stages.

Control: Prophylaxis is rarely necessary in ruminants.

Notes: The adults are usually found in the caecum but are only occasionally present in sufficient numbers to be clinically significant.

Trichuris discolor

Common name: Whipworms

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: Worms are similar to *T. globulosa* but the females are yellow–orange in colour.

Description, microscopic: Eggs measure about 65 by 30 μm .

Hosts: Cattle, buffalo, occasionally sheep, goat

Geographical distribution: Europe, Asia, USA

Details of the life cycle, pathogenesis, clinical signs, diagnosis, pathology, epidemiology, treatment and control are as for *T. globulosa*.

Homalogaster paloniae

Predilection site: Large intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Gastrodiscidae

Description, gross: The body is divided into two with a large anterior region and small cylindrical posterior region.

Hosts: Buffalo and cattle

Intermediate hosts: Water snails

Geographical distribution: Asia, Australasia

Pathogenesis: Generally considered to be non-pathogenic

Treatment and control: Not required

Eimeria bovis

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid or subspherical, colourless, 23–34 by 17–23 μm (mean 27.7 \times 20.3 μm) and have a smooth wall with an inconspicuous micropyle, no polar granule or oocyst residuum (Fig. 8.14). Sporocysts are elongate ovoid, 13–18 by 5–8 μm , and have an inconspicuous Stieda body and a sporocyst residuum. The sporozoites are elongate and lie lengthwise head to tail in the sporocysts and usually have a clear globule at each end.

Life cycle: There are two asexual generations. The first-generation meronts are in the endothelial cells of the lacteals of the villi in the posterior half of the small intestine, mature at 14–18 days after infection and can be seen grossly as whitish specks in the mucosa. Second-generation meronts occur in the epithelial cells of the caecum and colon, but may extend into the last metre of the small intestine in heavy infections. The sexual stages generally occur in the caecum and colon, but may extend into the ileum in heavy infections; they appear 17 days after infection. The prepatent period is 16–21 days and the patent period usually 5–15 days. The sporulation time is 2–3 days.

Figure 8.14 Oocysts of *Eimeria bovis*.

Geographical distribution: Worldwide

Pathogenesis: Particularly pathogenic, attacking the caecum and colon, causing mucosal sloughing and haemorrhage.

Pathology: The most severe pathological changes occur in the caecum, colon and terminal 30 cm of the ileum, and are due to the gamonts. The mucosa appears congested, oedematous and thickened with petechiae or diffuse haemorrhages. The gut lumen may contain a large amount of blood. Later in the infection the mucosa is destroyed and sloughs away. The submucosa may also be lost. If the animal survives, both the mucosa and submucosa regenerate.

Clinical signs: Severe enteritis and diarrhoea, or dysentery with tenesmus in heavy infections. The animal may be pyrexia, weak and dehydrated, and if left untreated loses condition and may die.

Epidemiology: Disease is dependent on conditions that precipitate a massive intake of oocysts, such as overcrowding in unhygienic yards or feedlots. It may also occur at pasture where livestock congregate around water troughs.

Eimeria zuernii

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are subspherical, colourless, 15–22 by 13–18 μm (mean 17.8 \times 15.6 μm), with no micropyle or oocyst residuum (Fig. 8.15). Sporocysts are ovoid, 7–14 by 4–8 μm , each with a tiny Stieda body, and a sporocyst residuum is usually absent. The sporozoites are elongate and lie head to tail in the sporocysts; each has a clear globule at the large end.

Life cycle: First-generation meronts are giant meronts and are found in the lamina propria of the lower ileum and mature at 14–16 days after infection, visible as whitish specks in the mucosa; second-generation meronts occur in the epithelial cells of the caecum and proximal colon from about 16 days after infection. The sexual stages generally occur within epithelial cells of the caecum and colon, but may extend into the ileum in heavy infections, appearing 16 days

Figure 8.15 Oocysts of *Eimeria zuernii*.

after infection. The prepatent period is 15–17 days and the patent period usually 5–17 days. The sporulation time is 2–10 days.

Geographical distribution: Worldwide

Pathogenesis: This is the most pathogenic species causing haemorrhagic diarrhoea through erosion and destruction of large areas of the intestinal mucosa. *Eimeria zuernii* is the most common cause of ‘winter coccidiosis’, which occurs primarily in calves during or following cold or stormy weather in the winter months. The exact aetiology of this syndrome is uncertain.

Pathology: Generalised catarrhal enteritis involving both the large and small intestines is present. The lower small intestine, caecum and colon may be filled with semi-fluid haemorrhagic material. Large or small areas of the intestinal mucosa may be eroded and destroyed. The mucous membrane may be thickened with irregular whitish ridges in the large intestine or smooth dull-grey areas in the small intestine or caecum. Diffuse haemorrhages are present in the intestines in acute cases, and petechial haemorrhages are seen in milder cases.

Clinical signs: In acute infections, *E. zuernii* causes haemorrhagic diarrhoea of calves. At first, the faeces are streaked with blood, but as the diarrhoea becomes more severe, bloody fluid, clots of blood and liquid faeces are passed. Tenesmus and coughing can result in the diarrhoea being spurted out up to 2–3 m. The animal’s hind-quarters are smeared with red diarrhoea. Secondary infections, especially pneumonia, are common. The acute phase may continue for 3–4 days. If the calf does not die in 7–10 days, it will probably recover.

Eimeria zuernii may also cause a more chronic form of disease. Diarrhoea is present, but there is little or no blood in the faeces. The animals are emaciated, dehydrated, weak and listless. Their coats are rough, their eyes sunken and their ears droop.

Treatment: Treatment of both *E. bovis* and *E. zuernii* is with a sulphonamide, such as sulphadimidine or sulphamethoxyypyridazine, given orally or parenterally and repeated at half the initial dose level on each of the next 2 days. Alternatively, decoquinatate in feed, or diclazuril and toltrazuril given orally may be used.

Control: Prevention is based on good management; in particular, feed troughs and water containers should be moved regularly and bedding kept dry.

Flagellate protozoa

The life cycle of the following flagellate protozoa is similar for all species found in cattle. The trophozoites reproduce by longitudinal binary fission, no sexual stages are known and there are no cysts. Transmission is thought to occur by ingestion of trophozoites from faeces. All are considered to be non-pathogenic and are generally only identified from smears taken from the large intestine of fresh carcasses.

Tetratrichomonas buttreyi

Synonym: *Trichomonas buttreyi*

Predilection site: Caecum, colon

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is ovoid or ellipsoidal, 4–7 by 2–5 μm (mean $6 \times 3 \mu\text{m}$) in size. Cytoplasmic inclusions are frequently present. There are three or four anterior flagella, which vary in length from a short stub to more than twice the length of the body, and each ends in a knob or spatulate structure. The undulating membrane runs the full length of the body and has three to five undulations ending in a posterior free flagellum. The accessory filament is prominent, and the costa relatively delicate. The axostyle is relatively narrow, has a spatulate capitulum and extends 3–6 μm beyond the body. There is no chromatic ring at its point of exit. A pelta is present. The nucleus is frequently ovoid ($2\text{--}3 \times 1\text{--}2 \mu\text{m}$) but is variable in shape and has a small endosome.

Hosts: Cattle, pig

Geographical distribution: Worldwide

Tritrichomonas enteris

Predilection site: Colon

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body measures 6–12 by 5–6 μm and there are three anterior flagella of equal length, which arise from a single blepharoplast. The flagellum at the edge of the undulating membrane is single and lacks an accessory filament. The undulating membrane extends three-quarters of the body length and a free flagellum extends beyond the undulating membrane. The axostyle is straight and slender, bending around the nucleus to give a spoon shape and extending at most one-quarter of the body length beyond the body.

Geographical distribution: Worldwide

Tetratrichomonas pavlovi

Synonyms: *Trichomonas bovis*, *Trichomonas pavlovi*

Predilection site: Caecum

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is pyriform and is usually 11–12 by 6–7 μm . It has four anterior flagella, which are about the same length as the body. The undulating membrane is well developed and has two to four waves that extend almost to the posterior end of the body. There is a posterior free flagellum, an accessory filament and a costa. The nucleus is round or ovoid. The axostyle is slender, broadening to form a capitulum at the anterior end.

Geographical distribution: Unknown

Retortamonas ovis

Predilection site: Large intestine

Phylum: Fornicata

Class: Retortamonadea

Family: Retortamonadorididae

Description: Trophozoites are pyriform and average 5.2 by 3.4 μm . There is a large cytostome near the anterior end containing a cytostomal fibril that extends across the anterior end and posteriorly along each side. An anterior flagellum and a posterior trailing flagellum emerge from the cytostomal groove. Cysts are pyriform and ovoid, containing one or two nuclei and retain the cytostomal fibril.

Geographical distribution: Worldwide

Buxtonella sulcata

Predilection site: Large intestine

Phylum: Ciliophora

Class: Litostomatea

Family: Pycnotrichidae

Description: The body is ovoid, 100 by 72 μm , and uniformly ciliated with a prominent curved groove bordered by two ridges running from end to end with a cyathostome at the anterior end, and an oval or bean-shaped macronucleus, 28 by 14 μm in size.

Geographical distribution: Worldwide

Parasites of the respiratory system

Mammomonogamus laryngeus

Synonym: *Syngamus laryngeus*

Common name: Gapeworm

Predilection site: Larynx

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: The worms are reddish in appearance and about 0.5–2 cm long. The females and males are found in permanent copulation. The buccal capsule lacks a cuticular crown.

Description, microscopic: Eggs are ellipsoid, 42–45 by 75–85 μm , with no operculum at either end.

Hosts: Cattle, buffalo, goat, sheep, deer, rarely human

Geographical distribution: Asia, Central Africa, South America and Caribbean islands

Pathogenesis: *Mammomonogamus laryngeus* is not very pathogenic for cattle. Worms are attached to the mucosa of the larynx and may cause laryngitis and bronchitis.

Clinical signs: Infections are usually asymptomatic but affected animals may cough and lose condition. Calves may develop bronchitis and aspiration pneumonia has been recorded.

Diagnosis: This is based on clinical signs and the finding of eggs in the faeces. Disease is probably best confirmed by postmortem examination of selected cases, when reddish worms will be found attached to the tracheal mucosa. The infected trachea often contains an increased amount of mucus.

Pathology: Not described

Epidemiology: Unknown

Treatment: Successful treatment has not been reported. Benzimidazoles and macrocyclic lactones are likely to be effective.

Control: No preventive or control measures have been described.

Notes: This genus, closely related to *Syngamus*, is parasitic in the respiratory passages of mammals. Infection has been reported in humans, causing a laryngo-pharyngeal syndrome.

Mammomonogamus nasicola

Synonyms: *Syngamus nasicola*, *Syngamus kingi*

Predilection site: Nasal cavities

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: The worms are reddish in appearance and about 0.5–2 cm long. Males are 4–6 mm and females 11–23 mm long and found in permanent copulation. The buccal capsule lacks a cuticular crown.

Description, microscopic: Eggs are ellipsoid, 54–98 μm , with no operculum at either end.

Hosts: Sheep, goat, cattle, deer

Geographical distribution: Central and South America, Central Africa, Caribbean islands

For more details on this species see Chapter 9.

Dictyocaulus viviparus

Common names: Bovine lungworm, husk, hoose, verminous pneumonia, parasitic bronchitis

Predilection site: Bronchi, trachea

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are slender thread-like worms; males measure around 4.0–5.5 cm and females 6–8 cm in length.

Description, microscopic: First-stage larvae present in fresh faeces are about 300–450 µm in length and 25 µm in width, the intestinal cells containing numerous brownish chromatin granules (see Fig. 1.36). The head is rounded, there being no protruding anterior knob (cf. *D. filaria* in sheep and goats). The oesophagus is simple strongyloid and the tail terminates in a blunt point.

Hosts: Cattle, buffalo, deer and camel

Geographical distribution: Worldwide, but especially important in temperate climates with a high rainfall.

Pathogenesis: Dictyocaulosis is characterised by bronchitis and pneumonia and typically affects young cattle during their first grazing season on permanent or semi-permanent pastures. Pathogenesis may be divided into three phases.

- 1 Prepatent phase: around days 8–25. This phase starts with the appearance of larvae within the alveoli where they cause alveolitis. This is followed by bronchiolitis and finally bronchitis as the larvae become immature adults and move up the bronchi. Towards the end of this phase bronchitis develops, characterised by immature lungworms in the airways and by cellular infiltration of the epithelium. Heavily infected animals, whose lungs contain several thousand developing worms, may die from day 15 onwards due to respiratory failure following the development of severe interstitial emphysema and pulmonary oedema.
- 2 Patent phase: around days 26–60. This is associated with two main lesions: first, a parasitic bronchitis characterised by the presence of hundreds or even thousands of adult worms in the frothy white mucus in the lumina of the bronchi (Fig. 8.16);

Figure 8.16 *Dictyocaulus viviparus* worms in the opened bronchi of an infected calf.

Figure 8.17 Typical distribution of pneumonic lesions of parasitic bronchitis.

and second, the presence of dark-red collapsed areas around infected bronchi (Fig. 8.17). This is a parasitic pneumonia caused by the aspiration of eggs and L₁ into the alveoli.

- 3 Postpatent phase: around days 61–90. In untreated calves, this is normally the recovery phase after the adult lungworms have been expelled. Although the clinical signs are abating, the bronchi are still inflamed and residual lesions such as bronchial and peribronchial fibrosis may persist for several weeks or months. Eventually the bronchopulmonary system becomes completely normal and coughing ceases. However, in about 25% of animals, which have been heavily infected, there can be a flare-up of clinical signs during this phase that is frequently fatal. This is caused by one of two entities. Most commonly, there is a proliferative lesion so that much of the lung is pink and rubbery and does not collapse when the chest is opened. This, often described as ‘epithelialisation’, is due to the proliferation of type 2 pneumocytes on the alveoli giving the appearance of a gland-like organ. Gaseous exchange at the alveolar surface is markedly impaired and the lesion is often accompanied by interstitial emphysema and pulmonary oedema. The aetiology is unknown, but is thought to be due to the dissolution and aspiration of dead or dying worm material into the alveoli. The clinical syndrome is often termed ‘postpatent parasitic bronchitis’. The other cause, usually in animals convalescing indoors, is a superimposed bacterial infection of the imperfectly healed lungs leading to acute interstitial pneumonia.

Clinical signs: Within any affected group, differing degrees of clinical severity are usually apparent. Mildly affected animals cough intermittently, particularly when exercised. Moderately affected animals have frequent bouts of coughing at rest, tachypnoea (60 respirations per minute) and hyperpnoea. Frequently, squeaks and crackles over the posterior lung lobes are heard on auscultation. Severely affected animals show severe tachypnoea (80 respirations per minute) and dyspnoea and frequently adopt the classic ‘air-hunger’ position of mouth breathing with the head and neck outstretched. There is usually a deep harsh cough, squeaks and crackles over the posterior lung lobes, salivation, anorexia and sometimes mild pyrexia. Often the smallest calves are most severely affected.

Calves may show clinical signs during the prepatent period and occasionally a massive infection can cause severe dyspnoea of sudden onset often followed by death in 24–48 hours.

Most animals gradually recover, although complete return to normality may take weeks or months. However, a proportion of convalescing calves suddenly develop severe respiratory signs, unassociated with pyrexia, which usually terminates fatally 1–4 days later (postpatent parasitic bronchitis).

Diagnosis: Usually the clinical signs, the time of year and a history of grazing on permanent or semi-permanent pastures are sufficient to enable a diagnosis to be made.

Larvae are found (50–1000/g) only in the faeces of patent cases so that faecal samples should be obtained from the rectum of a number of affected individuals. At necropsy, worms will often be apparent in the opened bronchi and their size is diagnostic. A lungworm ELISA can be used to detect antibodies to *D. viviparus*. Seroconversion takes 4–6 weeks and titres persist for 4–7 months. Serology can be helpful in cases of reinfection, as it will often detect larval stages. Cross-reactivity can occur with intestinal nematode species so test sensitivity and specificity requires validation and setting of appropriate optical density (OD) cut-off values when interpreting results.

Pathology: Two phases are recognised.

- 1 Prepatent phase. Cellular infiltrates of inflammatory cells temporarily plug the lumina of the bronchioles and cause collapse of other groups of alveoli. This lesion is largely responsible for the first clinical signs of tachypnoea and coughing.
- 2 Patent phase. The bronchial epithelium is hyperplastic and heavily infiltrated by inflammatory cells, particularly eosinophils. Aspirated eggs and larvae quickly provoke dense infiltrates of polymorphs, macrophages and multinucleated giant cells around them (Fig. 8.18). There may be varying degrees of interstitial emphysema and oedema.

Epidemiology: Generally only calves in their first grazing season are clinically affected, since on farms where the disease is endemic older animals have a strong acquired immunity. In endemic areas in the northern hemisphere, infection may persist from year to year in two ways.

- 1 Overwintered larvae: L₃ may survive on pasture from autumn until late spring in sufficient numbers to initiate infection or occasionally to cause disease.

Figure 8.18 Inflammatory response due to the presence of aspirated eggs and larvae in the bronchioles and alveoli.

- 2 Carrier animals: small numbers of adult worms can persist in the bronchi, particularly in yearlings, until the next grazing season. Chilling of infective larvae before administration to calves will produce arrested L₅; hypobiosis at this stage has also been observed in naturally infected calves in Switzerland, Austria and Canada, although the extent to which this occurs naturally after ingestion of larvae in late autumn and its significance in the transmission of the infection has not yet been fully established.

The dispersal of larvae from the faecal pat appears to be effected by a fungus rather than by simple migration as the infective larvae are relatively inactive. This fungus, *Pilobolus*, is commonly found growing on the surface of bovine faecal pats about 1 week after deposition. The larvae of *D. viviparus* migrate in large numbers up the stalks of the fungi on to, and even inside, the sporangium or seed capsule (Fig. 8.19). When the sporangium is discharged it is projected a distance of up to 3 m in still air to land on the surrounding herbage.

Parasitic bronchitis is predominantly a problem in areas such as northern Europe that have a mild climate, high rainfall and abundant permanent grass. Outbreaks of disease occur from June until November, but are most common from July until September. It is not clear why the disease is usually not apparent until calves, turned out to graze in the spring, have been at grass for 2–5 months. One explanation is that the initial infection, acquired from the ingestion of overwintered larvae in May, involves so few worms that neither clinical signs nor immunity is produced; however, sufficient numbers of larvae are seeded on to the pasture so that by July the numbers of L₃ are sufficient to produce clinical disease. Young calves, added to such a grazing herd in July, may develop clinical disease within 2–3 weeks. An alternative explanation is that L₃ overwinter in the soil and possibly only migrate on to pasture at some point between June and October.

Although dairy or dairy-cross calves are most commonly affected, autumn-born single-suckled beef calves are just as susceptible when

Figure 8.19 Larvae of *Dictyocaulus viviparus* on the fungus *Pilobolus*.

turned out to grass in early summer. Spring-born suckled beef calves grazed with their dams until housed or sold do not usually develop clinical signs, although coughing due to a mild infection is common. However, the typical disease may occur in weaned calves grazed until late autumn.

Adult cattle can be affected with parasitic bronchitis if they have not had sufficient exposure to lungworm larvae in previous years to develop adequate immunity and are subsequently grazed on heavily contaminated pastures. This is sometimes first seen as a reduction in milk yield with subsequent coughing.

In tropical countries, where disease due to *D. viviparus* may occur intermittently, the epidemiology is presumably quite different and probably depends more on pasture contamination by carrier animals, such as may occur during flooding when cattle congregate on damp high areas, rather than on the prolonged survival of infective larvae.

Treatment: The modern benzimidazoles, levamisole or the avermectin/milbemycins have been shown to be highly effective against all stages of lungworms with consequent amelioration of clinical signs. For maximum efficiency, all these drugs should be used as early as possible in the treatment of the disease. Where the disease is severe and well established in a number of calves one should be aware that anthelmintic treatment, while being the only course available, may exacerbate the clinical signs in one or more animals with a possible fatal termination. Whatever treatment is selected, it is advisable to divide affected calves into two groups, as the prognosis will vary according to the severity of the disease. Those calves which are only coughing and/or tachypnoeic are usually in the pre-patent stage of the disease or have a small adult worm burden and treatment of these animals should result in rapid recovery. Calves in this category may not have developed a strong immunity and after treatment should not be returned to grazing which was the source of infection; if this is not possible, parenteral ivermectin, doramectin or moxidectin may be used since their residual effect prevents reinfection for an extended period.

Any calves which are dyspnoeic, anorexic and possibly pyrexia should be kept indoors for treatment and further observation. The prognosis must be guarded as a proportion of these animals may not recover while others may remain permanently stunted. In addition to anthelmintics, severely affected animals may require antibiotics if pyrexia and may be in need of hydration if they are not drinking.

Control: The best method of preventing parasitic bronchitis is to immunise all young calves with lungworm vaccine. This live attenuated vaccine is currently only available in parts of Europe and is given orally to calves aged 8 weeks or more. Two doses of vaccine are given at an interval of 4 weeks and, in order to allow a high level of immunity to develop, vaccinated calves should be protected from challenge until 2 weeks after their second dose. Dairy calves or suckled calves can be vaccinated successfully at grass provided the vaccine is given prior to encountering a significant larval challenge.

Although vaccination is effective in preventing clinical disease, it does not completely prevent the establishment of small numbers of lungworms. Consequently, pastures may remain contaminated, albeit at a very low level. For this reason it is important that all the calves on any farm should be vaccinated whether they go to pasture in the spring or later in the year and a vaccination programme must be continued annually for each calf crop.

Control of parasitic bronchitis in first-year grazing calves has been achieved by the use of prophylactic anthelmintic regimens

either by strategic early-season treatments or by the administration of rumen boluses, as recommended in the control of bovine ostertagiosis. The danger of these measures, however, is that through rigorous control in the first grazing season, exposure to lungworm larvae is so curtailed that cattle may remain susceptible to husk during their second season; in such situations it may be advisable to consider vaccination prior to their second year at grass.

Because of the unpredictable epidemiology, the technique commonly used in ostertagiosis of 'dose and move' in midsummer does not prevent parasitic bronchitis.

Parasitic bronchitis in adult cattle Parasitic bronchitis is only seen in adult cattle under two circumstances.

- 1 As a herd phenomenon, or in a particular age group within a herd, if they have failed to acquire immunity through natural challenge in earlier years. Such animals may develop the disease if exposed to heavy larval challenge, as might occur on pasture recently vacated by calves suffering from clinical husk.
- 2 Disease is occasionally seen where an individual adult is penned in a heavily contaminated calf paddock.

The disease is most commonly encountered in the patent phase, although the other forms have been recognised. In addition to coughing and tachypnoea, a reduction in milk yield in cows is a common presenting sign.

In selecting an anthelmintic for treatment, one should consider the withdrawal period of milk for human consumption. Eprinomectin has no withdrawal period for milk.

Reinfection syndrome in parasitic bronchitis Normally, the natural challenge of adult cattle, yearlings or calves that have acquired immunity to *D. viviparus*, whether by natural exposure or by vaccination, is not associated with clinical signs. Occasionally, however, clinical signs do occur to produce the 'reinfection syndrome', which is usually mild but sometimes severe. It arises when an immune animal is suddenly exposed to a massive larval challenge that reaches the lungs, and migrates to the bronchioles where the larvae are killed by the immune response. The proliferation of lymphoreticular cells around dead larvae causes bronchiolar obstruction and ultimately the formation of a macroscopically visible, greyish-green, lymphoid nodule about 5.0 mm in diameter. Usually the syndrome is associated with frequent coughing and slight tachypnoea over a period of a few days; less frequently there is marked tachypnoea, hyperpnoea and, in dairy cows, a reduction in milk yield. Deaths rarely occur. It can be difficult to differentiate this syndrome from the early stages of a severe primary infection. The only course of action is treatment with anthelmintics and a change of pasture.

Echinococcus granulosus

For more details see Parasites of the liver.

Pneumocystis carinii

Synonym: *Pneumocystis jiroveci*

Common name: Pneumocystosis

Predilection site: Lung

Kingdom: Fungi

Phylum: Ascomycota

Class: Pneumocystidomycetes

Family: Pneumocystidaceae

Description: Two major forms of *P. carinii* have been consistently identified from histological and ultrastructural analysis of organisms found in human and rat lung. These are a trophic form and a larger cyst stage containing eight intracystic stages.

Hosts: Human, cattle, rat, ferret, mouse, dog, horse, pig and rabbit

Geographical distribution: Worldwide

Pathogenesis: *Pneumocystis* is one of the major causes of opportunistic mycoses in the immunocompromised, including those with congenital immunodeficiencies, retrovirus infections such as AIDS, and cases receiving immunosuppressive therapy.

Clinical signs: Infections in animals are generally asymptomatic. In humans, pneumocystosis is observed in four clinical forms: asymptomatic infections, infantile (interstitial plasma cell) pneumonia, pneumonia in immunocompromised host and extrapulmonary infections.

Diagnosis: Gomori's methenamine silver (GMS) and Giemsa stain may be used for microscopic visualisation of *Pneumocystis*. Toluidine blue (TBO) is the most effective for cyst stages while Giemsa stains are used to show trophozoites. Axenic culture methods have been described; however, *in vitro* cultivation, especially from clinical samples, is not always successful. Fluorescence antibody staining techniques can be used to detect both cyst and trophozoite stages of *P. carinii*. A number of polymerase chain reaction (PCR) tests have been reported which amplify specific regions of DNA from *P. carinii* and are approximately 100 times more sensitive than conventional staining techniques.

Pathology: Lesions are characterised by a massive plasma cell or histiocyte infiltration of the alveoli in which the organisms may be detected by a silver staining procedure. A foamy eosinophilic material is observed in the lungs during infection. This material is composed of masses of the organism, alveolar macrophages, desquamated epithelial alveolar cells, polymorphonuclear leucocytes and other host cells.

Epidemiology: The organism is apparently quite widely distributed in latent form in healthy human individuals, as well as a wide variety of domestic and wild animals. The organism is thought to be transmitted by aerosol, although the natural habitats and modes of transmission of infections in humans are current areas of research. *Pneumocystis* DNA has been detected in air and water, suggesting that the free forms of the organism may survive in the environment long enough to infect a susceptible host. However, little information on the means of transmission exists currently. In humans, infections appear to spread between immunosuppressed patients colonised with *Pneumocystis* and immunocompetent individuals transiently parasitised with the organism. Human and non-human *Pneumocystis* species have been shown to be different and host-specific, suggesting that zoonotic transmission does not occur.

The organism has been reported from a range of animals. In Denmark, examination of lungs from carcasses selected randomly in an abattoir detected *P. carinii* pneumocysts in 3.8% of calves, 3.6% of sheep and 6.7% of pigs. Studies in Japan detected *P. carinii* in cattle and a wide range of other animals. The organism has also been reported to have caused pneumonia in weaning pigs.

Treatment: Trimethoprim–sulphamethoxazole is the drug of choice for treatment and prophylaxis of *Pneumocystis* infections. Pentamidine and atovaquone are the alternative therapeutic agents in humans.

Control: Control is difficult given that details of the routes of transmission are unknown. Infection is generally asymptomatic in animals and is only likely to be detected in immunocompromised individuals.

Notes: Initially reported as a morphological form of *Trypanosoma cruzi*, this microorganism later proved to be a separate genus and was named *Pneumocystis carinii* and classified as a protozoan until the late 1980s. Following further taxonomic revision, *Pneumocystis* is now classified as a fungus, not a protozoan. The taxonomy is still complicated in that *Pneumocystis* from humans and other animals are quite different and there appear to be multiple species in this genus. Genetic variations and DNA sequence polymorphisms are often observed, suggesting the existence of numerous strains even within a single species of *Pneumocystis*.

Parasites of the liver

Fasciola hepatica

Common name: Liver fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description, gross: The young fluke at the time of entry into the liver is 1.0–2.0 mm in length and lancet-like. When it has become fully mature in the bile ducts it is leaf-shaped, grey–brown in colour and is around 2.5–3.5 cm in length and 1.0 cm in width. The anterior end is conical and marked off by distinct shoulders from the body (Fig. 8.20; see also Fig. 1.70a).

Description, microscopic: The tegument is covered with backwardly projecting spines. An oral and ventral sucker may be readily seen. The egg is thin-shelled, oval with symmetrical barrel-shaped

Figure 8.20 Adult *Fasciola hepatica* flukes.

side walls, operculate, brownish-yellow and large (130–150 × 65–90 µm), and about twice the size of a trichostrongyle egg (see Figs 4.3 and 9.1). The granular contents fill the whole of the egg.

Final hosts: Sheep, cattle, goat, horse, deer, human and other mammals

Intermediate hosts: Snails of the genus *Galba* (*Lymnaea*). The most common, *Galba* (syn. *Lymnaea*) *truncatula*, is an amphibious snail with a wide distribution throughout the world. Other important vectors of *F. hepatica* outside Europe are:

| | |
|----------------------|---|
| <i>L. tomentosa</i> | Australia, New Zealand |
| <i>L. columella</i> | Central and North America, Australia, New Zealand |
| <i>L. bulimoides</i> | Northern and southern USA and the Caribbean |
| <i>L. humilis</i> | North America |
| <i>L. viator</i> | South America |
| <i>L. diaphena</i> | South America |
| <i>L. cubensis</i> | South America |
| <i>L. viridis</i> | China, Papua New Guinea |

Geographical distribution: Worldwide

Pathogenesis: This varies according to the number of metacercariae ingested, the phase of parasitic development in the liver and the species of host involved. Essentially the pathogenesis is twofold. The first phase occurs during migration in the liver parenchyma and is associated with liver damage and haemorrhage. The second occurs when the parasite is in the bile ducts, and results from the haematophagic activity of the adult flukes and from damage to the biliary mucosa by their cuticular spines. Most studies have been in sheep and the disease in this host is discussed in more detail in Chapter 9. The seasonality of outbreaks described is that which occurs in western Europe.

Although acute and subacute disease may occasionally occur under conditions of heavy challenge, especially in young calves, the chronic form of the disease is by far the most important and, as in sheep, is seen in the late winter/early spring.

The pathogenesis is similar to that in sheep but has the added features of calcification of the bile ducts and enlargement of the gallbladder. The calcified bile ducts often protrude from the liver surface, giving rise to the term 'pipe-stem liver'. Aberrant migration of the flukes is more common in cattle and encapsulated parasites are often seen in the lungs. On reinfection of adult cows, migration to the fetus has been recorded, resulting in prenatal infection. There is some experimental evidence that fasciolosis increases the susceptibility of cattle to infection with *Salmonella dublin*.

Fasciola infections may cause a loss of production in milking cows during winter. Clinically, these are difficult to detect since the fluke burdens are usually low and anaemia is not apparent. The main effects are a reduction in milk yield and quality, particularly of the solids-non-fat component.

Clinical signs: In heavy infections in cattle, where anaemia and hypoalbuminaemia are severe, submandibular oedema frequently occurs (Fig. 8.21). With smaller fluke burdens, the clinical effect is minimal and the loss of productivity is difficult to differentiate from inadequate nutrition. It must be emphasised that diarrhoea is not a feature of bovine fasciolosis unless it is complicated by the presence of *Ostertagia* spp. Combined infection with these two parasites has been referred to as the fasciolosis/ostertagiosis complex.

Diagnosis: This is based primarily on clinical signs, seasonal occurrence, prevailing weather patterns, and a previous history of

Figure 8.21 Submandibular oedema in a cow infected with *Fasciola hepatica*.

fasciolosis on the farm or the identification of snail habitats. While diagnosis of ovine fasciolosis should present few problems, especially when a postmortem examination is possible, diagnosis of bovine fasciolosis can sometimes prove difficult. In this context, routine haematological tests and examination of faeces for fluke eggs (note that eggs of *Fasciola* are brownish-yellow and eggs of Paramphistomidae are colourless) are useful and may be supplemented by other laboratory tests.

Routine haematology will often show the presence of anaemia (normochromic and normocytic) as a result of haemorrhage resultant from the direct feeding of the flukes. The packed cell volume (PCV) is also reduced. Fluke infection also leads to an eosinophilia (Table 8.4).

Fluke infections lead to a decrease in the albumin/globulin ratio. Hypoalbuminaemia due to protein loss occurs during the parenchymal stage of infection by immature flukes, and also due to the presence of adult fluke in the bile ducts. Globulin levels increase as a result of increased immunoglobulin synthesis.

Serum concentrations of liver-specific enzymes are generally higher in acute liver disease than in chronic liver disease and may be within normal limits in the later stages of subacute or chronic hepatic disease. Glutamate dehydrogenase (GLDH) is released when parenchymal cells are damaged and levels become elevated within the first few weeks of infection. Another enzyme, gamma-glutamyltranspeptidase (GGT), indicates damage to the epithelial cells lining the bile ducts; elevation of this enzyme takes place mainly after

Table 8.4 Haematological/biochemical parameters in normal and fluke-infected cattle.

| Parameter | Normal | Fluke infected |
|---|------------|--|
| PCV (%) | 32 (24–40) | ≥20 |
| Eosinophils (%) | 2–20 | >20% |
| (×10 ³ /µL) | 0–2.4 | |
| Glutamate dehydrogenase (GLDH) (iu/L) | 2–23 | 5× normal (50–120) Elevated ≥6 weeks post infection |
| Gamma-glutamyltranspeptidase (GGT) (iu/L) | 20–46 | Up to 10× normal levels in chronic fluke |

the flukes reach the bile ducts and raised levels are maintained for a longer period. Interpretation of raised liver enzyme activity can be difficult and careful analysis of laboratory values in conjunction with clinical findings is essential.

Detection of antibodies against components of flukes in serum or milk samples can also be undertaken, the ELISA and the passive haemagglutination test being the most reliable. Antibodies to liver fluke can be detected in serum 2–4 weeks post infection but levels may rise or fall over time. A positive result does not necessarily indicate a current infection but a history of exposure. Serological testing is not widely available and may vary from country to country as to availability for either cattle or sheep. A bulk-tank milk ELISA for cattle gives a positive result when the prevalence in a herd is more than 25%. Interpretation can be difficult as false positives can occur. A coproantigen test is also available which detects fluke proteins in faeces.

Pathology: In cattle, the pathogenesis is similar to that seen in sheep with the added features of calcification of the bile ducts and enlargement of the gallbladder. The calcified bile ducts often protrude from the liver surface, giving rise to the term ‘pipe-stem liver’ (Fig. 8.22). Aberrant migration of flukes is more common in cattle and encapsulated parasites are often seen in the lungs.

Epidemiology: For a more detailed description, see entry in Chapter 9.

Treatment: The older drugs such as carbon tetrachloride, hexachloroethane and hexachlorophene may still be used in some countries, but these have been largely replaced by more efficient and less toxic compounds and only the latter are discussed.

At present there is only one drug, triclabendazole, which will remove the early immature (around 2 weeks of age in cattle) parenchymal stages. Apart from triclabendazole, the other drugs most commonly used for subacute or chronic fasciolosis are closantel, nitroxylin and oxcyclozanide, and several others, such as clorsulon, rafoxanide and niclofolan, are also marketed in some countries.

Figure 8.22 Gross appearance of the liver in bovine fasciolosis.

Albendazole, ricobendazole and netobimin are also effective against adult fluke at an increased dosage rate. In lactating cows, where the milk is used for human consumption, the above drugs are either banned or have extended withdrawal periods, and are more usually given during the dry period. An exception is oxcyclozanide, which is licensed for use in lactating animals in many countries and has a nil or very short milk-withholding time. At times of the season when the fluke burden predominantly comprises adults, the use of narrow-spectrum flukicides with activity against adult stages only will help to reduce the selection pressure on drugs such as triclabendazole. Combination products with activity against fluke and gastrointestinal nematodes should only be used where both helminths are present. Resistance to flukicides has been reported with triclabendazole use in sheep but is not currently considered to be as significant a problem with fluke in cattle.

Control: Control of fasciolosis may be approached in two ways: by reducing populations of the intermediate snail host or by using anthelmintics (for a more detailed description see entry in Chapter 9). The timing of treatments will depend on the spectrum of activity of the flukicide and it is also important to monitor the need for treatment. The use of meteorological forecasting for fasciolosis is described in detail in Chapter 9.

A typical treatment schedule for non-lactating cattle in the northern hemisphere in an average rainfall season would be as follows.

- Dose cattle in autumn with a flukicide that is effective against young immature fluke to reduce liver damage from fluke migration. This is irrespective of whether cattle will be housed or overwintered.
- Dose grazing cattle in winter with a flukicide that is effective against adult fluke and immature stages. Cattle wintered inside need to be treated after housing (timing of the dose varies with the flukicide used).
- Dose overwintered cattle in spring with a flukicide that is effective against adult stages. This will remove fluke burdens and reduce contamination of pastures with fluke eggs and thus reduce the summer infection of snails.

Dairy cows can be treated at drying-off but particular attention needs to be paid to contraindications relating to both stage of pregnancy and lactation.

Fasciola gigantica

Common name: Tropical large liver fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description, gross: The adult fluke is larger than *F. hepatica*, the body is more transparent, and can reach 7.5 cm in length and 1.5 cm in breadth. The shape is more leaf-like, the conical anterior end is very short and the shoulders, characteristic of *F. hepatica*, are barely perceptible (see Fig. 1.70b).

Description, microscopic: The eggs are larger than those of *F. hepatica*, measuring 170–190 by 90–100 µm.

Final hosts: Cattle, buffalo, sheep, goat, pig, camel, deer, human

Intermediate hosts: Snails of the genus *Lymnaea* (syn. *Galba*); in southern Europe it is *L. auricularia*, which is also the important species in the southern USA, the Middle East and the Pacific Islands. Other important vectors of *F. gigantica* are:

| | |
|----------------------|---------------------|
| <i>L. natalensis</i> | Africa |
| <i>L. rufescens</i> | Indian subcontinent |
| <i>L. acuminata</i> | Indian subcontinent |
| <i>L. rubiginosa</i> | Southeast Asia |
| <i>L. viridis</i> | China and Japan |

All these snails are primarily aquatic snails and are found in streams, irrigation channels and marshy swamps.

Geographical distribution: Africa, Asia, Europe, USA

Clinical signs: Clinical signs are similar to those of *F. hepatica*.

Diagnosis: This is based primarily on clinical signs, seasonal occurrence, prevailing weather patterns and a previous history of fasciolosis on the farm or the identification of snail habitats. Diagnosis can be confirmed by the identification of the typical operculate eggs in faeces samples.

Pathogenesis: Acute and chronic infection occurs in sheep but only the chronic form predominates in cattle. Like *F. hepatica*, *F. gigantica* is capable of infecting humans.

Pathology: The pathology is similar to that described for *F. hepatica*. In cattle, the pathology is similar to that seen in sheep with the added features of calcification of the bile ducts and enlargement of the gallbladder. The calcified bile ducts often protrude from the liver surface giving rise to the term ‘pipe-stem liver’.

Epidemiology: The snails that carry the larval stages of *F. gigantica* are primarily aquatic and as a result the disease is associated with animals grazing on naturally or artificially flooded areas or around permanent water channels or dams. In subtropical or tropical countries with distinct wet and dry seasons, it appears that optimal development of eggs to miracidia occurs at the start of the wet season and development within the snail is complete by the end of the rains. Shedding of cercariae then commences at the start of the dry season when the water level is still high and continues as the water level drops. Under laboratory conditions, a large number of metacercariae simply encyst on the surface of the water rather than on herbage, and under natural conditions this could have a very significant effect on the dissemination of infection. Metacercariae are acquired by animals utilising such areas during the dry season and clinical problems, depending on the rate of infection, occur at the end of that season or at the beginning of the next wet season. Metacercariae encyst on plants under water, such as rice plants, and can survive for up to 4 months on stored plants, such as rice straw.

Treatment: The drugs and dose rates given for the treatment of *F. hepatica* are also generally applicable for the treatment of *F. gigantica*. Triclabendazole is effective against both mature and immature stages of *F. gigantica* in cattle.

Control: The principles are the same as for the control of *F. hepatica* and are based on the routine use of anthelmintics together with measures to reduce populations of the snail intermediate host. However, there is the important difference that the latter are water snails whose control depends on a different approach from that for the mud snail *G. (Lymnaea) truncatula*.

Routine anthelmintic treatment of animals at seasons when heavy infections of adult flukes accumulate in the host is recommended

using a drug effective against adult and immature flukes. This should prevent serious losses in production, but for optimal benefit should be accompanied by snail control.

When watering of stock is from a reservoir or stream, complete control can be achieved by fencing the water source and leading a pipe to troughs. To do this effectively from streams, the water may require to be pumped and in remote areas simple water-driven pumps whose power source depends on the water flow have been found useful. It is important that the water troughs be cleaned out regularly since they can become colonised by snails.

Where grazing depends on the dry-season use of marshy areas around receding lakebeds, snail control is difficult. Molluscicides are usually impractical because of the large body of water involved and their possible effect on fish, which may form an important part of the local food supply. Apart from repeated anthelmintic treatment to prevent patency of acquired infections of *F. gigantica*, there is often little one can do. Ideally, such areas are often best suited to irrigation and the growing of cash crops, the profit from which can be used to improve the dry-season food and water supply to cattle.

Fascioloides magna

Common name: Large American liver fluke

Predilection site: Liver and bile ducts

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description, gross: Flukes are large and thick and measure up to 10 by 2.5 cm. The flukes are oval, with a rounded posterior end. They possess no anterior cone and when fresh are flesh-coloured (Fig. 8.23).

Figure 8.23 *Fascioloides magna*.

Description, microscopic: Eggs are large, operculate, measure 109–168 by 75–96 µm and have a protoplasmic appendage at the pole opposite the operculum.

Final hosts: Deer, cattle, sheep, goat, pig, horse, llama

Intermediate hosts: A variety of freshwater snails, *Fossaria* spp., *Lymnaea* spp., *Stagnicola* spp.

Geographical distribution: Mainly occurs in North America, central, eastern and southwestern Europe, South Africa and Mexico

Pathogenesis: In deer and cattle, the flukes are frequently encapsulated in thin-walled fibrous cysts in the liver parenchyma and this restricted migration results in low pathogenicity. In cattle and pigs the flukes may become entrapped in a thick-walled fibrous capsule and there is no connection to the bile ducts and consequently it is rare to find fluke eggs in faeces in these livestock. Sometimes flukes can also be found in calcified cysts. Although haemorrhage and fibrosis may be present in the liver, there is often no obvious clinical sign of infection.

Clinical signs: In deer and cattle the parasites can cause hepatic damage on reaching the liver but the flukes rapidly become encapsulated by the host reaction and clinical signs are minimal.

Diagnosis: This is based primarily on clinical signs, and history of contact with grazing deer in known endemic areas. Cysts and the large flukes are usually seen on postmortem examination. Faecal examination for the presence of fluke eggs is a useful aid to diagnosis.

Pathology: In cattle and pigs, thick-walled cysts with fibrous capsules or calcified cysts may be present in the liver.

Epidemiology: The various snail intermediate hosts tend to occur in stagnant semi-permanent water that contains large amounts of dead or dying vegetation, swamp areas, or pools and streams. *Fascioloides magna* is indigenous to North America and is common in Canada and the Great Lake areas where the white-tailed deer and the elk are commonly infected. Domestic cattle and sheep become infected when they graze pasture where parasitised deer occur.

Treatment: For cattle and sheep the commonly used flukicides, such as triclabendazole, closantel, clorisulon and albendazole, are effective. Mature *F. magna* are susceptible to oxcyclosanide.

Control: Avoid grazing sheep or cattle on areas which are frequented by deer. Elimination of the snail intermediate hosts is difficult due to their varied habitats. Similarly, removal of Cervidae may not be practical. Because of these factors sheep rearing, particularly, is difficult in areas where the parasite is prevalent.

Notes: *Fascioloides magna* is primarily a parasite of deer (Cervidae) and is commonly found in white-tailed deer, elk and moose. For more details see Chapter 14.

Dicrocoelium dendriticum

Synonym: *Dicrocoelium lanceolatum*

Common name: Small lanceolate fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Dicrocoeliidae

Description, gross: There is no possibility of confusion with other flukes in the bile ducts of ruminants as *Dicrocoelium* is 0.6–1.0 cm long and 1.5–2.5 mm wide, distinctly lanceolate and semi-transparent. The oral sucker is smaller than the ventral sucker (see Fig. 1.74).

Description, microscopic: The gut is simple, consisting of two branches and resembles a tuning fork. Behind the ventral sucker the testes lie in tandem with the ovary immediately posterior. There are no spines on the cuticle (cf. *Fasciola*). The thick-shelled egg is small, 35–45 µm in length by 22–30 µm in width, dark brown with small round poles and slightly barrel-shaped walls and operculate, usually with a flattened side. The operculum is often difficult to see. It contains a miracidium that completely fills the egg when passed in the faeces.

Final hosts: Sheep, goat, cattle, deer and rabbit, occasionally horse, dog and pig

Intermediate hosts: Two are required.

- 1 Land snails of many genera, principally *Cionella lubrica* in North America and *Zebrina detrita* in Europe. Some 29 other species have been reported to serve as first intermediate hosts, including the genera *Abida*, *Theba*, *Helicella* and *Xerophila*.
- 2 Brown ants of the genus *Formica*, frequently *F. fusca*.

Geographical distribution: Worldwide except for South Africa and Australia. In Europe the prevalence is high but in the British Isles prevalence is low, being confined to small foci throughout the country.

For more information on pathogenesis, epidemiology, treatment and control see Chapter 9.

Dicrocoelium hospes

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Dicrocoeliidae

Hosts: Cattle, ox and occasionally sheep, goat

Description: Details are essentially similar to *D. dendriticum* and the flukes are usually found in the liver and gallbladder.

Geographical distribution: Parts of Africa

Gigantocotyle explanatum

Synonyms: *Explanatum explanatum*, *Paramphistomum explanatum*

Predilection site: Liver, intrahepatic ductules, bile ducts, gallbladder, duodenum

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Description, gross: These are conical pinkish flukes when fresh. Adult flukes are 8–10 mm in length by 4.7–5.7 mm in width.

Description, microscopic: The body tapers anteriorly and is curved ventrally with no tegumental papillae. The acetabulum is very large and the genital pore is bifurcal. The oval eggs measure 180–200 by 110–130 µm, are colourless and have an operculum.

Final hosts: Cattle, buffalo and other ruminants

Intermediate hosts: Snails

Geographical distribution: Indian subcontinent, Southeast Asia, tropical and subtropical regions of the Middle East and Africa

Pathogenesis: Large numbers of immature flukes can cause amphistomosis with enteritis that in some cases, particularly young buffaloes, can be fatal to the host. The flukes can cause connective tissue proliferation and haemorrhages at the site of attachment.

Clinical signs: General wasting of body condition, diarrhoea and loss of weight.

Pathology: There is extensive fibrosis and hyperplasia of the bile ducts and multifocal granulomatous nodules occur over their luminal surface.

***Echinococcus granulosus*, *Echinococcus orteleppi* (G5)**

Common names: Dwarf dog tapeworm, hydatidosis

Predilection site: Mainly liver and lungs (intermediate hosts); small intestine (definitive hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: Hydatid cysts are large fluid-filled vesicles, 5–10 cm in diameter, with a thick concentrically laminated cuticle and an internal germinal layer.

Description, microscopic: The germinal layer produces numerous small vesicles or brood capsules each containing up to 40 scolices, invaginated into their neck portions and attached to the wall by stalks. Brood capsules may become detached from the wall of the vesicle and float freely in the vesicular fluid and form ‘hydatid sand’.

Final hosts: Dog and many wild canids

Intermediate hosts: Cattle (G5), sheep, camel, pig, buffalo, deer, human

Geographical distribution: Worldwide

Notes: *Echinococcus granulosus* possesses a high degree of genetic divergence and various strains (G1–G10) have been described that show differences in morphology, host range, pathogenicity and geographical distribution. *Echinococcus orteleppi* (the former cattle strain G5) is now recognised as an individual species.

For more details on pathology, treatment and control see Chapter 9.

Stilesia hepatica

Predilection site: Bile ducts

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description: The adult tapeworm measures 20–50 cm long by 2–3 mm wide. The neck is narrow and the scolex is large with prominent suckers. The genital organs are single and the opening pores alternate irregularly. There are 10–12 testes on either side lying dorsal to the ventral canal. The proglottids are short.

Final hosts: Sheep, cattle and other ruminants

Intermediate hosts: The intermediate host is probably an oribatid mite.

Geographical distribution: Africa and Asia

For more details see Chapter 9.

Taenia hydatigena

Synonyms: *Taenia marginata*, *Cysticercus tenuicollis*

Predilection site: Abdominal cavity, liver (intermediate hosts); small intestine (definitive hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description: The semi-transparent cysticercus may be up to 5–7 cm in size and contains a watery fluid and invaginated scolex with a long neck.

Final hosts: Dog, fox, weasel, stoat, polecat, wolf, hyena

Intermediate hosts: Sheep, cattle, deer, pig, horse

Geographical distribution: Worldwide

Notes: The correct nomenclature for the intermediate host stage is the ‘metacestode stage of *Taenia hydatigena*’ rather than ‘*Cysticercus tenuicollis*’.

For more details see Chapter 9.

Thysanosoma actinioides

For more details see Parasites of the small intestine.

Parasites of the pancreas

Eurytrema pancreaticum

Synonyms: *Distoma pancreaticum*, *Eurytrema ovis*

Common name: Pancreatic fluke

Predilection site: Pancreatic ducts, rarely the bile ducts

Phylum: Platyhelminthes

Class: Trematoda

Family: Dicrocoeliidae

Description, gross: Oval, leaf-shaped, reddish-brown flukes measuring around 8–16 by 5–8.5 mm.

Description, microscopic: The body is thick and the juvenile flukes are armed with spines, which are often absent by the adult stage. The oral sucker is larger than the ventral sucker and the pharynx and oesophagus are short. The testes are positioned horizontally just behind the ventral sucker. A tubular cirrus sac is present. The uterus completely occupies the posterior body. Eggs measure around 40–50 by 25–35 μm and are similar to those of *Dicrocoelium*.

Final hosts: Cattle, buffalo, sheep, goat, pig, camel and human

Intermediate hosts: Two are required:

- 1 Land snails, particularly of the genus *Bradybaena*.
- 2 Grasshoppers of the genus *Conocephalus* or tree crickets (*Oecanthus*).

Geographical distribution: South America, Asia and Europe

Pathogenesis: Low to moderate infections produce little effect on the host. Heavy infections may cause a sporadic wasting syndrome and emaciation.

Clinical signs: No specific signs but general weight loss may occur in heavy infections.

Diagnosis: Usually reported as an incidental finding at necropsy.

Pathology: Large numbers of flukes can cause dilation and thickening of the pancreatic ducts and extensive fibrosis. Flukes may also be embedded in the pancreatic parenchyma causing chronic interstitial pancreatitis and there is sometimes a granulomatous reaction around fluke eggs that have penetrated the walls of the ducts.

Epidemiology: Infection is influenced by the availability of the invertebrate intermediate hosts.

Treatment: There is no specific treatment for eurytrematosis, although praziquantel 20 mg/kg for 2 days or albendazole 7–10 mg/kg have been reported to be effective.

Control: This is not feasible where the intermediate hosts are endemic.

Eurytrema coelomaticum

Synonym: *Distoma coelomaticum*

Common name: Pancreatic fluke

Predilection site: Pancreatic ducts and occasionally the bile ducts and the duodenum

Phylum: Platyhelminthes

Class: Trematoda

Family: Dicrocoeliidae

Description, gross: A leaf-shaped reddish-brown fluke with adults measuring around 8–12 by 6–7 mm.

Geographical distribution: Eastern Asia and South America

Details of the life cycle, host range, pathogenesis, clinical signs, diagnosis, pathology, epidemiology, treatment and control are as for *E. pancreaticum*.

Thysanosoma actinioides

For more details see Parasites of the small intestine.

Parasites of the circulatory system

Elaeophora poeli

Common name: Large aortic filariosis

Predilection site: Blood vessels

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Slender worms, males measuring around 4–7 cm and females up to 30 cm in length.

Description, microscopic: There are no lips and the oesophagus is very long. The tail of the male bears five to seven pairs of papillae, two pairs being pre-cloacal. Microfilariae are 340–360 μm .

Final hosts: Cattle, buffalo, zebu

Intermediate hosts: Not known, possibly tabanid flies

Geographical distribution: Parts of Africa, Asia and the Far East

Pathogenesis: In cattle, nodules, from which the female worms protrude, form on the intima of the vessels but in other animals the adults appear to provoke little reaction.

Clinical signs: Infection is usually asymptomatic.

Diagnosis: This is not normally required. Infection is usually diagnosed as an incidental finding on postmortem examination of thickened blood vessels, or those containing nodules.

Pathology: The main affected area is the thoracic region of the aorta. In light infections, the lesions are found chiefly on the dorsal wall of the aorta, near the openings of the intercostal arteries. In heavy infections, the artery becomes swollen, the wall is thickened and the intima contains fibrous tracts. The raised nodules can measure up to 1 cm in diameter.

Epidemiology: Because of the innocuous nature of the infection in cattle, the distribution of the species in these hosts is not completely known.

Treatment: Treatment is not indicated.

Control: Any reduction in vector numbers will reduce transmission.

Onchocerca armillata

Common name: Aortic filariosis

Predilection site: Aorta

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Slender whitish worms. Male worms are about 7 cm and female worms up to 70 cm long.

Description, microscopic: Microfilariae are unsheathed and measure 346–382 μm .

Final hosts: Cattle, buffalo, sheep, goat, rarely camel

Intermediate hosts: Midges (*Culicoides*), blackflies (*Simulium*)

Geographical distribution: Africa, Middle East, India

Pathogenesis: It is interesting that *O. armillata*, though occurring in a strategically important site in the bovine aorta, is not usually associated with clinical signs. It is usually only discovered at the abattoir, surveys in the Middle East having shown a prevalence as high as 90%.

Clinical signs: Infection is usually inapparent.

Diagnosis: Typical nodular lesions may be found in the wall of the aorta on postmortem examination. Microfilariae may also be found in skin biopsy samples taken from affected areas. The piece of skin is placed in warm saline and teased to allow emergence of the microfilariae, and is then incubated for about 8–12 hours. The microfilariae are readily recognised by their sinuous movements in a centrifuged sample of the saline. Another option is to scarify the skin of a predilection site and examine the fluid exudate for microfilariae.

Pathology: *Onchocerca armillata* is found in grossly visible nodules in the intima, media and adventitia of the aorta (Fig. 8.24), and atheromatous plaques are commonly seen on the intima. In chronic infections, the aortic wall is thickened and the intima shows tortuous tunnels with numerous nodules containing yellow caseous fluid and coiled worms. Aortic aneurysms have been noted in about one-quarter of infections.

Epidemiology: Prevalence is very high; in some regions 80–90% of animals are infected.

Treatment: Rarely indicated. Daily administration of diethylcarbamazine over a period of 21 days acts as a microfilaricide, and a single dose of ivermectin is highly efficient in this respect, although the dying microfilariae may provoke local tissue reactions.

Figure 8.24 *Onchocerca armillata* within the aorta.

Control: With the ubiquity of the insect vectors there is little possibility of efficient control, though the use of microfilaricides will reduce the numbers of infected flies. In any case, with the relatively innocuous nature of the infection there is unlikely to be any demand for control.

Schistosomes

Schistosomes are flukes found in the circulatory system in which the sexes are separate, the small adult female lying permanently in a longitudinal groove, the gynaecophoric canal, in the body of the male. The genus has been divided into four groups – *haematobium*, *indicum*, *mansoni* and *japonicum* – but the genus as currently defined is paraphyletic so revisions are likely.

Haematobium group

Schistosoma bovis

Common name: Blood fluke, bilharziosis

Predilection site: Portal and mesenteric veins, urogenital veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The sexes are separate; the males are 9–22 mm long and 1–2 mm wide, and the female 12–28 mm long. The suckers and the body of the male behind the suckers are armed with minute spines, while the dorsal surface of the male bears small cuticular tubercles. The slender female worm lies permanently in a ventral groove in the broad flat body of the male.

Description, microscopic: The eggs are usually spindle-shaped, but smaller eggs may be oval and have a mean measurement of 187 by 65 µm when passed in the faeces. There is no operculum.

Final hosts: Cattle, sheep, goat, camel

Intermediate hosts: Snails (*Bulinus contortus*, *B. truncatus*, *Physopsis africana*, *P. nasuta*)

Geographical distribution: Africa, Middle East, southern Asia, southern Europe

Pathogenesis: The young flukes cause some damage during migration but most serious damage is caused by the irritation produced by the parasite eggs in the intestine and the blood-sucking habit of the worms. Acute disease is characterised by diarrhoea and anorexia due to the response to deposition of eggs in the mesenteric veins and their subsequent infiltration in the intestinal mucosa. The presence of the worms in veins of the bladder in cattle may cause damage to the bladder wall and haematuria.

Clinical signs: These are diarrhoea, sometimes blood-stained and containing mucus, anorexia, thirst, anaemia and emaciation. In cattle, the presence of the worms in the vesical veins may cause haematuria.

Diagnosis: This is based mainly on the clinicopathological picture of diarrhoea, wasting and anaemia, coupled with a history of access to natural water sources. The relatively persistent diarrhoea, often blood-stained and containing mucus, may help to differentiate this syndrome from fasciolosis.

The demonstration of the characteristic eggs in the faeces or in squash preparations of blood and mucus from the faeces is useful in the period following patency but less useful as egg production drops in the later stages of infection.

In general, when schistosomosis is suspected, diagnosis is best confirmed by a detailed postmortem examination which will reveal the lesions and, if the mesentery is stretched, the presence of numerous schistosomes in the veins. In epidemiological surveys, serological tests may be of value.

Pathology: At necropsy during the acute phase of the disease there are marked haemorrhagic lesions in the mucosa of the intestine, but as the disease progresses the wall of the intestine appears greyish, thickened and oedematous due to confluence of the egg granulomas and the associated inflammatory changes. The liver may be larger than normal, depending on the stage of the disease, and may be markedly cirrhotic in long-standing infections. On microscopic examination there is pigmentation of the liver and numerous eggs may be found, surrounded by cellular infiltration and fibrous tissue. The spleen may be slightly swollen and lymph glands are usually pigmented.

Epidemiology: The epidemiology is totally dependent on water as a medium for infection of both the intermediate and final host. Small streams, irrigation canals, wet savannah and marshy or damp areas are the main snail habitats. Eggs, miracidia and cercariae are short-lived with seasonal transmission directly related to rainfall and temperature. The fact that percutaneous infection may occur encourages infection where livestock are obliged to wade in water. In cattle, high prevalence is usually associated with low numbers of worms, although worm burdens increase with age while egg excretion declines markedly in animals above 2 years of age due to the development of partial immunity.

Treatment: For economic reasons, chemotherapy is not suitable for the control of schistosomosis in domestic stock except during severe clinical outbreaks. Care has to be exercised in treating clinical cases of schistosomosis since the dislodgement of the damaged flukes may result in emboli being formed and subsequent occlusion of major mesenteric and portal blood vessels with fatal consequences. Older drugs still used in some areas are the antimonial preparations tartar emetic, antimosan and stibophen, and niridazole and trichlorphon, all of which have to be given over a period of days at high dosage rates. Fatalities associated with the use of these drugs are not uncommon. Praziquantel, which is the drug of choice for treatment of human schistosomosis, is also effective in ruminants at 15–20 mg/kg *per os* but may be cost-prohibitive.

Control: This is similar to that outlined for *F. gigantica* and *Paramphistomum* infections. Since the prevalence of snail populations varies according to temperature, local efforts should be made to identify the months of maximum snail population, and cattle movements planned to avoid their exposure to dangerous stretches of water at these times.

When watering of stock is from a reservoir or stream, fencing the water source and leading a pipe to troughs can achieve control. To do this effectively from streams, the water may require to be pumped and in remote areas simple water-driven pumps whose power source depends on the water flow have been found useful. It is important that the water troughs be cleaned out regularly since they can become colonised by snails.

When grazing depends on the dry-season use of marshy areas around receding lakebeds, snail control is difficult. Molluscicides are usually impractical because of the large body of water involved and their possible effect on fish, which may form an important part

of the local food supply. Apart from repeated anthelmintic treatment to prevent patency of acquired infections of *Schistosoma*, there is often little one can do. Ideally, such areas are often best suited to irrigation and the growing of cash crops, the profit from which can be used to improve the dry-season food and water supply to cattle.

Schistosoma mattheei

Predilection site: Portal, mesenteric and bladder veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The sexes are separate; the males are 9–22 mm long and 1–2 mm wide, and the females 12–28 mm long. The suckers and the body of the male behind the suckers are armed with minute spines, while the dorsal surface of the male bears small cuticular tubercles.

Description, microscopic: The eggs passed in faeces are usually spindle-shaped, but smaller ones may be oval. They measure 170–280 by 72–84 μm . There is no operculum.

Final hosts: Cattle, sheep, goat, camel, rodents, human

Intermediate hosts: Snails (*Bulinus* and *Physopsis* spp.)

Geographical distribution: South and Central Africa, Middle East

Notes: Thought to be synonymous with *S. bovis* but differs on morphological and pathological grounds and is restricted to the alimentary canal.

Schistosoma leiperi

Predilection site: Mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: Similar to *S. spindale*. The eggs are large and resemble those of *S. spindale*, measuring 240–300 by 40–60 μm .

Final hosts: Antelope, cattle

Intermediate hosts: Snails (*Bulinus*)

Geographical distribution: Africa

Indicum group

Schistosoma indicum

Predilection site: Portal, pancreatic, hepatic and mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The sexes are separate; the males measure 5–19 mm and the females 6–22 mm in length.

Description, microscopic: The eggs are oval with a terminal spine and measure 57–140 by 18–72 μm .

Final hosts: Cattle, sheep, goat, horse, donkey, camel, buffalo

Intermediate hosts: Snails (*Indoplanorbis*)

Geographical distribution: India

Schistosoma nasale

Common name: Snoring disease

Predilection site: Veins of nasal mucosa

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The sexes are separate; the male, which is broad and flat and about 6–11 mm long, carries the female (5–11 mm) in the hollow of its inwardly curved body. The flukes closely resemble *S. spindale*.

Description, microscopic: The eggs measure 350–380 by 50–80 μm and are boomerang-shaped, with a terminal spine.

Final hosts: Cattle, goat, sheep, buffalo, horse

Intermediate hosts: Snails (*Lymnaea luteola*, *L. acuminata*, *Indoplanorbis exustus*)

Geographical distribution: India, Pakistan, Southeast Asia

Pathogenesis: In heavy infections there is a copious mucopurulent discharge, snoring and dyspnoea. The main pathogenic effects are associated with the eggs, which cause abscess formation in the mucosa. Fibrous granulomatous growths occur which may occlude the nasal passages.

Clinical signs: Coryza, sneezing, dyspnoea and snoring

Diagnosis: Infection is confirmed by the presence of the spindle-shaped eggs in the nasal discharge.

Pathology: The mucosa of the nasal sinuses is studded with small abscesses that contain the eggs of the worms, and later show much fibrous tissue and proliferating epithelium (Fig. 8.25).

Figure 8.25 *Schistosoma nasale* lesions in nasal mucosa.

Epidemiology: The epidemiology is totally dependent on water as a medium for infection of both the intermediate and final host.

Treatment and control: As for *S. bovis*

Several other *Schistosoma* species have been reported in cattle. Details on the life cycle, pathogenesis, epidemiology, treatment and control are essentially similar to those for *S. bovis*.

Schistosoma spindale

Predilection site: Mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The sexes are separate, with the male, which is broad and flat and measures up to about 1.5 cm in length, carrying the female in the hollow of its inwardly curved body.

Description, microscopic: The eggs are spindle-shaped, measure 200–300 by 70–90 μm and have a lateral or terminal spine. There is no operculum.

Hosts: Cattle, buffalo, horse, pig and occasionally dog

Geographical distribution: Parts of Asia and the Far East

Japonicum group

Schistosoma japonicum

Common name: Blood fluke, bilharziosis

Predilection site: Portal and mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The sexes are separate; the male, which is broad and flat and 9.5–20 mm long, carries the female (12–26 mm long) in the hollow of its inwardly curved body. The suckers lie close together near the anterior end. The cuticle is spiny on the suckers and in the gynaecophoric canal. This characteristic and the vascular predilection site are sufficient for generic identification.

Description, microscopic: The eggs are short, oval, measuring 70–100 by 50–80 μm , and may have a small lateral subterminal spine. There is no operculum.

Final hosts: Cattle, horse, sheep, goat, dog, cat, rabbit, pig, rodents, human

Intermediate hosts: Snails belonging to the genus *Oncomelania*

Geographical distribution: South and East Asia

Pathogenesis: The penetration of the cercariae through the skin causes dermatitis, which is evident about 24 hours after infection. Passage through the lungs may cause pneumonia in gross infections and abdominal organs such as the liver may become congested during the early stages of the disease due to the arrival of immature

worms in the intrahepatic portal blood vessels. The most serious damage is caused by the adult parasites in the egg-laying stage due to the irritation caused by eggs lodged in the tissues, which are forced to find their way through small venules to the epithelium and lumen of the gut. The masses of eggs become surrounded by inflamed areas and an infiltration of leucocytes, particularly eosinophils, gives rise to a rather characteristic type of abscess. The abscesses in the intestinal wall usually burst, discharging their contents into the lumen of the gut and eventually heal forming scar tissue. In the liver the abscesses become encapsulated and eventually become calcified, a large number of such foci leading to liver enlargement, cirrhosis and ascites.

Acute disease, characterised by diarrhoea and anorexia, occurs 7–8 weeks after heavy infection and is entirely due to the inflammatory and granulomatous response to the deposition of eggs in the mesenteric veins and their subsequent infiltration in the intestinal mucosa. Following massive infection death can occur rapidly, but more usually the clinical signs abate slowly as the infection progresses. As this occurs, there appears to be a partial shift of worms away from the intestinal mucosa and reactions to these migrating parasites and their eggs can occur in the liver.

Schistosomosis is generally considered to be a much more serious and important infection in sheep than in larger ruminants, and even where a high prevalence of the parasite is detected in slaughtered cattle, clinical signs of the disease are seen only rarely. In sheep, anaemia and hypoalbuminaemia have been shown to be prominent during the clinical phase apparently as a result of mucosal haemorrhage, dyshaemopoiesis and an expansion in plasma volume. The significance of low-level infection is not known, but it has been suggested that this may have a considerable effect on productivity.

There is experimental evidence of acquired resistance to reinfection by homologous species and, from natural infections, that resistance may develop as a result of prior exposure to a heterologous species.

Pathology: This is similar to that seen in *S. bovis*. Scar tissue and frequent papillomatous growths may be seen on the intestinal mucosa. On sections of the liver there is also evidence of egg granulomas and of portal fibrosis provoked by eggs which have inadvertently been swept into small portal vessels. The mesentery, mesenteric lymph nodes and spleen are frequently altered due to the presence of abnormal amounts of connective tissue.

Details of the clinical signs, diagnosis, epidemiology, treatment and control are as for *S. bovis*.

Other schistosomes

Schistosoma turkestanica

Synonym: *Orientobilharzia turkestanicum*

Predilection site: Mesenteric veins and small veins of the pancreas and liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: This is a small species, the male measuring 4.2–8 mm and the female 3.4–8 mm in length.

Description, microscopic: The spirally coiled ovary is positioned in the anterior part of the body. In the male there are around 70–80 testes. The female uterus is short and contains only one egg at a time, which measures 72–77 by 16–26 μm with a terminal spine and a short appendage at the opposite end.

Final hosts: Cattle, buffalo, sheep, goat, camel, horse, donkey, mule and cat

Intermediate hosts: Snail (*Lymnaea euphratica*)

Geographical distribution: Asia, Middle East and parts of Europe

Pathogenesis: Of little significance in cattle but can produce marked debility in sheep and goats, causing hepatic cirrhosis and nodules in the wall of the intestines. This is often accompanied by loss of body weight in small ruminants.

Trypanosomes

Members of the genus *Trypanosoma* are haemoflagellates of overwhelming importance in cattle in sub-Saharan Africa as a cause of trypanosomosis. See Chapter 2 for general descriptions.

Salivarian trypanosomes

A number of species of *Trypanosoma*, found in domestic and wild animals, are all transmitted cyclically by *Glossina* in much of sub-Saharan Africa. The presence of trypanosomosis precludes the rearing of livestock in many areas, while in others where the vectors are not so numerous trypanosomosis is often a serious problem, particularly in cattle. The disease, sometimes known as nagana, is characterised by lymphadenopathy and anaemia accompanied by progressive emaciation and, often, death.

Pathogenesis: The signs and effects of the various trypanosomes found in domestic animals are more or less similar. The pathogenesis of trypanosomosis may be considered under three headings.

- 1 Lymphoid enlargement and splenomegaly** develop. This is associated with plasma cell hyperplasia and hypergammaglobulinaemia, which is primarily due to an increase in IgM. Concurrently there is a variable degree of suppression of immune responses to other antigens such as microbial pathogens or vaccines. Ultimately, in infections of long duration, the lymphoid organs and spleen become shrunken due to exhaustion of their cellular elements.
- 2 Anaemia** is a cardinal feature of the disease, particularly in cattle, and initially is proportional to the degree of parasitaemia. Anaemia is caused mainly by extravascular haemolysis through erythrophagocytosis in the mononuclear phagocytic systems of the spleen, liver and lungs, but as the disease becomes chronic there may be decreased haemoglobin synthesis. Leucopenia and thrombocytopenia are caused by mechanisms that predispose leucocytes and platelets to phagocytosis. Immunological mechanisms in the pathogenesis lead to extensive proliferation of activated macrophages, which engulf or destroy erythrocytes, leucocytes, platelets and haematopoietic cells. Later, in infections of several months' duration, when the parasitaemia often becomes low and intermittent, the anaemia may resolve to a variable degree. However, in some chronic cases it may persist despite chemotherapy.

3 Cell degeneration and inflammatory infiltrates occur in many organs, such as the skeletal muscle and the central nervous system (CNS), but perhaps most significantly in the myocardium where there is separation and degeneration of the muscle fibres. The mechanisms underlying these changes are still under study.

Clinical signs: In cattle, the major signs are anaemia, generalised enlargement of the superficial lymph glands (Fig. 8.26), lethargy and progressive loss of bodily condition. Fever and loss of appetite occur intermittently during parasitaemic peaks, the latter becoming marked in the terminal stages of the disease. Typically, the disease is chronic, extending over several months, and usually terminates fatally if untreated. As a herd phenomenon, the growth of young animals is stunted while adults show decreased fertility, and if pregnant may abort or give birth to weak offspring. In the terminal stages, animals become extremely weak, the lymph nodes are reduced in size and there is often a jugular pulse. Death is associated with congestive heart failure due to anaemia and myocarditis. Occasionally, the disease is acute, death occurring within 2–3 weeks of infection preceded by fever, anaemia and widespread haemorrhages.

Diagnosis: The clinical signs of the disease, although indicative, are not pathognomonic. Confirmation of clinical diagnosis depends on the demonstration of trypanosomes in the blood. If a herd or flock is involved, a representative number of blood samples should be examined, since in individual animals the parasitaemia may be in remission or in long-standing cases may be extremely scanty. Occasionally, when the parasitaemia is massive it is possible to detect motile trypanosomes in fresh films of blood. More usually, both thick and thin smears of blood are air-dried and examined later. Thick smears, de-haemoglobinised before staining with Giemsa or Leishman's stain, offer a better chance of finding trypanosomes, while the stained thin smears are used for differentiation of the trypanosome species.

More sensitive techniques utilise centrifugation in a microhaematocrit tube followed by microscopic examination of the interface between the buffy coat and the plasma; alternatively, the tube may be snapped, the buffy coat expressed onto a slide, and the contents examined under dark-ground or phase-contrast microscopy for motile trypanosomes. With these techniques, the PCV is also obtained which is of indirect value in diagnosis if one can eliminate other causes of anaemia, especially helminthosis.

Figure 8.26 Enlarged prescapular lymph node of Zebu with trypanosomiasis.

A number of serological tests have been described and include the indirect fluorescent antibody test and ELISA and have been partially validated but require further evaluation and standardisation.

Pathology: The carcass is often pale and emaciated and there may be oedematous swellings in the lower part of the abdomen and genital organs with serous atrophy of fat. The liver, lymph nodes and spleen are enlarged and the viscera are congested. Petechiae may appear on lymph nodes, pericardium and intestinal mucosa. The liver is hypertrophic and congested with degeneration and necrosis of the hepatocytes, dilation of blood vessels and parenchymal infiltration of mononuclear cells. A non-suppurative myocarditis, sometimes associated with hydropericarditis, has been reported accompanied by degeneration and necrosis of the myocardial tissue. Other lesions can include glomerulonephritis, renal tubular necrosis, non-suppurative meningo-encephalomyelitis, focal poliomyelitis, keratitis, ophthalmitis, orchitis, interstitial pneumonia and bone marrow atrophy. Splenic and lymph node hypertrophy occur during the acute phase but the lymphoid tissues are usually exhausted and fibrotic in the chronic stage.

Epidemiology: The vectors are various species of *Glossina* including *G. morsitans*, *G. palpalis*, *G. longipalpis*, *G. pallidipes* and *G. austeni*. *Trypanosoma congolense* can also be transmitted mechanically by other biting flies in tsetse-free areas, although this is uncommon. Since the life cycle of *T. vivax* is short, it is more readily transmitted than other species and mechanical transmission of *T. vivax* by tabanids allows it to spread outside the tsetse belt. The disease can also be transmitted mechanically through contaminated needles and instruments.

The epidemiology depends on three factors: the distribution of the vectors, virulence of the parasite and the response of the host.

- **The vectors.** Of the three groups of tsetse flies (see *Glossina*), the savannah and riverine are the most important since they inhabit areas suitable for grazing and watering. Although the infection rate of *Glossina* with trypanosomes is usually low, ranging from 1 to 20% of the flies, each is infected for life, and their presence in any number makes the rearing of cattle, pigs and horses extremely difficult. Biting flies may act as mechanical vectors, but their significance in Africa is still undefined.
- **The parasites.** Since parasitaemic animals commonly survive for prolonged periods, there are ample opportunities for fly transmission. Perhaps the most important aspect of trypanosomiasis which accounts for the persistent parasitaemia is the way in which the parasite evades the immune response of the host. As noted previously, metacyclic and bloodstream trypanosomes possess a glycoprotein coat which is antigenic and provokes the formation of antibodies that cause opsonisation and lysis of the trypanosomes. Unfortunately, by the time the antibody is produced, a proportion of the trypanosomes have altered the chemical composition of their glycoprotein coat and now, displaying a different antigenic surface, are unaffected by the antibody. Those trypanosomes possessing this new **variant antigen** multiply to produce a second wave of parasitaemia; the host produces a second antibody, but again the glycoprotein coat has altered in a number of trypanosomes so that a third wave of parasitaemia occurs. This process of **antigenic variation** associated with waves and remissions of parasitaemias, often at weekly intervals, may continue for months, usually with a fatal outcome. The repeated switching of the glycoprotein coat is now known to depend on a loosely ordered sequential expression of an undefined number of

Figure 8.27 Trypanotolerant N'Dama breed of West Africa.

genes, each coding for a different glycoprotein coat. This, together with the finding that metacyclic trypanosomes may be a mixture of antigenic types, each expressing a different genetic repertoire, explains why domestic animals, even if treated successfully, are often immediately susceptible to reinfection. The complexity of antigens potentially involved has also defeated attempts at vaccination.

- **The hosts.** Trypanosomosis is basically an infection of wildlife in which, by and large, it has achieved a *modus vivendi* in that the animal hosts are parasitaemic for prolonged periods but generally remain in good health. This situation is known as **trypanotolerance**. In contrast, rearing of domestic livestock in endemic areas has always been associated with excessive morbidity and mortality, although there is evidence that a degree of adaptation or selection has occurred in several breeds. Thus in West Africa, small humpless cattle of the *Bos taurus* type, notably the N'Dama, survive and breed in areas of heavy trypanosome challenge despite the absence of control measures (Fig. 8.27). However, their resistance is not absolute and trypanosomosis exacts a heavy toll, particularly in productivity. In other areas of Africa, indigenous breeds of sheep and goats are known to be trypanotolerant, although this may be partly due to their being relatively unattractive hosts for *Glossina*. Precisely how trypanotolerant animals cope with antigenic variation is unknown. It is thought that the control and gradual elimination of their parasitaemias may depend on the possession of a particularly rapid and effective antibody response, although other factors may also be involved.

Trypanosoma brucei brucei

Common name: Nagana

Predilection site: Blood. *Trypanosoma brucei brucei* is also found extravascularly in, for example, the myocardium, CNS and reproductive tract.

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Trypanozoon*

Figure 8.28 Trypomastigotes of *Trypanosoma brucei*.

Description: *Trypanosoma brucei brucei* is pleomorphic in form and ranges from long and slender, up to 42 μm (average 29 μm), to short and stumpy, 12–26 μm (mean 18 μm), the two forms often being present in the same blood sample. The undulating membrane is conspicuous, the kinetoplast is small and subterminal and the posterior end is pointed. In the slender form the kinetoplast is up to 4 μm from the posterior end, which is usually drawn out, tapering almost to a point, and has a well-developed free flagellum; in the stumpy form the flagellum is either short or absent and the posterior end is broad and rounded with the kinetoplast almost terminal. Intermediate forms average 23 μm long and have a blunt posterior end and moderately long flagellum (Fig. 8.28; see also Fig. 2.6). A fourth form with a posterior nucleus may be seen in laboratory animals. In fresh unfixed blood films, the organism moves rapidly within small areas of the microscope field.

Hosts: Cattle, horse, donkey, zebu, sheep, goat, camel, pig, dog, cat, wild game species, particularly antelope

Geographical distribution: Approximately 10 million km^2 of sub-Saharan Africa between latitudes 14° N and 29° S.

Pathogenesis: In *T. brucei brucei* infections, the disease is usually more chronic in cattle and animals may survive for several months and may recover.

Treatment: The two drugs in common use are isometamidium and diminazene aceturate. These are usually successful except where trypanosomes have developed resistance to the drug or in some very chronic cases. Treatment should be followed by surveillance since reinfection, followed by clinical signs and parasitaemia, may occur within a week or two. Alternatively, the animal may relapse after chemotherapy, due to a persisting focus of infection in its tissues or because the trypanosomes are drug resistant.

Notes: Antelope are the natural host species and are reservoirs of infection for domestic animals. Horses, mules and donkeys are very susceptible, and the disease is very severe in sheep, goats, camels and dogs (see respective hosts).

Other subspecies of *T. brucei* – *T. brucei evansi* and *T. brucei equiperdum* – are described separately under their respective subspecies and definitive hosts.

Two other subspecies, *T. brucei gambiense* and *T. brucei rhodesiense*, are important causes of 'sleeping sickness' in humans.

Trypanosoma brucei evansi

Synonyms: *Trypanosoma evansi*, *Trypanosoma equinum*

Common names: Surra, el debab, mbori, murrina, mal de Caderas, doukane, dioufar, thaga

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Trypanozoon*

Hosts: Horse, donkey, camel, cattle, zebu, goat, pig, dog, water buffalo, elephant, capybara, tapir, mongoose, ocelot, deer and other wild animals. Many laboratory and wild animals can be infected experimentally.

Geographical distribution: North Africa, Central and South America, central and southern Russia, parts of Asia (India, Burma, Malaysia, southern China, Indonesia, Philippines)

Pathogenesis: Domestic species such as cattle, buffalo and pigs are commonly infected, but overt disease is uncommon and their main significance is as reservoirs of infection.

Treatment and control: Suramin or quinapyramine (Trypacide) are the drugs of choice for treatment and also confer a short period of prophylaxis. For more prolonged protection a modified quinapyramine known as Trypacide Pro-Salt is also available. Unfortunately, drug resistance, at least to suramin, is not uncommon.

Notes: The original distribution of this parasite coincided with that of the camel, and is often associated with arid deserts and semi-arid steppes.

For more details see Chapter 10.

Trypanosoma congolense

Common names: Nagana, paranagana, Gambia fever, ghindi, gobial

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Nannomonas*

Description: *Trypanosoma congolense* is small, monomorphic in form and 8–20 µm long. The undulating membrane is inconspicuous, the medium-sized kinetoplast is marginal and the posterior end is blunt. There is no free flagellum (Fig. 8.29; see also Fig. 2.5). In fresh blood films the organism moves sluggishly, often apparently attached to red cells.

Hosts: Cattle, sheep, goat, horse, camel, dog, pig. Reservoir hosts include antelope, giraffe, zebra, elephant and warthog.

Geographical distribution: Widely distributed in tropical Africa between latitudes 15° N and 25° S.

Figure 8.29 Trypomastigotes of *Trypanosoma congolense*.

Pathogenesis: With *T. congolense*, there are many strains which differ markedly in virulence. In cattle, the parasite can cause an acute fatal disease resulting in death in about 10 weeks, a chronic condition with recovery in about 1 year, or a mild almost asymptomatic condition. The signs caused by this species are similar to those caused by other trypanosomes, but the CNS is not affected.

Treatment and control: In infected cattle, the two drugs in common use are diminazene aceturate (Berenil) and homidium salts (Ethidium and Novidium). As with *T. brucei*, these drugs are usually successful except where trypanosomes have developed resistance to the drug or in some very chronic cases.

Additional comments made for treatment and control of *T. brucei* infections equally apply to *T. congolense*.

Notes: *Trypanosoma congolense congolense* is the most important trypanosome of cattle in tropical Africa. The African disease nagana is caused by *T. congolense*, often in mixed infection with *T. brucei* and *T. vivax*.

Trypanosoma vivax

Common names: Nagana, souma

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Duttonella*

Description: *Trypanosoma vivax* is monomorphic, ranging from 20 to 27 µm. The undulating membrane is inconspicuous, the large kinetoplast is terminal and the posterior end is broad and rounded. A short free flagellum is present (Fig. 8.30; see also Fig. 2.4). In fresh blood films, *T. vivax* moves rapidly across the microscope field.

Hosts: Cattle, sheep, goat, camel, horse; antelope and giraffe are reservoirs.

Geographical distribution: Central Africa, West Indies, Central and South America (Brazil, Venezuela, Bolivia, Colombia, Guyana, French Guiana), Mauritius

Figure 8.30 Tryptomastigotes of *Trypanosoma vivax*.

Pathogenesis: *Trypanosoma vivax* is most important in cattle. Generally, strains of *T. vivax* in West Africa are more pathogenic than ones in East Africa, except for one strain in East Africa that causes acute haemorrhagic disease which is very pathogenic.

Treatment: As for *T. congolense*

Notes: There are three subspecies.

- *Trypanosoma vivax vivax* causes the disease souma in Africa and is found in mixed infections with *T. congolense* and *T. brucei*.
- *Trypanosoma vivax viennei* occurs in the New World and is transmitted by horse flies. This subspecies occurs in cattle, horses, sheep and goats in northern South America, Central America, West Indies and Mauritius.
- *Trypanosoma vivax uniforme* is similar to *T. vivax vivax* but is smaller, 12–20 μm long (mean 16 μm). It occurs in cattle, sheep, goats and antelopes in Uganda and Zaire, causing a disease similar to that of *T. vivax vivax*.

Salivarian trypanosomosis control This currently depends on the control of tsetse flies, discussed under Tsetse flies (*Glossina* spp.) in Chapter 17, and on the use of drugs (Table 8.5).

In cattle, and if necessary in sheep and goats, isometamidium is the drug of choice since it remains in the tissues and has a prophylactic effect for 2–6 months. Otherwise, diminazene may be used as cases arise, these being selected either by clinical examination or on the haematological detection of anaemic animals. To reduce the possible development of drug resistance it may be advisable periodically to change from one trypanocidal drug to another. To further enhance the effective use of trypanocidal drugs, they may be used as ‘sanative’ pairs and treatment restricted to individual clinically affected animals.

Table 8.5 Drugs used in the treatment and control of Nagana in cattle.

| Drug | Recommended dose | Comments |
|---------------------------------------|-------------------|---|
| Diminazene aceturate | 3–10 mg/kg i.m. | <i>T. brucei</i> , <i>T. congolense</i> , <i>T. vivax</i> |
| Isometamidium | 0.25–1 mg/kg i.m. | <i>T. brucei</i> , <i>T. congolense</i> , <i>T. vivax</i> Local reaction |
| Homidium bromide Homidium chloride | 1 mg/kg s.c. | <i>T. congolense</i> , <i>T. vivax</i> Prophylaxis for 6 weeks |
| Pyrididium bromide | 2–2.5 mg/kg | <i>T. congolense</i> , <i>T. vivax</i> Prophylaxis for 4 months |

Two important aspects of control are:

- the necessity to protect cattle from a tsetse-free zone while being trekked to market through an area of endemic trypanosomosis;
- an awareness of the dangers of stocking a tsetse-free ranch with cattle from areas where trypanosomosis is present, as mechanical transmission may cause an outbreak of disease.

In both cases treatment with a trypanocidal drug at an appropriate time is advisable.

An alternative approach, using trypanotolerant breeds of ruminants, perhaps combined with judicious drug therapy, may in the future offer a realistic solution in many areas where the disease is endemic and this aspect is currently under intensive study.

Stercorarian trypanosomes

These are relatively large trypanosomes found in the blood of cattle, with faecal transmission by tabanid flies (*Tabanus*, *Haematopota*).

Trypanosoma theileri

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: Megatrypanum

Description: Large trypanosome, 60–70 μm in length, although may be up to 120 μm with posterior end long and pointed (Fig. 8.31; see also Fig. 2.7). There is a medium-sized kinetoplast with a prominent undulating membrane and a free flagellum. Both trypomastigote and epimastigote forms may appear in the blood.

Hosts: Cattle

Geographical distribution: Worldwide

Pathogenesis: Infection produces transient parasitaemias, but is generally considered to be non-pathogenic. Under conditions of stress it may cause abortion and even death.

Clinical signs: Infections are usually asymptomatic.

Figure 8.31 Tryptomastigotes of *Trypanosoma theileri*.

Diagnosis: Can only be usually diagnosed by incubating blood in culture medium suitable for the multiplication of trypanosomes.

Epidemiology: *Trypanosoma theileri* is transmitted by tabanid flies (*Tabanus*, *Haematopota*); the worldwide distribution of the trypanosome corresponds to the range and prevalence of its intermediate hosts. The metacyclic trypomastigotes, present in the faeces of the vector, gain access to the blood of their mammalian host by penetrating abraded skin, by contamination of mucous membranes, or following ingestion of the vector when the liberated trypanosomes penetrate the mucosa. Intrauterine infection has been reported.

Treatment and control: Not usually required, although general fly control measures may help limit potential transmission from tabanid flies.

Notes: Often referred to as a ‘non-pathogenic trypanosome’.

Babesiosis

Babesia are intraerythrocytic parasites of domestic animals and are transmitted by ticks. Babesiosis is particularly severe in naive cattle introduced into endemic areas and is a considerable constraint on livestock development in many parts of the world.

Epidemiology: The epidemiology of the bovine *Babesia* species depends on the interplay of a number of factors.

- 1 The virulence of the particular species of *Babesia*. *Babesia bigemina* and *B. bovis* in tropical and subtropical regions are highly pathogenic, *B. divergens* in northern Europe is relatively pathogenic, while *B. major* produces only mild and transient anaemia.
- 2 The age of the host. It is frequently stated that there is an inverse age resistance to *Babesia* infection in that young animals are less susceptible to babesiosis than older animals. The reason for this is not known.
- 3 The immune status of the host. In endemic areas, the young animal first acquires immunity passively, in the colostrum of the dam and, as a result, often suffers only transient infections with mild clinical signs. However, these infections are apparently sufficient to stimulate active immunity, although recovery is followed by a long period during which they are carriers when, although showing no clinical signs, their blood remains infective to ticks for many months. It used to be thought that this active immunity was dependent on the persistence of the carrier state and the phenomenon was termed ‘preimmunity’. However, it seems unlikely that this is the case since it is now known that such animals may lose their infection either naturally or by chemotherapy, but still retain a solid immunity.
- 4 The level of tick challenge. In endemic areas, where there are many infected ticks, the immunity of the host is maintained at a high level through repeated challenge and overt disease is rare. In contrast, where there are few ticks or when they are confined to limited areas, the immune status of the population is low and the young animals receive little if any colostrum protection. If, in these circumstances, the number of ticks suddenly increase due to favourable climatic conditions or to a reduction in dipping frequency, the incidence of clinical cases may rise sharply. This situation is known as enzootic instability.
- 5 Stress. In endemic areas, the occasional outbreak of clinical disease, particularly in adult animals, is often associated with some form of stress, such as parturition or the presence of another disease, such as tick-borne fever.

Babesia bigemina

Common name: Texas fever

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: *Babesia bigemina* is a large pleomorphic babesia but characteristically is seen and identified by the pear-shaped bodies joined at an acute angle within the mature erythrocyte (Fig. 8.32). Round forms measure 2 µm and the pear-shaped elongated ones 4–5 µm.

Hosts: Cattle, buffalo

Geographical distribution: Australia, Africa, North, Central and South America, Asia and southern Europe

Pathogenesis: The rapidly dividing parasites in the red cells produce rapid destruction of the erythrocytes with accompanying haemoglobinuria, haemoglobinuria and fever.

Generally, *B. bigemina* infections are not as virulent as those of *B. bovis*, despite the fact that the parasites may infect 40% of the red cells. Otherwise the disease is typically biphasic, the acute haemolytic crisis, if not fatal, being followed by a prolonged period of recovery.

Clinical signs: Calves are relatively resistant to infection and do not usually show clinical disease. In older animals, clinical signs can be very severe; however, differences in pathogenicity may occur with various *B. bigemina* isolates associated with different geographical areas. The first sign is usually a high fever with rectal temperatures reaching 41.5°C (106.7°F). There is anorexia and ruminal atony. Often the first visible appearance of infection is that the animal isolates itself from the herd, becomes uneasy, seeks shade and may lie down. Cattle may stand with an arched back, have a roughened hair coat and show evidence of dyspnoea and tachycardia. The mucous membranes are first inflamed and reddened, but as erythrocytic lysis occurs they become pallid and show signs of anaemia. Anaemia is a contributory factor to the weakness and loss of condition seen in cattle that survive the acute phase of the disease. The anaemia may occur very rapidly, with 75% or more of the erythrocytes being

Figure 8.32 Intraerythrocytic stages of *Babesia bigemina*.

destroyed in just a few days. This is usually associated with severe haemoglobinaemia and haemoglobinuria. After onset of fever, the crisis will usually pass within a week, and if the animal survives there is usually severe weight loss, drop in milk production, possible abortion and a protracted recovery. Mortality is extremely variable and may reach 50% or higher, but in the absence of undue stress most animals will survive.

Diagnosis: As for *B. bovis*.

Pathology: Acute infections as for *B. bovis*. In cattle that have suffered a more prolonged illness, acute lesions are much less conspicuous. Subepicardial petechial haemorrhages may be present, the carcass is usually emaciated and icteric, the blood is thin and watery, the intermuscular fascia is oedematous, the liver yellowish-brown, and the bile may contain flakes of semi-solid material. The kidneys are pale and often oedematous, and the bladder may contain normal urine, depending on how long after the haemolytic crisis the necropsy is performed. Although the spleen is enlarged, the pulp is firmer than in acute babesiosis.

Epidemiology: *Rhipicephalus (Boophilus) annulatus*, *Rhipicephalus (Boophilus) microplus* and *Rhipicephalus (Boophilus) decoloratus* are the principal vectors of *B. bigemina*. Mechanical transmission is possible, but it is not efficient enough to maintain infection in the absence of specific tick vectors.

Treatment: As with *B. bovis*, successful treatment of *B. bigemina* depends on early diagnosis and the prompt administration of effective drugs. If medication is administered early, success is the rule, for there are several effective compounds. One of the first successful treatments was trypan blue. This treatment may be used to determine the type of infection present: *B. bigemina* is susceptible to trypan blue treatment, whereas *B. bovis* is not. Generally, the small babesias are more resistant to chemotherapy. The most commonly used compounds for treatment are diminazene diaceturate (3–5 mg/kg), imidocarb (1–3 mg/kg) and amicarbalide (5–10 mg/kg); however, the quinuronium and acridine derivatives are also effective where these are available. Treatment of *B. bigemina* is so effective in some instances that radical cures occur that will eventually leave the animal susceptible to reinfection. For this reason, reduced drug levels are sometimes indicated. Imidocarb has been successfully used as a chemoprophylactic that will prevent clinical infection for as long as 2 months, but will allow mild subclinical infection to occur as the drug level wanes resulting in premunition and immunity.

Control: Specific control measures are not usually necessary for animals born of mothers in endemic areas, since their colostrum-acquired immunity is gradually reinforced by repeated exposure to infection. Indeed, the veterinary importance of babesiosis is chiefly that it acts as a constraint to the introduction of improved livestock from other areas. Areas of enzootic instability also create problems when tick numbers suddenly increase or animals, for some reason, are forced to use an adjacent tick-infested area.

Immunisation, using blood from carrier animals, has been practised for many years in tropical areas, and more recently in Australia; rapidly passaged strains of *Babesia*, which are relatively non-pathogenic, have been widely utilised in live vaccines. In the near future, these may be superseded by adjuvanted vaccines prepared from several recombinant *Babesia* antigens. Otherwise the control of babesiosis in susceptible animals introduced into endemic areas depends on surveillance for the first few months after their arrival and, if necessary, treatment.

Vaccination of cattle against *B. bigemina* infection is commonly practised in many countries by inoculating blood from donor animals. This is usually obtained from a recently recovered case, any untoward reactions in the 'vaccinates' being controlled by babesicidal drugs. In Australia, the procedure is more sophisticated in that the vaccine is produced from acute infections produced in splenectomised donors. For economy, the blood is collected by exchange transfusion rather than by exsanguination. It is interesting that the rapid passage of the parasite by blood inoculation in splenectomised calves has fortuitously had the very desirable effect of decreasing the virulence of the infection in non-splenectomised calves to the extent that post-vaccination surveillance of cattle is frequently not performed. The parasite count of the blood determines the dilution of the latter, which is dispensed in plastic bags, packed in ice and despatched in insulated containers. Each dose of vaccine contains about 10 million parasites. Most of the vaccine is used in cattle under 12 months of age living in conditions of enzootic instability. The degree of protection induced is such that only 1% of vaccinated cattle subsequently develop clinical babesiosis from field challenge, compared with 18% of unvaccinated cattle.

The primary disadvantage of red cell vaccines is their lability and the fact that unless their preparation is carefully supervised, they may spread diseases such as enzootic bovine leucosis. Obviously there will be no such problem with a vaccine based on recombinant antigens.

A regimen of four injections of long-acting oxytetracycline at weekly intervals, administered to naive cattle during their first month of grazing on tick-infested pastures, has been shown to confer prophylaxis against *B. bigemina* during this period, after which the cattle were immune to subsequent challenge.

Notes: *Babesia bigemina*, a large babesia, is of particular interest historically since it was the first protozoan infection of humans or animals demonstrated to have an arthropod intermediate host. This was shown in 1893 by Smith and Kilborne while investigating the cause of the locally known 'Texas fever' in cattle in the USA. The disease has since been eradicated in that country.

Babesia bovis

Synonym: *Babesia argentina*

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: *Babesia bovis* is a small pleomorphic babesia, typically identified as a single body, as small round bodies, or as paired pear-shaped bodies joined at an obtuse angle within the centre of the mature erythrocyte. The round forms measure 1–1.5 µm and the pear-shaped bodies 1.5 by 2.4 µm in size. Vacuolated signet ring forms are especially common.

Hosts: Cattle, buffalo, deer

Geographical distribution: Australia, Africa, Central and South America, Asia and southern Europe

Pathogenesis: *Babesia bovis* is generally regarded as the most pathogenic of the bovine babesia. Although the classical signs of

fever, anaemia and haemoglobinuria occur, the degree of anaemia is disproportional to the parasitaemia since haematocrit levels below 20% may be associated with infections of less than 1% of the red cells. The reason for this is unknown. In addition, *B. bovis* infection is associated with sludging of the red cells in the small capillaries. In the cerebrum this causes blockage of the vessels by clumps of infected red cells, leading to anoxia and tissue damage. The resulting clinical signs of aggression, incoordination or convulsions and depression are invariably fatal. Finally, recent work has indicated that some of the severity of *B. bovis* infection may be associated with the activation of certain plasma components, leading to circulatory stasis, shock and intravascular coagulation.

Clinical signs: Incoordination, convulsions, depression, death

Diagnosis: The history and clinical signs of fever, anaemia, jaundice and haemoglobinuria in cattle located in enzootic areas where *Rhipicephalus (Boophilus)* ticks occur are usually sufficient to justify a diagnosis of babesiosis. For confirmation, the examination of blood films stained with Giemsa will reveal the parasites in the red cells. However, once the acute febrile phase has subsided they are often impossible to find since they are rapidly removed from the circulation. In addition, a technique of brain biopsies has been described that has proven very useful in detecting and diagnosing *B. bovis* infections. The characteristic low parasitaemias in the circulating blood make this technique very useful in improving the chances of seeing the organism. There is a marked concentration of infected erythrocytes in the capillaries of the brain.

From each animal six blood smears should be made, air-dried and fixed in methanol and/or a sample of whole blood in an anticoagulant and serum should be collected. In cases of chronic infection, diagnosis is usually made using a variety of serological tests for the detection of specific antibodies, since the organism disappears or is present in extremely low numbers soon after the acute infection. Presently, immunofluorescence assay is the test of choice in the serologic diagnosis of *B. bovis*.

Other conditions that should be considered and which may resemble babesiosis are anaplasmosis, trypanosomosis, theileriosis, leptospirosis, bacillary haemoglobinuria, haemobartonellosis and eperythrozoonosis.

Pathology: At necropsy, the carcass is pale and jaundiced and the lungs may be oedematous and congested in cattle that have died early in the course of infection. The pericardial sac may contain serosanguineous fluid and subepicardial and subendocardial petechial haemorrhages. The liver is enlarged and icteric, and the gallbladder, which may have haemorrhage on the mucous surface, is distended with thick dark-green bile. The spleen is markedly enlarged, and has a dark pulpy consistency. The abomasal and intestinal mucosa may be icteric with patches of subserosal haemorrhages (Fig. 8.33). The blood is thin and watery. The urinary bladder is frequently distended, with dark reddish-brown urine. Jaundice is commonly distributed in the connective tissue. The lymph nodes are oedematous and often have petechiation.

Epidemiology: *Babesia bovis* is transmitted by the same ticks that transmit *B. bigemina*, i.e. *Rhipicephalus (Boophilus) annulatus* and *Rhipicephalus (Boophilus) microplus*. The tick *Rhipicephalus (Boophilus) decoloratus*, which is widely distributed in Africa, does not appear to transmit *B. bovis* even though it readily transmits *B. bigemina*. There are reports from Europe of *B. bovis*, for which the vector is thought to be *Ixodes ricinus*.

Figure 8.33 Postmortem findings with *Babesia bovis* infections.

Treatment: Successful treatment depends on early diagnosis and the prompt administration of effective drugs. There is less likelihood of success if treatment is delayed until the animal has been weakened by fever and anaemia. Chemotherapy is generally effective, although *B. bovis* is usually somewhat more difficult to treat than other *Babesia* species, and a second treatment, or slightly increased dose rates, may be desirable. The most commonly used compounds for the treatment of babesiosis are diminazene diaceturate (3–5 mg/kg), imido-carb (1–3 mg/kg) and amicarbalide (5–10 mg/kg); however, the quinuronium and acridine derivatives are also effective where these are available. Trypan blue is not effective against *B. bovis*.

Control: The numbers of ticks and therefore the quantum of *Babesia* infection may be reduced by regular spraying or dipping with acaricides. In addition, the selection and breeding of cattle which acquire a high degree of resistance to ticks is practised, particularly in Australia. Widespread use of tick vaccines may also have a significant influence on the incidence of infection in cattle (see control of *B. bigemina*).

Repeated passage of *B. bovis* in splenectomised calves results in the attenuation of the organism and for many years this attenuated vaccine has been produced and successfully used in Australia for the prevention of *B. bovis*. In some cattle (older, and producing dairy cows), chemotherapy may be indicated, but usually the vaccine may be used without treatment.

The development of *in vitro* techniques for the cultivation of *B. bovis* on bovine erythrocytes has led to the isolation of soluble antigens which, when combined with adjuvants, have proven immunogenic. Although they do not prevent infection, these non-infectious vaccines appear to be responsible for moderating the effects of infection. They do not produce as high a level of protection as seen with premunising vaccines but are safe and do not yield carriers. In some instances, these vaccines, although protective against homologous challenge, may not protect against immunological variants. The continuous *in vitro* passage of *B. bovis* has been shown to induce a level of attenuation similar to that seen with passage of the organism in splenectomised calves and infection with this attenuated organism has been reported to prevent clinical infection following a challenge with virulent *B. bovis*. The primary disadvantage of red cell vaccines is their lability and the fact that, unless their preparation is carefully supervised, they may spread diseases such as enzootic bovine leucosis. Obviously there will be no such problem with a vaccine based on recombinant antigens.

Babesia divergens

Common name: Redwater fever

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: Examination of stained blood films shows the organisms to be within red cells, almost always singly or as pairs, often arranged at a characteristic angle with their narrow ends opposed. Typically, they are pyriform, but may be round, elongated or cigar-shaped. *Babesia divergens* is a 'small babesia' and in blood films typically appears as paired, widely divergent organisms, 1.5 by 0.4 μm , lying near the edge of the red cell (see Fig. 2.31). Other forms may be present measuring 2 by 1 μm , some are circular up to 2 μm in diameter and a few may be vacuolated.

Hosts: Cattle

Geographical distribution: Northern Europe

Pathogenesis: The rapidly dividing parasites in the red cells produce rapid destruction of the erythrocytes with accompanying haemoglobinuria, haemoglobinuria and fever. This may be so acute as to cause death within a few days, during which the PCV falls below 20%. The parasitaemia, which is usually detectable once the clinical signs appear, may involve between 0.2 and 45% of the red cells. Milder forms of the disease, associated with relatively resistant hosts, are characterised by fever, anorexia and perhaps slight jaundice for a period of several days.

Clinical signs: Typically the acute disease occurs 1–2 weeks after the tick commences to feed and is characterised by fever and haemoglobinuria ('redwater'). The mucous membranes, at first congested, become jaundiced, the respiratory and pulse rates are increased, the heartbeat is usually very audible, and in cattle ruminal movements cease and abortion may occur. If untreated, death commonly occurs in this phase. Otherwise, convalescence is prolonged, there is loss of weight and milk production and diarrhoea followed by constipation is common. In animals previously exposed to infection, clinical signs may be mild or even inapparent.

Diagnosis: The history and clinical signs are usually sufficient to justify a diagnosis of babesiosis. For confirmation, the examination of blood films stained with Giemsa will reveal the parasites in the red cells (Fig. 8.34). However, once the acute febrile phase has subsided they are often impossible to find since they are rapidly removed from the circulation.

Pathology: At necropsy, the carcass is pale and jaundiced, the bile is thick and granular and there may be subepicardial and subendocardial haemorrhages.

Epidemiology: *Babesia divergens* is transmitted by *Ixodes ricinus*, and is widespread and pathogenic, with clinical cases occurring during the periods of tick activity, primarily in the spring and autumn. Infection in the tick is transovarially transmitted and the larvae, nymphs and adults of the next generation are all able to transmit infection to cattle.

Treatment: Amicarbalide, diminazene aceturate and imidocarb are the most commonly used drugs. Recently, long-acting preparations

Figure 8.34 Intraerythrocytic stages of *Babesia divergens*.

of oxytetracycline have been shown to have a prophylactic effect against *B. divergens* infection. Imidocarb, due to its persistence in the tissues, has a prophylactic effect for several weeks. During the convalescent phase of the disease, blood transfusions may be valuable as are drugs designed to stimulate food and water intake.

Control: Normally no effort is made to control this infection in endemic areas, although cattle recently introduced require surveillance for some months since, on average, one in four will develop clinical disease and of these one in six will die if untreated. However, in some parts of mainland Europe, such as the Netherlands, where ticks are confined to rough vegetation on the edge of pastures and on roadsides, it is often possible to take evasive measures. It is thought that red and roe deer are not important reservoir hosts since only mild infections have been experimentally produced in splenectomised deer.

Notes: Since 1957, several cases of fatal babesiosis due to *B. divergens* infection have occurred in humans in the former Yugoslavia, Russia, Ireland and Scotland. In each case, the individual had been splenectomised sometime previously or was currently undergoing immunosuppressive treatment.

Babesia major

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: A 'large babesia', with pyriform bodies 2.6 by 1.5 μm , being characteristically paired at an acute angle less than 90° and found in the centre of the erythrocyte (Fig. 8.35). Round forms about 1.8 μm in diameter may form.

Hosts: Cattle

Geographical distribution: Europe, North Africa, South America

Pathogenesis: *Babesia major* is only mildly pathogenic.

Clinical signs: Clinical signs with *B. major* are usually inapparent but where symptoms do occur these are characterised by a

Figure 8.35 Intraerythrocytic stages of *Babesia major*.

haemolytic syndrome with elevated temperature, mild anaemia and haemoglobinuria.

Diagnosis: Examination of blood films stained with Giemsa will reveal the parasites in the red cells.

Epidemiology: *Babesia major* is transmitted by the three-host tick *Haemaphysalis punctata*.

Treatment: Not usually required but amicarbalide, diminazene aceturate and imidocarb are effective.

Control: Specific control measures are not usually necessary for animals born of mothers in endemic areas since, as noted previously, their colostrally acquired immunity is gradually reinforced by repeated exposure to infection. Tick numbers may be reduced by regular spraying or dipping with acaricides. The control of infection in susceptible animals introduced into endemic areas depends on surveillance for the first few months after their arrival and, if necessary, treatment.

Other species of *Babesia* in cattle

See Table 8.6.

Theileriosis

Diseases caused by several species of *Theileria* (theileriosis) are a serious constraint to livestock production in Africa, Asia and the Middle East. The parasites, which are tick transmitted, undergo repeated merogony in the lymphocytes ultimately releasing small merozoites that invade the red cells to become piroplasms.

Table 8.6 Other species of *Babesia* in cattle.

| Species | Hosts | Vectors | Distribution |
|--------------------------|--|------------------------------------|---------------------------|
| <i>Babesia jakimovi</i> | Cattle, deer (roe deer, elk, reindeer) | <i>Ixodes ricinus</i> | Northern Europe (Siberia) |
| <i>Babesia ovata</i> | Cattle | <i>Hyalomma longicornis</i> | Japan, China |
| <i>Babesia occultans</i> | Cattle | <i>Hyalomma marginatum rufipes</i> | Southern Africa |

Theileria are widely distributed in cattle in Africa, Asia, Europe and Australia, have a variety of tick vectors and are associated with infections which range from clinically inapparent to rapidly fatal. Although the speciation of many *Theileria* is still controversial, largely because of their morphological similarity, there are two species of major veterinary importance in cattle. Minor and mildly pathogenic species infecting cattle include *T. velifera* and *T. taurotragi* in Africa, *T. mutans* and the *T. sergenti/orientalis/buffeli* complex.

Theileria parva

Subspecies: *Theileria parva parva*, *Theileria parva lawrencei*

Common name: East Coast fever, corridor fever

Predilection site: Blood and lymphatics

Phylum: Apicomplexa

Class: Aconoidasida

Family: Theileriidae

Description: Trophozoite forms in the erythrocyte are predominantly rod-shaped ($1.5\text{--}2.0 \times 0.1\text{--}1.0 \mu\text{m}$), but may also be round, oval and comma-shaped (Fig. 8.36). Koch bodies are present in the lymphocytes and endothelial cells of the spleen or lymph nodes where they are very numerous and average $8 \mu\text{m}$ but can range up to $12 \mu\text{m}$ or more. Two types have been described: macroschizonts containing chromatin granules $0.4\text{--}2.0 \mu\text{m}$ in diameter (Fig. 8.37), these dividing further to become microschizonts that contain chromatin granules $0.3\text{--}0.8 \mu\text{m}$ in diameter and produce merozoites $0.7\text{--}1 \mu\text{m}$ in diameter.

Hosts: Cattle, buffalo

Geographical distribution: East and Central Africa

Pathogenesis: The sequence of events in a typical acute and fatal infection progresses through three phases, each spanning about 1 week. The first is the incubation period of about 1 week when neither parasite nor lesions can be detected. This is followed during the second week by marked hyperplasia and expansion of the infected lymphoblast population, initially in the regional lymph node draining the site of the tick bite and ultimately throughout the body. During the third week, there is a phase of lymphoid depletion and disorganisation

Figure 8.36 Intraerythrocytic stages of *Theileria parva*.

Figure 8.37 Macroscopic forms of *Theileria parva* in a smear of a lymph node.

associated with massive lymphocytolysis and depressed leucopoiesis. The cause of the lymphocytolysis is unknown, but is due perhaps to the activation of natural killer cells like macrophages.

Theileria parva lawrencei is transmitted from the African buffalo and becomes indistinguishable in its behaviour from *T. parva parva* following several passages in cattle.

Clinical signs: About 1 week after infection, in a fully susceptible animal, the lymph node draining the area of tick bite, usually the parotid, becomes enlarged and the animal becomes pyrexia (40–41.7°C, 104–107°F). Within a few days there is generalised swelling of the superficial lymph nodes, ears, eyes and submandibular regions. The animal becomes anorexic, shows decreased milk production and rapidly loses condition, ceases rumination, becomes weak with a rapid heartbeat, and petechial haemorrhages may occur under the tongue and on the vulva. Affected animals become emaciated and dyspnoeic and there is terminal diarrhoea, often blood-stained. Recumbency and death almost invariably occur, usually within 3 weeks of infection. Occasionally nervous signs, the so-called ‘turning sickness’, have been reported and attributed to the presence of meronts in cerebral capillaries.

Milder infections show a mild fever lasting 3–7 days, listlessness and swelling of superficial lymph nodes.

Diagnosis: East Coast fever only occurs where *R. appendiculatus* is present, although occasionally outbreaks outwith such areas have been recorded due to the introduction of tick-infected cattle from an enzootic area. In sick animals, macroscopic forms are readily detected in biopsy smears of lymph nodes and in dead animals in impression smears of lymph nodes and spleen. In advanced cases, Giemsa-stained blood smears show piroplasms in the red cells, up to 80% of which may be parasitised.

The indirect fluorescent antibody test is of value in detecting cattle which have recovered from East Coast fever.

Pathology: Necropsy during the terminal phase shows lymph nodes to be swollen, with atrophy of the cellular content of the lymph nodes and variable hyperaemia. The spleen is usually enlarged with soft pulp and prominent Malpighian corpuscles. The liver is enlarged, friable, brownish-yellow, with parenchymatous degeneration. The kidneys are either congested or pale brown, with variable number of infarcts. The meninges may be slightly congested.

The heart is flabby, with petechiae on the epicardium and endocardium. The lungs are often congested and oedematous. There may be hydrothorax and hydropericardium, and the kidney capsule may contain a large amount of serous fluid. There may be petechiae in the visceral and parietal pleura, adrenal cortex, urinary bladder and mediastinum. There are characteristic ulcers 2–5 mm or more in diameter in the abomasum and small and large intestines. Peyer’s patches are swollen, and the intestinal contents yellowish.

Epidemiology: Since the tick vector, *Rhipicephalus appendiculatus*, is most active following the onset of rain, outbreaks of East Coast fever may be seasonal or, where rainfall is relatively constant, may occur at any time. Fortunately, indigenous cattle reared in endemic areas show a high degree of resistance and, although transient mild infection occurs in early life, mortality is negligible. The mechanism of this resistance is unknown. However, such cattle may remain carriers and act as a reservoir of infection for ticks. Susceptible cattle introduced into such areas suffer high mortality, irrespective of age or breed, unless rigid precautions are observed.

In areas where survival of the tick vector is marginal, challenge is low and indigenous cattle may have little immunity. Such areas, during a prolonged period of rain, may become ecologically suitable for the survival and proliferation of the ticks, ultimately resulting in disastrous outbreaks of East Coast fever. In some parts of East and Central Africa where populations of cattle and wild African buffalo overlap there is an additional epidemiological complication due to the presence of a strain of *T. parva* known as *T. parva lawrencei*. This occurs naturally in African buffalo, many of which remain as carriers. The tick vector is also *R. appendiculatus* and, in cattle, the disease causes high mortality. Since infected ticks may survive for nearly 2 years, physical contact between buffalo and cattle need not be close.

Treatment: Although the tetracyclines have a therapeutic effect if given at the time of infection, they are of no value in the treatment of clinical cases. The drugs of choice in clinical cases of East Coast fever are the naphthoquinone compounds parvaquone and buparvaquone and the anticoccidial drug halofuginone.

Control: Traditionally, the control of East Coast fever in areas where improved cattle are raised has relied on legislation to control the movement of cattle, on fencing to prevent access by nomadic cattle and buffalo and on repeated treatment of cattle with acaricides. In areas of high challenge, such treatments may require to be carried out twice weekly in order to kill the tick before the infective sporozoites develop in the salivary glands. This is not only expensive, but creates a population of fully susceptible cattle; if the acaricide fails, through human error or the acquisition of acaricide resistance by the ticks, the consequences can be disastrous.

Great efforts have been made to develop a suitable vaccine, but these have been thwarted by the complex immunological mechanisms involved in immunity to East Coast fever and by the discovery of immunologically different strains of *T. parva* in the field. However, an ‘infection and treatment’ regimen that involves the concurrent injection of a virulent stabilate of *T. parva* and long-acting tetracycline has been shown to be successful, although it has not been used on a large scale as yet. Apparently, the tetracycline slows the rate of schizogony, giving the immune response time to develop.

Notes: Because of the wide distribution of its tick vector, *Rhipicephalus*, and the fact that infection in cattle introduced into enzootic areas can be associated with a mortality of 100%, *T. parva* infection is an immense obstacle to livestock improvement.

Theileria annulata

Common names: Mediterranean theileriosis, Mediterranean Coast fever

Predilection site: Blood and lymphatics

Phylum: Apicomplexa

Class: Aconoidasida

Family: Theileriidae

Description: Trophozoite forms in the erythrocyte are predominantly round (0.5–2.7 μm) to oval ($2 \times 0.6 \mu\text{m}$), but may also be rod-shaped or comma-shaped ($1.2 \times 0.5 \mu\text{m}$). Division by binary fission may form two or four daughter cells, the latter in the shape of a cross. Koch bodies are present in the lymphocytes of the spleen or lymph nodes or even free in these organs. They average 8 μm but can be up to 27 μm . Two types have been described: macromeronts containing chromatin granules 0.4–1.9 μm in diameter, these dividing further to become micromeronts that contain chromatin granules 0.3–0.8 μm in diameter and produce merozoites 0.7–1 μm in diameter.

Hosts: Cattle, domestic buffalo

Geographical distribution: Mediterranean countries (Portugal and Spain, the Balkans), the Middle East, Indian subcontinent and China

Pathogenesis: The pathogenesis and clinical signs are initially similar to those of East Coast fever with pyrexia and lymph node enlargement, but in the late stages there is a haemolytic anaemia and often icterus. Convalescence is protracted in those cases that recover.

Clinical signs: In the acute form there is fever (40–41.7°C, 104–107°F), inappetence, cessation of rumination, rapid heartbeat, weakness, decreased milk production, swelling of superficial lymph nodes and eyelids, diarrhoea (containing blood and mucus), jaundice and petechial haemorrhages. Affected animals become emaciated and death can occur. In the more chronic form there is intermittent fever, inappetence, emaciation, anaemia and jaundice.

Diagnosis: Diagnosis depends on the detection of meronts in both lymph node biopsy specimens and, unlike *T. parva*, in blood smears. A low-grade piroplasm parasitaemia, in the absence of schizonts, is usually indicative of a recovered carrier animal.

Pathology: The lymph nodes are often but not always swollen; the spleen is often much enlarged and infarcts are usually present in the kidneys. The lungs are usually oedematous; characteristic ulcers are present in the abomasum and small and large intestines.

Epidemiology: *Theileria annulata* is transmitted transtadially by ticks of the genus *Hyalomma*: *H. detritum* in North Africa; *H. detritum* and *H. excavatum* in the former Soviet states; *H. truncatum* in parts of Africa; *H. dromedarii* in central Asia; *H. excavatum*, *H. turanicum* and *H. marginatum* in Asia Minor; *H. marginatum* in India; and *H. longicornis* in Siberia and the Far East. Like East Coast fever, indigenous cattle in endemic areas are relatively resistant while improved cattle, particularly European breeds, are highly susceptible. However, unlike East Coast fever, the disease in such cattle is not uniformly fatal, although the mortality rate may reach 70%.

Congenital infection can occur occasionally in calves.

Treatment: See under *T. parva*

Control: In many areas, the prevention of *T. annulata* infection in imported dairy stock is based on permanent housing. However, this is expensive and there is always the possibility that infected ticks may be brought in with the fodder to cause disease and colonise crevices in the cattle accommodation. In some countries immunisation with meronts attenuated by prolonged *in vitro* culture has given excellent results.

Theileria orientalis complex

Synonyms: *Theileria mutans*, *Theileria buffeli*, *Theileria sergenti*

Common name: Benign theileriosis

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Theileriidae

Description: Trophozoite forms in erythrocytes are round (1–2 μm diameter), oval ($1.5 \times 0.6 \mu\text{m}$), pyriform, or comma-shaped (Fig. 8.38). Binary fission produces two or four daughter cells. There are relatively few Koch bodies (8–20 μm) in the lymphocytes of the spleen and lymph nodes, which contain 1–80 chromatin granules (1–2 μm in diameter).

Hosts: Cattle, buffalo

Geographical distribution: Southern Europe, Middle East, Asia, Australia

Pathogenesis: Mildly pathogenic

Clinical signs: Similar in appearance to the mild form of *T. annulata* causing anaemia, with jaundice and lymphadenopathy occasionally present.

Diagnosis: Giemsa-stained blood smears may show piroplasms in the red cells, or macroschizonts may be detected in biopsy smears of lymph nodes.

Figure 8.38 Intraerythrocytic stages of *Theileria orientalis* (*mutans*).

Pathology: In acute cases the spleen and liver are swollen, the lungs may be oedematous and there are characteristic ulcers in the abomasum; infarcts may be present in the kidneys. Macroschizonts may also be found in impression smears of lymph nodes and spleen taken from dead animals.

Epidemiology: Vectors are *Amblyomma variegatum*, *A. cohaerens* and *A. hebraeum*. *Haemaphysalis bispinosa* and *H. bancrofti* are the probable vectors in Australia.

Treatment: Little information is available on treatment, although the drugs of choice in clinical cases are likely to be parvaquone and buparvaquone.

Control: Tick control methods may be considered including fencing and dipping or cleaning cattle of ticks but these are not usually required.

Notes: The taxonomy of benign theileriosis species is complicated and it is now considered that *T. orientalis* is part of a complex with *T. sergenti*, *T. buffeli* and *T. mutans*.

Theileria taurotragi

Synonym: *Cytauxzoon taurotragi*

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Theileriidae

Description: Erythrocytic forms are similar in appearance to *T. parva*. Trophozoite forms in the erythrocyte are predominantly round to oval, but may also be rod-shaped or comma-shaped ($1.2 \times 0.5 \mu\text{m}$).

Hosts: Cattle, antelope, particularly the eland (*Taurotragi oryx*)

Geographical distribution: Africa

Pathogenesis: Mildly pathogenic

Clinical signs: Mild transient fever and anaemia

Diagnosis: Presence of erythrocytic forms in blood smears or meronts in lymph node biopsy specimens. *Theileria taurotragi* is morphologically indistinguishable from more pathogenic forms, but generally differentiated on clinical signs and history.

Pathology: Meront stages have been reported in liver, lung and lymph nodes.

Epidemiology: Vectors are *R. appendiculatus* and *R. pulchellus*.

Treatment and control: Not usually required

Theileria velifera

Synonym: *Haematoxenus veliferus*

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Theileriidae

Description: Trophozoite forms in erythrocytes are pleomorphic and most often appear as small rods $1\text{--}2 \mu\text{m}$ long. The great majority have a rectangular 'veil' $1\text{--}3.5 \mu\text{m}$ extending out from the side.

Hosts: Cattle, zebu

Geographical distribution: Africa

Pathogenesis: Non-pathogenic

Clinical signs: Not reported

Diagnosis: Giemsa-stained blood smears may show the characteristic 'veiled' piroplasms in the red cells.

Pathology: No associated pathology

Epidemiology: Known vectors are *Amblyomma variegatum*, *A. lepidu* and *A. hebraeum*.

Treatment and control: Not usually required

Rickettsia

While the Rickettsia are now considered to be in the Kingdom Bacteria, for historical reasons they are included within parasitological texts and for this reason mention is made to some genera and species of importance in cattle.

Anaplasma marginale

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: In Giemsa-stained blood films the organisms of *A. marginale* are seen as small round dark-red 'inclusion bodies' approximately $0.3\text{--}1.0 \mu\text{m}$ within the red cell (Fig. 8.39). Often there is only one organism in a red cell and characteristically this lies at the outer margin; however, these two features are not constant.

Figure 8.39 Intraerythrocytic stages of *Anaplasma marginale*.

Hosts: Cattle, wild ruminants

Geographical distribution: Africa, southern Europe, Australia, South America, Asia, former Soviet states and USA

Pathogenesis: Typically, the changes are those of an acute febrile reaction accompanied by a severe haemolytic anaemia. After an incubation period of around 4 weeks, fever and parasitaemia appear, and as the latter develops the anaemia becomes more severe so that within a week or so up to 70% of the erythrocytes are destroyed. The clinical signs are usually very mild in naive cattle under 1 year old. Thereafter, susceptibility increases so that cattle aged 2–3 years develop typical and often fatal anaplasmosis, while in cattle over 3 years the disease is often peracute and frequently fatal.

Clinical signs: Clinical signs are attributed to severe anaemia and include depression, weakness, fever, laboured breathing, inappetance, dehydration, constipation and jaundice. The acute stage of the disease is characterised by fever (39.4–41.7°C, 103–107°F) that persists for 3–7 days. During the febrile phase there is decreased rumination, dryness of the muzzle, loss of appetite, dullness and depression. Lactating cows show a depression in milk yield and abortion is a common feature in advanced pregnancy. The severity of the disease increases with age, with animals over 3 years of age showing the peracute and possibly fatal disease.

Diagnosis: The clinical signs, supplemented if possible by haematocrit estimation and the demonstration of *Anaplasma* inclusions in the red cells, are usually sufficient for diagnosis. For the detection of immune carriers, complement fixation and agglutination tests are available; an indirect fluorescent antibody test and DNA probe have also been developed.

Pathology: Gross pathological lesions are those usually associated with anaemia. Mucous membranes are jaundiced and there is pallor of the tissues. The spleen is often greatly enlarged with enlarged splenic follicles. The liver may be enlarged with rounded borders. The gallbladder is enlarged and obstructed with dark thick bile. Petechiae may be observed on the epicardium, pericardium, pleura and diaphragm. The lymph glands are enlarged. Microscopically there is hyperplasia of the bone marrow. The spleen shows a decrease in lymphoblasts and increased vacuolation and degeneration of reticular cells and there is reduction of the white pulp and accumulation of pigment resembling haemosiderin.

Epidemiology: The organism is distributed throughout the tropics corresponding to the distribution of the main tick vectors, *Rhipicephalus* (*Boophilus*) *annulatus*, *Rhipicephalus* (*Boophilus*) *decoloratus* and *Rhipicephalus* (*Boophilus*) *microplus*. In the USA, the main tick vectors are *Dermacentor andersoni*, *D. occidentalis* and *D. variabilis*. Horse flies (Tabanidae), stable flies (*Stomoxys*), deer flies (*Chrysops*), horn flies and mosquitoes have also been incriminated as potential vectors. Reservoirs of infection are maintained in carrier cattle and in wild ruminants such as deer. Cattle, especially adults, introduced into endemic areas are particularly susceptible, the mortality rate being up to 80%. In contrast, cattle reared in endemic areas are much less susceptible, presumably due to previous exposure when young, although their acquired immunity usually coexists with a carrier state. This balance may, on occasions, be disturbed and clinical anaplasmosis supervenes when cattle are stressed by other diseases such as babesiosis.

Treatment: Tetracycline compounds are effective in treatment if given early in the course of the disease and especially before the

parasitaemia has reached its peak. More recently, imidocarb has been shown to be effective and may also be used to sterilise carrier animals.

Control: Vaccination of susceptible stock with small quantities of blood containing the mildly pathogenic *A. centrale* or a relatively avirulent strain of *A. marginale* is practised in several countries, any clinical signs in adults being controlled by drugs. In the USA, a killed *A. marginale* vaccine containing erythrocyte stroma is also available. Although all are generally successful in the clinical sense, challenged cattle become carriers and so perpetuate transmission. The killed vaccine has the disadvantage that antibodies produced to the red cell stroma, if transferred in the colostrum, may produce isoerythrolysis in nursing calves. Improved inactivated vaccines are currently under development. Otherwise, control at present depends largely on the reduction of ticks and biting flies.

Anaplasma centrale

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: As for *A. marginale*, except that the organisms are commonly found in the centre of the erythrocyte.

Hosts: Cattle, wild ruminants (and perhaps sheep may act as reservoirs of infection)

Geographical distribution: Worldwide in tropics and subtropics including southern Europe. It is also present in some temperate areas, including parts of the USA.

Pathogenesis: Similar to *A. marginale* but generally considered to be less pathogenic.

Clinical signs: The clinical features include pyrexia, anaemia and often jaundice, anorexia, laboured breathing and, in cows, a severe drop in milk yield or abortion. Occasionally peracute cases occur, which usually die within a day of the onset of clinical signs.

Pathology: Necropsy at this time often reveals a jaundiced carcass, a grossly enlarged gallbladder and, on section, a liver suffused with bile. The spleen and lymph nodes are enlarged and congested and there are petechial haemorrhages in the heart muscle. The urine, unlike that in babesiosis, is normal in colour. In survivors, recovery is prolonged.

Epidemiology: Apart from the various modes of transmission previously described, little information is available. Reservoirs of infection are maintained in carrier cattle and perhaps in wild ruminants or sheep. Cattle, especially adults, introduced into endemic areas are particularly susceptible, the mortality rate being up to 80%. In contrast, cattle reared in endemic areas are much less susceptible, presumably due to previous exposure when young, although their acquired immunity usually coexists with a carrier state. This balance may, on occasion, be disturbed and clinical anaplasmosis supervenes when cattle are stressed by other diseases such as babesiosis.

Details on the life cycle, diagnosis, treatment and control are as for *A. marginale*.

Anaplasma phagocytophilum

Synonyms: *Anoplasma phagocytophila*, *Ehrlichia phagocytophila*, *Cytoecetes phagocytophila*

Common names: Tick-borne fever, pasture fever, canine granulocytic ehrlichiosis, human granulocytic ehrlichiosis, equine granulocytic ehrlichiosis

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: Blood smears stained with Giemsa or Wright's stain reveal one or more loose aggregates (morulae or inclusion bodies, 1.5–5 µm in diameter) of blue–grey to dark-blue coccoid, coccobacillary or pleomorphic organisms within the cytoplasm of neutrophils (see Fig. 9.56).

For more detailed descriptions on pathogenesis, epidemiology, treatment and control see Chapter 9.

Ehrlichia bovis

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: Round or irregular-shaped intracytoplasmic organisms (2–10 µm in diameter) present in mononuclear cells, particularly monocytes.

Hosts: Cattle

Geographical distribution: Africa, Middle East (Turkey, Iran), India, Sri Lanka

Pathogenesis: Has been associated with acute and fatal disease in some regions of Africa.

Clinical signs: Affected animals show anorexia, weakness, muscular trembling, drunken gait and bulging eyes.

Diagnosis: The rickettsiae can be demonstrated by staining blood or organ smears with Giemsa.

Pathology: In fatal cases there is hydropericardium, hydrothorax, splenomegaly and swollen lymph nodes. Monocytosis may occur in terminal infections.

Epidemiology: Transmitted by ticks of the genera *Hyalomma*, *Rhipicephalus* and *Amblyomma*. Known vectors are *Hyalomma*

anatolicum, *Rhipicephalus appendiculatus*, *Amblyomma cajennense* and possibly *A. variegatum*.

Treatment: Little information is available although, as with other member of this group, tetracyclines may be effective.

Control: Specific control measures have not been reported but tick control may assist in preventing infection with *E. bovis*.

Ehrlichia ruminantium

Synonym: *Cowdria ruminantium*

Common names: Heartwater, cowdriosis, malkopsiekte (Afrikaans)

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: Organisms are seen as close-packed colonies consisting of less than ten to many hundred cocci. The organism varies in size from 0.2 to greater than 1.5 µm. The diameter of individual organisms in a given cluster is rather uniform but groups are very pleomorphic. The small granules tend to be coccoid, with larger ones looking like rings, horseshoes, rods and irregular masses.

Hosts: Cattle, sheep, goat, buffalo and wild ruminants

Geographical distribution: Africa, south of the Sahara; Caribbean (Guadeloupe, Marie-Galante and Antigua)

Pathogenesis: In the ruminant host the organism is first found in reticuloendothelial cells and then parasitises vascular endothelial cells. Division is by binary fission and it produces morula-like colonies in the cytoplasm of infected cells. The pathogenesis of the disease is far from clear. Hydropericardium may lead to cardiac insufficiency and hydrothorax and pulmonary oedema to respiratory difficulties. Oedema is often so pronounced in peracute heartwater that it is responsible for sudden death by asphyxia. The occasional sudden fall in plasma volume preceding death has been associated with the development of the transudates. Brain lesions are not sufficiently consistent to explain the nervous symptoms.

Clinical signs: The average natural incubation period is 2 weeks, but can vary from 10 days to 1 month. In most cases, heartwater is an acute febrile disease, with a sudden rise in body temperature; temperature may exceed 41°C within 1–2 days. It remains high with small fluctuations and drops shortly before death.

A peracute form occurs in exotic breeds introduced into an endemic region. The animal appears clinically normal, but if examined will have a marked pyrexia. It may then suddenly collapse, go into convulsions and die. Thoracic auscultation will often reveal oedema in the lungs and bronchi.

In the acute form, fever is followed by inappetence, sometimes listlessness, diarrhoea (particularly in cattle) and dyspnoea indicative of lung oedema. The course of infection is 3–6 days and consists of pyrexia (often over 41°C, 106°F). A mild cough may be heard and, on auscultation, hydrothorax, hydropericardium and lung

oedema are noted. A profuse diarrhoea is often present or there may be blood in the faeces. Nervous signs develop gradually. The animal is restless, walks in circles, makes sucking movements and stands rigidly with tremors of the superficial muscles. Cattle may push their head against a wall or present aggressive or anxious behaviour. Finally, the animal falls to the ground, pedalling and exhibiting opisthotonus, nystagmus and chewing movements. The animal usually dies during or following such a nervous attack.

In the subacute form, the signs are like those of the acute form but they are much less severe with a transient fever and sometimes diarrhoea. Disease may last for over a week and the animal usually improves gradually but a few cases progress to collapse and death. This is often the most severe form seen in indigenous cattle and those previously infected. In these stock, symptoms are usually absent.

Diagnosis: There is no specific method for diagnosis in the living animal. A tentative diagnosis of heartwater is based on the presence of *Amblyomma* vectors, of clinical nervous signs and of transudates in the pericardium and thorax at postmortem examination. Provisional indication can be gained from the history and clinical signs. Lymph node material can be aspirated to examine for vacuoles containing organisms in the cytoplasm of the reticular cells. Serum can be examined using a capillary flocculation test. A number of serological tests have been described but all suffer from false-positive reactions due to cross-reactions with other *Ehrlichia* species.

Diagnosis is easier at postmortem as the organism can be discerned in brain tissue capillaries that have been fixed in methyl alcohol and stained with Giemsa. Typical colonies of *E. ruminantium* can be observed in brain smears made after death. Slides are examined for the presence of the characteristic colonies. Experience is required to differentiate from other haemoparasites (*Babesia bovis*), certain blood cells (thrombocytes, granulocytes), normal subcellular structures (mitochondria, mast cell granules) or stain artefacts (stain precipitates). The specificity of the reading can be improved by staining formalin-fixed brain sections using immunoperoxidase techniques. Transmission electron microscopy can be used to demonstrate organisms inside a vacuole-like structure, which is surrounded by a membrane in the endothelial cell's cytoplasm.

Differential clinical diagnosis should be made with anthrax, theileriosis, anaplasmosis, botulism, and, in nervous cases, rabies, tetanus, strychnine poisoning, cerebral theileriosis, cerebral babesiosis and hypomagnesaemia.

Pathology: The lesions present are very variable and not pathognomonic. In the peracute form there are few gross lesions, but in some there is marked lung oedema with tracheal and bronchial fluids. In the acute form the most common macroscopic lesions are hydropericardium, hydrothorax, pulmonary oedema, intestinal congestion, oedema of the mediastinal and bronchial lymph nodes, petechiae on the epicardium and endocardium, congestion of the brain and moderate splenomegaly. The liver is often engorged, with the gallbladder distended. The spleen is occasionally enlarged. There may be congestion of the meningeal blood vessels.

Epidemiology: Distribution of heartwater coincides with that of the *Amblyomma* ticks, which require a warm humid climate and bushy grass. A number of African species of the genus *Amblyomma* (*A. hebraeum*, *A. variegatum*, *A. pomposum*, *A. gemma*, *A. lepidum*, *A. tholloni*, *A. sparsum*, *A. astrion*, *A. cohaerens*, *A. marmoratum*) and American species of *Amblyomma* (*A. maculatum*, *A. cajennense*, *A. dissimile*) are able to transmit infection. Transmission

usually appears to be trans-stadial, although transovarian transmission can occur more rarely. The level of infection is often unknown as indigenous domestic and wild animals often show no signs. It is only when susceptible exotic species are introduced that infection becomes apparent. Besides cattle, sheep, goats, Asian buffalo, antelopes and deer are susceptible to infection and disease. Indigenous cattle undergo inapparent infection. Calves under 3 weeks old, even from susceptible stock, are difficult to infect. Heartwater can occur throughout the year, but incidence declines in the dry season due to reduced tick activity. The incubation period is variable, from 7 to 28 days, with fever starting on average after 18 days. Mortality can be up to 60% in exotic breeds, but less than 5% in local cattle.

Treatment: Therapy is most effective when carried out early in disease. Tetracyclines can be used and do not interfere with development of immunity.

Control: Prevention is aimed at controlling the tick vector by dipping cattle at weekly intervals with reliable acaricides. However, ticks of the genus *Amblyomma* are less susceptible than those from other genera. As the tick may transmit infection after 24 hours on the host, better control is obtained by applying acaricide by dipping or spraying every 3 days. Resistance to organophosphates and arsenic has been reported. Care should also be taken not to introduce *Amblyomma* on infected animals or in forage to uninfected cows.

In areas where disease is endemic most cattle are immune. A carrier state develops after infection and remains for several weeks. Non-infected resistance persists a variable time, lasting from a few months to several years. After this time reinfection can occur.

The only method of immunisation is an infection and treatment method using infected blood or homogenised pre-fed infected ticks followed by tetracycline treatment as soon as pyrexia develops.

Notes: Heartwater is one of the main obstacles to the improvement of livestock productivity in sub-Saharan Africa. It was first recognised as a major disease in southern Africa after the introduction of exotic breeds. Its importance depends to a very large extent on the type of livestock present. There are very few reliable figures about its importance in local breeds in endemic areas. However, there is no doubt that in endemic areas indigenous cattle are far more resistant than exotic or crossbred cattle, presumably because of natural selection. In contrast, small ruminants in general, and goats in particular, are not always very resistant.

The name 'heartwater' was used because hydropericardium was regarded as a pathognomonic lesion of the disease. The disease is still also generally known as 'cowdriosis'.

Eperythrozoon wenyonii

Synonym: *Mycoplasma wenyonii*

Predilection site: Blood

Kingdom: Bacteria

Phylum: Firmicutes

Order: Mycoplasmatales

Family: Mycoplasmataceae

Description: Coccoid, ring- or rod-shaped structures on the surface of red cells, blue to purple when stained (see Diagnosis).

Figure 8.40 *Eperythrozoon wenyonii* on the surface of erythrocytes.

Hosts: Cattle

Geographical distribution: Worldwide

Pathogenesis: Typically present on red cells, it produces mild and clinically inapparent infections in a variety of domestic animals throughout the world.

Clinical signs: *Eperythrozoon wenyonii* is occasionally responsible for fever, anaemia and loss of weight.

Diagnosis: Identification of parasites from staining artefacts requires good blood films and filtered Giemsa stain. They appear as cocci or short rods on the surface of the erythrocytes, often completely surrounding the margin of the red cell (Fig. 8.40). However, the organisms of *Eperythrozoon* are relatively loosely attached to the red cell surface and are often found free in the plasma.

Epidemiology: Vectors are thought to be involved in transmission but precise details are not known.

Treatment: Susceptible to tetracyclines.

Control: Lack of detailed knowledge on the vectors limits any vector control measures.

Notes: The taxonomy of this species is subject to much debate and there is a proposal to reclassify it into the bacterial genus *Mycoplasma* (class Mollicutes) based on 16S rRNA gene sequences and phylogenetic analysis.

Rickettsia conorii

Common names: Boutonneuse fever, Mediterranean spotted fever, Indian tick typhus, East African tick typhus

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Rickettsiaceae

Description: Small, pleomorphic, Gram-negative, coccoid, obligatory intracellular organisms infecting endothelial cells of smaller blood vessels.

For more detailed descriptions on pathogenesis, epidemiology, treatment and control see Chapter 12.

Parasites of the nervous system

Taenia multiceps

For more details see Chapter 12.

Thelazia rhodesi

Common name: Cattle eyeworm

Predilection site: Eye, conjunctival sac, lacrimal duct

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Small thin yellowish-white worms, 1.0–2.0 cm long. Males are 8–12 mm and females 12–20 mm.

Description, microscopic: A mouth capsule is present and the cuticle has prominent striations at the anterior end. The male worms have about 14 pairs of pre-cloacal and three pairs of post-cloacal papillae.

Final hosts: Cattle, buffalo, occasionally sheep, goat, camel

Intermediate host: Muscid flies, particularly *Fannia* spp.

Geographical distribution: Worldwide

Pathogenesis: Lesions are caused by the serrated cuticle of the worm and most damage results from movement by the active young adults causing lacrimation, followed by conjunctivitis. In heavy infections the cornea may become cloudy and ulcerated. There is usually complete recovery in about 2 months, although in some cases areas of corneal opacity can persist. Infection may predispose to infectious keratoconjunctivitis ('pink eye') caused by *Moraxella*.

Clinical signs: Lacrimation, conjunctivitis and photophobia. Flies are usually clustered around the eye because of the excessive secretion. In severe cases, the whole cornea can be opaque and, without treatment, progressive keratitis and ulceration of the cornea may occur.

Diagnosis: The presence of a conjunctivitis that is coincident with the season of fly activity is an indication of possible infection. In some cases the *Thelazia* worms may be seen on the surface of the conjunctiva or in the conjunctival sac. Sometimes eggs or larvae can be recovered from lacrimal secretions. It may be necessary to instil a few drops of local anaesthetic to facilitate manipulation of the third eyelid.

Pathology: Invasion of the lacrimal gland and ducts may cause inflammation and necrotic exudation leading to occlusion and reduced tear production. Mechanical irritation of the conjunctiva produces inflammation, while damage to the cornea leads to opacity, keratitis and corneal ulceration.

Epidemiology: *Thelazia* infections occur seasonally and are linked to periods of maximum fly activity. The parasite can survive in the eye for several years, but since it is only the young adult which is pathogenic a reservoir of infection may persist in symptomless carrier cattle. Survival of larvae also occurs in the pupal stages of flies during the winter.

Treatment: Treatment was at one time based on manual removal of the worms under a local anaesthetic, but this is now replaced by administering an effective anthelmintic such as levamisole or an avermectin; the former drug may be applied topically as a 1% aqueous solution.

Control: Prevention is difficult because of the ubiquitous nature of the fly vectors. Fly control measures aimed at protecting the face, such as insecticide-impregnated ear tags, aid in the control of eye-worm infection.

Two other species of eyeworm (*T. gulosa* and *T. skrjabini*) are found in cattle. Details are essentially similar to *T. rhodesii*.

Thelazia gulosa

Synonym: *Thelazia alfortensis*

Common name: Cattle eyeworm

Predilection site: Eye, conjunctival sac and lacrimal duct

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description: *Thelazia gulosa* are milky-white worms, with thin transverse cuticular striations (less evident in the rear part of the body) and a large, deep, cup-shaped buccal cavity. Males are 4.8–10.9 mm long and have a variable number of pre-cloacal papillae (from 8 to 33 pairs) and three pairs of post-cloacal papillae. There are two asymmetric spicules. The females are 4.8–18.8 mm long with a tapered caudal extremity.

Geographical distribution: Probably worldwide

Thelazia skrjabini

Common name: Cattle eyeworm

Predilection site: Eye, conjunctival sac and lacrimal duct

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description: Adult worms are whitish in colour, with transverse fine cuticular striations. The buccal cavity is small and shallow. Males are 5–11.5 mm long and curved posteriorly with 16–32 pairs of pre-cloacal and three pairs of post-cloacal papillae. The spicules are unequal in length. The females are 7.5–21 mm long with a truncated caudal extremity.

Geographical distribution: North America, parts of Asia and Europe

Railletia auris

Predilection site: Ear canal

Class: Arachnida

Subclass: Acari

Order: Mesostigmata

Family: Halarachnidae

Description, gross: The mites are oval and pale yellow, adults measuring approximately 1 mm in length. They have a smooth cuticle with relatively few setae.

Description, microscopic: The holodorsal shield is heavily patterned but with a well-developed tritosternum, longer peritremes and the presence of both a genital and sternal shield in the female. This species has a long dorsal shield (700–800 µm) with 12 pairs of setae.

Final host: Cattle

Clinical signs: Infestations are usually inapparent but the presence of mites in the ear canal may lead to otitis media and otitis interna, with head shaking, head rotation, circling and incoordination.

Hypoderma bovis

For more details see Parasites of the integument.

Toxoplasma gondii

For more details see Parasites of the locomotory system.

Trypanosoma brucei brucei

For more details see Parasites of the circulatory system.

Parasites of the reproductive/urogenital system

Stephanurus dentatus

Common name: Pig kidney worm

Predilection site: Kidney, perirenal fat

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description: A large stout worm up to 4.5 cm long, with a prominent buccal capsule and transparent cuticle through which the internal organs may be seen. Males are 2–3 cm and females 3–4.5 cm long. The colour is usually pinkish. The size and site are diagnostic. The buccal capsule is cup-shaped with small leaf crowns and six external cuticular thickenings (epaulettes) of which the ventral and dorsal are most prominent, and six cusped teeth at the base. The

male bursa is short and the two spicules of either equal or unequal length.

Hosts: Pig, wild boar, rarely cattle

Pathogenesis: *Stephanurus* may occasionally cause severe liver damage in calves grazing on contaminated ground.

For a more detailed description see Chapter 11.

Tritrichomonas foetus

Synonym: *Trichomonas foetus*

Predilection site: Prepuce, uterus

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The organism is pear-shaped, approximately 10–25 µm long and 3–15 µm wide, and has a single nucleus and four flagella, each arising from a basal body situated at the anterior rounded end. Three of the flagella are free anteriorly, while the fourth extends backwards to form an undulating membrane along the length of the organism and then continues posteriorly as a free flagellum (Fig. 8.41; see also Fig. 2.10). The axostyle, a hyaline rod with a skeletal function, extends the length of the cell and usually projects posteriorly. The costa is prominent but there is no pelta.

In fresh preparations, the organism is motile and progresses by rolling jerky movements, the flickering flagella and the movements of the undulating membrane being readily seen. Occasionally, rounded immobile forms are observed and these are possibly effete.

Hosts: Cattle

Geographical distribution: Worldwide. However, the prevalence has now decreased dramatically in areas where artificial insemination is widely practised and in Britain, for example, the disease is now probably extinct.

Pathogenesis: In the bull, a preputial discharge associated with small nodules on the preputial and penile membranes may develop shortly after infection. Organisms are present in small numbers in

Figure 8.41 *Tritrichomonas foetus* showing three anterior flagella and trailing posterior flagellum.

the preputial cavity of bulls, with some concentration in the fornix and around the glans penis. The chronically infected bull shows no gross lesions.

In the cow, the initial lesion is a vaginitis, which can be followed in animals that become pregnant by invasion of the cervix and uterus. Various sequelae can result, including a placentitis leading to early abortion (1–16 weeks), uterine discharge and pyometra. Abortion before the fourth month of pregnancy is the commonest sequela and this is normally followed by recovery. Occasionally the developing fetal membranes are retained leading to a purulent endometritis, a persistent uterine discharge and anoestrus; infrequently the corpus luteum is retained and the cervical seal remains closed, when a massive pyometra develops which visually simulates the appearance of pregnancy. In some cases, despite infection, pregnancy is not terminated by abortion and a normal full-term calf is born.

Clinical signs: In the bull, there are no clinical signs once the infection is established. In the cow, early abortion is a characteristic feature although this is often undetected because of the small size of the fetus and the case may present as one of an irregular oestrous cycle. Other clinical signs are those of purulent endometritis or a closed pyometra and, in these cases, the cow may become permanently sterile. On a herd basis, cows exhibit irregular oestrous cycles, uterine discharge, pyometra and early abortion. The cow usually recovers and generally becomes immune, at least for that breeding season, after infection or abortion.

Diagnosis: A tentative diagnosis of trichomonosis is based on the clinical history, signs of early abortion, repeated returns to service, or irregular oestrous cycles. Confirmation depends on the demonstration of organisms in placental fluid, stomach contents of the aborted fetus, uterine washings, pyometra discharge or vaginal mucus. Apart from a problem of infertility, which usually follows the purchase of a mature bull, confirmation of diagnosis depends on the demonstration of the organism. Vaginal mucus collected from the anterior end of the vagina by suction into a sterile tube, or preputial washings from the bull, may be examined using a warm-stage microscope for the presence of organisms. The number of organisms varies in different situations. They are numerous in the aborted fetus, in the uterus several days after abortion and, in recently infected cows, they are plentiful in the vaginal mucus 12–20 days after infection. Thereafter the number of organisms varies according to the phase of the oestrous cycle, being highest 3–7 days after ovulation. In the infected bull *T. foetus* organisms are present in highest numbers on the mucosa of the prepuce and penis, apparently not invading the submucosal tissues. It is generally recommended to allow 1 week after the last service before taking a preputial sample. Since the organism is often only present intermittently, the examination may need to be repeated several times. Under phase illumination, the number of flagella observed is an important characteristic as this can help to differentiate *T. foetus* from some bovine flagellates that appear similar. Organisms may be cultured *in vitro*, in Diamond's medium, Clausen's medium or *Trichomonas* medium, which is available commercially. A field culture test that allows for growth of the trichomonads and direct microscopic examination without aspiration of the inoculum has been developed in the USA (InPouch TF).

Alternatively, on a herd basis, samples of vaginal mucus may be examined in the laboratory for the presence of specific agglutinins against laboratory cultures of *T. foetus*.

Pathology: Infection in females causes cervicitis and endometritis leading to infertility, abortion or pyometra. The inflammatory changes in the endometrium and cervix are relatively mild and non-specific, although there may be a copious mucopurulent discharge. The exudates may be continuous or intermittent in their discharge, and the number and activity of the trichomonads can vary considerably. Abortions may occur at any time but mainly in the first half of pregnancy. There are no specific fetal lesions, but large numbers of protozoa may be found in the fetal fluids and stomach. The placenta may be covered by white or yellowish flocculent exudates in small amounts, and thickening and haemorrhage without necrosis may be evident on the cotyledons. Pyometra, when it develops, may be copious with watery exudates containing floccules which may be brownish and sticky and contain swarms of trichomonads.

Epidemiology: Bulls, once infected, remain so permanently. The organisms inhabit the preputial cavity and transmission to the cow occurs during coitus. From the vagina, the trichomonads reach the uterus via the cervix to produce a low-grade endometritis. Intermittently, organisms are flushed into the vagina, often 2 or 3 days before oestrus. Infection is usually followed by early abortion, the organisms being found in the amniotic and allantoic fluid. Subsequently cows appear to ‘self-cure’ and, in most cases, appear to develop a sterile immunity.

Treatment: Since the disease is self-limiting in the female only symptomatic treatment and sexual rest for 3 months is normally necessary. In the bull, slaughter is the best policy, although dimetridazole orally or intravenously has been reported to be effective.

Control: Artificial insemination from non-infected donors is the only entirely satisfactory method of control. If a return to natural service is contemplated, recovered cows should be disposed of since some may be carriers.

Notes: Normally one might expect the overall prevalence of trichomonosis to be high, since it is venereally transmitted by bulls, which show no clinical signs. In fact, the advent of supervised schemes of artificial insemination has largely eradicated the disease, and today it is limited to areas where there are many small farms each with their own bulls, or to countries where veterinary supervision is limited.

In a few early studies, three serotypes were recognised based on agglutination: the ‘Belfast’ strain, reportedly predominated in Europe, Africa and the USA; the ‘Brisbane’ strain in Australia; and the ‘Manley’ strain, which has been reported in only a few outbreaks.

A morphologically identical organism (*T. suis*) has been identified in pigs, in which it commonly causes asymptomatic infection of the nasal cavity, stomach and intestine (see Chapter 11). This organism is now considered synonymous with *T. foetus*. The organism has also been reported in cats to be associated with large bowel diarrhoea (see Chapter 12).

Neospora caninum

Predilection site: Blood

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystidae

Description: Tachyzoites measure 6 by 2 µm and are usually located in the cytoplasm of cells. Tissue cysts are oval, 107 µm long, have a thick wall (up to 4 µm) and are found only in neural tissue.

Intermediate hosts: Cattle, sheep, goat, deer, horse, dog, fox, chicken, wild birds

Final hosts: Dog, coyote, wolf, dingo

Geographical distribution: Worldwide

Pathogenesis: *Neospora caninum* is a major cause of abortion in both dairy and beef cattle. Cows of any age can abort from 3 months of gestation to full term, although most abortions occur at 5–6 months. Fetuses can be born alive or may die *in utero* and be mummified or reabsorbed. Calves that are infected may be born underweight, weak or with neurological symptoms such as ataxia, decreased reflexes and exophthalmia. Infection is thought to reduce milk production in adult dairy cows through its effects on fertility.

Clinical signs: Abortion, mummification, weak calves with ataxia, exophthalmia

Diagnosis: Diagnosis is based on histological examination of freshly aborted fetuses. The lesions in the heart and CNS are significantly characteristic for diagnosis but can be confirmed by immunocytochemistry. An ELISA is commercially available and can be used to test serum samples for *Neospora*-specific antibodies and several PCR-based tests have been reported. Bulk milk sampling can also be used but is generally only useful in herds where more than 10–20% of cows are infected.

Pathology: Tachyzoites and tissue cysts are found intracellularly in the CNS and retina of affected cattle. Although infection can be found in many organs, the commonest site is the brain. Microscopic lesions of non-suppurative encephalitis and myocarditis may be seen in the brain, spinal cord and heart of aborted fetuses. Hepatitis can also be found in epidemic abortions.

Epidemiology: The dog and other canids are the final host, and can also act as intermediate hosts in prenatal infections. In cattle, infection can be both vertically transmitted from dam to calf *in utero* and lactogenically and naturally by ingestion of food and water contaminated with dog faeces containing *Neospora caninum* oocysts. *Neospora caninum* is one of the most efficiently transplacentally transmitted parasites and in certain herds it has been found that virtually all calves born alive are born infected but without symptoms of infection. Transmission from infected bulls is thought not to occur. The presence of birds on pasture has been correlated with higher infection rates in cattle and birds may be an important link in the transmission of *N. caninum* to other animals.

In some countries, there appears to be an increase in abortion rates associated with mild wet seasons. Infections with other disease agents, such as bovine viral diarrhoea, leptospirosis and *Salmonella*, appear to increase the risk or recrudescence of latent infection and are likely to be associated with a higher risk of abortion in infected cows. It is possible for cattle that have previously aborted due to *Neospora* infection to have a repeat abortion, such that infected cows are more likely to abort than non-infected cows. Offspring born alive are likely to be infected themselves and go on to have a higher risk of abortion.

Treatment: There is no effective treatment in cattle.

Control: Control of *Neospora*-induced abortion in cattle depends on protecting food and water sources from possible contamination

with the faeces of any animal and the disposal of aborted fetuses and placentas by incineration. The lack of complete knowledge of both the life cycle and the range of definitive hosts has limited effective control measures but there is a strong argument for the culling of seropositive animals from a herd. Seropositive animals have been shown to suffer a higher risk of abortion than seronegative animals in the herd. Dogs should not be allowed to eat aborted fetuses or fetal membranes, and their faeces should be prevented from contaminating bovine feedstuffs.

Where *Neospora* has not previously been isolated in a herd, there are several measures which can be taken to reduce the risk of the disease entering the herd.

- Quarantine and testing of all replacements before entry to the herd to ensure freedom from infection.
- Preventing transmission by keeping dogs away from foodstuffs, and ensuring that dogs have no access to either placentas or aborted fetuses.
- Reducing the risk of water-borne transmission by using a mains water supply and avoiding cattle drinking from stagnant water such as ponds.
- Maintaining good rodent control as some studies have implicated rodents in the spread of disease.

In herds where *Neospora* is present, further methods can be used to reduce the risk of animals aborting.

- Testing and culling: *N. caninum*-infected cows should be considered a reservoir of infection with the potential to transmit the infection to other cows. This can occur either by giving birth to live infected offspring or by environmental contamination. Although this method of control is effective, it is not always economically realistic. It can be applied as follows:
 - test and cull either seropositive or seropositive aborting cows;
 - test and inseminate seropositive cows with beef semen only; or
 - test and exclude the progeny of seropositive cows from breeding.

If testing of cows is carried out and cattle are culled on the basis of these results, it is important to ensure that steps are also taken to prevent infection from the environment.

A commercial vaccine (Bovilis Neoguard) was developed to reduce abortion in pregnant cattle resulting from infection with *N. caninum* and was available in the USA, New Zealand and some other countries. This vaccine comprised inactivated whole tachyzoites and inoculation aimed to reduce the transmission of the parasite to the developing fetus. However, the vaccine has been withdrawn from the market by the manufacturer.

Trypanosoma brucei brucei

For more details see Parasites of the circulatory system.

Parasites of the locomotory system

Taenia saginata

Synonyms: *Cysticercus bovis*, *Taeniarhynchus saginata*

Common names: Beef tapeworm, 'beef measles'

Predilection site: Small intestine (definitive host); muscle, liver, kidney (intermediate host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: The adult tapeworm is found only in humans and ranges from 5 to 15 m in length.

Description, microscopic: The scolex, exceptional among the species of *Taenia*, has neither rostellum nor hooks.

In cattle, the mature cysticercus, *C. bovis*, is greyish-white, oval, about 0.5–1.0 by 0.5 cm long, and filled with fluid in which the scolex is usually clearly visible. As in the adult tapeworm, it has neither rostellum nor hooks.

A subspecies, *Taenia saginata asiatica*, has a rostellum and posterior protruberances on segments and 11–32 uterine buds. The metacestodes are small, about 2 mm, and have a rostellum and two rows of primitive hooks, those of the outer row being numerous and tiny.

Final host: Human

Intermediate host: Cattle, although other ruminants can serve as intermediate hosts

Geographical distribution: Worldwide. Particularly important in Africa and South America.

Pathogenesis: Although *C. bovis* may occur anywhere in the striated muscles, the predilection sites, at least from the viewpoint of routine meat inspection, are the heart, the tongue and the masseter and intercostal muscles (Fig. 8.42). Under natural conditions the presence of cysticerci in the muscles of cattle is not associated with clinical signs although, experimentally, calves given massive infections of *T. saginata* eggs have developed severe myocarditis and heart failure associated with developing cysticerci in the heart.

Clinical signs: In humans, the adult tapeworm may produce diarrhoea and hunger pains, but the infection is usually asymptomatic and is mainly objectionable on aesthetic grounds.

Diagnosis: Individual countries have different regulations regarding the inspection of carcasses, but invariably the masseter muscle, tongue and heart are incised and examined and the intercostal muscles and diaphragm inspected; the triceps muscle is also incised in many countries. The inspection is inevitably a compromise between

Figure 8.42 *Cysticercus bovis* in skeletal muscle.

detection of cysticerci and preservation of the economic value of the carcass.

Immunoserology has some usefulness for screening infected herds. In humans, the presence of tapeworms is recognised by the passage of proglottids and/or eggs in faeces.

Pathology: Cysticerci commence to degenerate 4–6 months after infection and by 9 months a substantial number may be dead. With light infections cysticerci may remain viable for 2 years or more.

Epidemiology: There are two quite distinct epidemiological patterns found in developing countries and developed countries respectively.

- Developing countries. In many parts of Africa, Asia and Latin America cattle are reared on an extensive scale, human sanitation is poorly developed and cooking fuel is expensive. In these circumstances the incidence of human infection with *T. saginata* is high, in certain areas being well over 20%. Because of this, calves are usually infected in early life, often within the first few days after birth, from infected stockmen whose hands are contaminated with *Taenia* eggs. Prenatal infection of calves may also occur but is rare. Of the cysts which develop, a proportion persist for years even though the host has developed an acquired immunity and is completely resistant to further infection. Based on routine carcass inspection, the infection rate is often around 30–60%, although the real prevalence is considerably higher.
- Developed countries. In areas such as Europe, North America, Australia and New Zealand, the standards of sanitation are high and meat is carefully inspected and generally thoroughly cooked before consumption. In such countries, the prevalence of cysticercosis is low, being less than 1% of carcasses inspected. Occasionally, however, a cysticercosis ‘storm’, where a high proportion of cattle are infected, has been reported on particular farms. In Britain and in Australia, this has been associated with the use of human sewage on pasture as a fertiliser in the form of sludge, i.e. sedimented or bacterial-digested faeces. Since *T. saginata* eggs may survive for more than 200 days in sludge, the occurrence of these ‘storms’ is perhaps not surprising. Other causes of a sudden high incidence of infection on particular farms are due to a tapeworm infection in a stockman occurring either as a random event or, as has been reported from feedlots in some of the southern states of the USA, as a result of the use of migrant labour from a country with a high prevalence of infection. As distinct from these ‘storms’, the cause of the low but persistent prevalence of infection in cattle is obscure, but is thought to be due to the access of cattle to water contaminated with sewage effluents, to the carriage and dispersal of *T. saginata* eggs by birds which frequent sewage works or feed on effluent discharged into rivers or the sea, and to occasional fouling of pasture by itinerant infected individuals. In contrast to the epidemiology in developing countries, cattle of any age are susceptible to infection since they generally possess no acquired immunity. There is also evidence that when cattle are first infected as adults the longevity of the cysticerci is limited, most being dead within 9 months.

Treatment: As yet there is no licensed drug available that will effectively destroy all the cysticerci in the muscle, although praziquantel has shown efficacy in experimental situations.

Control: In developed countries the control of bovine cysticercosis depends on a high standard of human sanitation, on the general practice of cooking meat thoroughly (the thermal death point of

cysticerci is 57°C) and on compulsory meat inspection. Regulations usually require that infected carcasses are frozen at –10°C for at least 10 days, which is sufficient to kill the cysticerci although the process reduces the economic value of the meat. Where relatively heavy infections of more than 25 cysticerci are detected, it is usual to destroy the carcass. In agricultural practice the use of human sludge as a fertiliser should be confined to cultivated fields or to those on which cattle will not be grazed for at least 2 years. In developing countries the same measures are necessary, but are not always economically feasible, and at present the most useful step would appear to be the education of communities in both sanitary hygiene and the thorough cooking of meat.

Notes: The intermediate stages of this tapeworm, found in the muscles of cattle, frequently present economic problems to the beef industry and are a public health hazard.

Onchocerca dukei

Predilection site: Muscle connective tissue

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Slender whitish worms; males measure 2–6 cm, while females are up to 60 cm long or more.

Description, microscopic: Microfilariae are 250–265 µm long and unsheathed.

Final host: Cattle

Intermediate hosts: Probably blackflies (*Simulium*)

Geographical distribution: Africa

Pathogenesis: *Onchocerca dukei* is of little clinical or economic importance. Losses may occur by condemnation of localised areas at meat inspection caused by nodular damage.

Clinical signs: Infection in cattle is asymptomatic.

Diagnosis: Diagnosis is often made at meat inspection. Nodules are found particularly in the thorax and abdomen and may need to be differentiated from *Cysticercus bovis*. Microfilariae may be identified after soaking skin biopsy specimens in physiological saline for 12 hours and staining with Giemsa.

Epidemiology: The incidence of infection can be very high in endemic areas, though the parasite is rarely detected.

Treatment and control: Not required

Sarcocystosis

The previously complex nomenclature for the large number of *Sarcocystis* spp. has largely been discarded by many workers in favour of a new system based on their biology. The new names generally incorporate those of the **intermediate** and **final hosts** in that order. Although unacceptable to systematists, this practice has the virtue of simplicity. The three species of *Sarcocystis* reported in cattle are summarised in Table 8.7 and described below. Further details are given in Chapter 2.

Table 8.7 *Sarcocystis* species found in the muscles of cattle.

| Species | Synonym | Definitive host | Pathogenicity (cattle) | Pathogenicity (final host) |
|------------------------------|--|-------------------|------------------------|----------------------------|
| <i>Sarcocystis bovicanis</i> | <i>S. cruzi</i> , <i>S. fusiformis</i> | Dog, coyote, wolf | +++ | 0 |
| <i>Sarcocystis bovis</i> | <i>S. hirsuto</i> | Cat | 0 | 0 |
| <i>Sarcocystis bovis</i> | <i>S. hominis</i> | Human, primates | 0 | + |

0, non-pathogenic; +, mildly pathogenic; +++, severe pathogenicity.

Diagnosis: Most cases of *Sarcocystis* infection are only diagnosed at meat inspection when the grossly visible sarcocysts in the muscle are discovered. However, in heavy infections of cattle, diagnosis is based on the clinical signs and on histological demonstration of meronts in the blood vessels of organs such as kidney or heart and the presence of cysts in the muscles at necropsy or biopsy. An indirect haemagglutination test, using bradyzoites as antigen, is also a useful aid to diagnosis; however, the presence of a titre need not imply active lesions of *Sarcocystis*. Also, animals may die prior to a detectable humoral response. In cattle, the degenerative muscle changes closely resemble those of vitamin E/selenium deficiency, although the latter lacks an inflammatory cellular response. Examination of faeces from dogs or cats on the farm for the presence of sporocysts may be helpful in the diagnosis.

Epidemiology: Little is known of the epidemiology, but from the high prevalence of symptomless infections observed in abattoirs, it is clear that where dogs or cats are kept in close association with farm animals or their feed, then transmission is likely. Sheepdogs are known to play an important part in the transmission of *S. bovicanis* and farm cats in the transmission of *S. bovis* so care should be exercised that only cooked meat is fed to dogs or cats. Acute outbreaks are probably most likely when livestock, which have been reared without dog or cat contact, are subsequently exposed to large numbers of the sporocysts from dog or cat faeces. The longevity of the sporocysts shed in the faeces is not known.

Treatment and control: There is no effective treatment for infection, in either the final or the intermediate host. Where an outbreak occurs in cattle, it has been suggested that the introduction of amprolium (100 mg/kg *per os*, daily over 30 days) into the diet of the animals has a prophylactic effect.

The only control measures possible are those of simple hygiene. Farm dogs and cats should not be housed in, or allowed access to, fodder stores nor should they be allowed to defecate in pens where livestock are housed. It is also important that they are not fed uncooked meat.

Sarcocystis bovicanis

Synonyms: *Sarcocystis cruzi*, *Sarcocystis fusiformis*

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: In cattle, the meronts found in the endothelial cells are quite small, measuring 2–8 µm in diameter. In contrast, the bradyzoite cysts can be very large and visible to the naked eye as whitish streaks running in the direction of the muscle fibres. They

have been reported as reaching several centimetres in length, but more commonly they range from 0.5 to 5.0 mm (Fig. 8.43). The cyst wall is thin and smooth and has a small number of flattened protrusions 0.3–0.6 µm long, without fibrils.

Intermediate hosts: Cattle

Final hosts: Dog, fox, wolf, coyote

Geographical distribution: Worldwide

Pathogenesis: Infection in the final host is normally non-pathogenic, although mild diarrhoea has occasionally been reported. The principal pathogenic effect is attributable to the second stage of merogony in the vascular endothelium. Heavy experimental infections of calves with *S. bovicanis* have resulted in mortality 1 month later, with necropsy showing petechial haemorrhages in almost every organ including the heart, together with generalised lymphadenopathy. Experimental infection of adult cows has resulted in abortion.

A naturally occurring chronic disease of cattle, Dalmeny disease, has been recognised in Canada, the USA and Britain. This is characterised by emaciation, submandibular oedema, recumbency and exophthalmia; at postmortem examination, numerous meronts are found in endothelial cells, and developing sarcocysts in areas of degenerative myositis.

Clinical signs: In heavy infections there is anorexia, fever, anaemia, loss of weight, a disinclination to move and sometimes recumbency. In cattle, there is often a marked loss of hair at the end of the tail. These signs may be accompanied by submandibular oedema, exophthalmia and enlargement of lymph nodes. Abortions may occur in breeding stock.

Pathology: Meronts present in endothelial cells of capillaries in various organs lead to endothelial cell destruction. As the organisms enter muscle, a wide range of change may be encountered.

Figure 8.43 Meronts of *Sarcocystis bovicanis* in muscle.

Microscopic inspection of *Sarcocystis*-infected muscle often reveals occasional degenerate parasitic cysts surrounded by variable numbers of inflammatory cells (very few of which are eosinophils) or, at a later stage, macrophages and granulation tissue. Usually there is no muscle fibre degeneration, but there may be thin linear collections of lymphocytes between fibres in the region. The extent of muscle change bears little relationship to the numbers of developing cysts, but generally very low numbers of *Sarcocystis* produce no reaction. As cysts mature, the cyst capsule within the enlarged muscle fibre becomes thicker and more clearly differentiated from the muscle sarcoplasm.

Sarcocystis bovifelis

Synonym: *Sarcocystis hirsuta*

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: The first-generation meronts measure 37 by 22 μm and contain more than 100 tachyzoites. Second-generation meronts when mature measure 14 by 6.5 μm and contain up to 35 tachyzoites. Sarcocysts are up to 8 mm long with a striated wall, 7 μm thick, and may be visible to the naked eye as whitish streaks running in the direction of the muscle fibres.

Intermediate hosts: Cattle

Final host: Cat

Geographical distribution: Worldwide

Pathogenesis: Infections are generally non-pathogenic; any pathogenic effect is attributable to the second stage of merogony in the vascular endothelium.

Clinical signs: Infections are usually asymptomatic. Heavy infections may occasionally produce anorexia, fever, diarrhoea, anaemia and weight loss.

Pathology: In cattle, the tissue cysts may be visible to the naked eye especially in the oesophagus but are more likely to be detected on histopathology (Fig. 8.44).

Figure 8.44 *Sarcocystis bovifelis* in oesophageal muscle.

Sarcocystis bovi hominis

Synonym: *Sarcocystis hominis*

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: In the intermediate host, sarcocysts are compartmented with a radially striated wall of about 6 μm in thickness.

Intermediate hosts: Cattle

Final hosts: Human, primates

Geographical distribution: Worldwide

Pathogenesis: The species is slightly if at all pathogenic for calves.

Clinical signs: Infection is usually asymptomatic in calves.

Pathology: Sarcocysts are present in striated muscle. Usually there is no muscle fibre degeneration, but there may be thin linear collections of lymphocytes between fibres in the region.

Toxoplasma gondii

Predilection site: Muscle, lung, liver, reproductive system, CNS

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Intermediate hosts: Any mammal, including human, or birds. Note that the final host, the cat, may also be an intermediate host and harbour extra-intestinal stages.

Final hosts: Cat, other felids

Geographical distribution: Worldwide

Pathogenesis: Most *Toxoplasma* infections in cattle are light and consequently asymptomatic. Infections are usually acquired via the digestive tract, and so organisms are disseminated by the lymphatics and portal system with subsequent invasion of various organs and tissues. Pathogenic effects are always related to the extra-intestinal phase of development. In heavy infections, the multiplying tachyzoites may produce areas of necrosis in vital organs such as the myocardium, lungs, liver and brain, and during this phase the host can become pyrexial and lymphadenopathy occurs. As the disease progresses bradyzoites are formed, with this chronic phase being usually asymptomatic.

Clinical signs: There are only a few reports of clinical toxoplasmosis associated with fever, dyspnoea, nervous signs and abortion in cattle.

Pathology: In heavy infections, the multiplying tachyzoites may produce areas of necrosis in vital organs such as the myocardium, lungs, liver and brain.

Epidemiology: The cat plays a central role in the epidemiology of toxoplasmosis and the disease is virtually absent from areas where cats do not occur. Compared with sheep, toxoplasmosis in cattle is relatively uncommon and rarely causes clinical signs.

Treatment: Not indicated

Control: Control on farms is more difficult, but where possible animal feedstuffs should be covered to exclude access by cats.

For more detailed description see Chapter 9.

Trypanosoma brucei brucei

For more details see Parasites of the circulatory system.

Parasites of the connective tissue

Several species of *Onchocerca* are found in the connective tissue of cattle and are summarised in Table 8.8.

Onchocerca gutturosa

Synonym: *Onchocerca lienalis*

Common name: Ligamentary onchocercosis

Predilection site: Connective tissue, ligamentum nuchae, gastro-splenic ligament

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Slender whitish worms; males measure 2–6 cm, while females are up to 60 cm long or more.

Description, microscopic: Microfilariae are 250–265 µm long and unsheathed.

Final host: Cattle

Intermediate hosts: Blackflies (*Simulium*)

Geographical distribution: Worldwide. In Australia and North America, the parasite *O. lienalis* (considered to be synonymous) is found in the gastro-splenic ligament.

Pathogenesis: *Onchocerca gutturosa* is of little clinical or economic importance.

Figure 8.45 Microfilariae of *Onchocerca gutturosa* in subdermal connective tissue of the back.

Clinical signs: Infection in cattle is asymptomatic.

Diagnosis: Diagnosis is rarely called for and depends on the finding of microfilariae in skin biopsy samples taken from affected areas (Fig. 8.45). The microfilariae are concentrated in the preferred feeding sites of the vectors, which are the back, ears and neck. The piece of skin is placed in warm saline and teased to allow emergence of the microfilariae, and is then incubated for about 8–12 hours. The microfilariae are readily recognised by their sinuous movements in a centrifuged sample of the saline. Another option is to scarify the skin of a predilection site and examine the fluid exudate for microfilariae.

Pathology: Adult worms, which are found in pairs, are most frequently located in the ligamentum nuchae adjacent to the thoracic spines and less frequently in the connective tissue on the scapula, humerus and femur. The worms do not stimulate nodule formation but lie loose in the connective tissue and cause no disease or reaction.

Epidemiology: The incidence of infection can be very high in endemic areas, although the parasite is rarely detected.

Treatment: Not required

Control: With the ubiquity of the insect vectors there is little possibility of efficient control, though the use of microfilaricides will reduce the numbers of infected flies. In any case, with the relatively

Table 8.8 Bovine onchocercosis.

| Species | Site | Distribution | Vector | Significance |
|---|---|----------------------------|-------------------------------------|---|
| <i>Onchocerca gutturosa</i> (syn. <i>O. lienalis</i>) | Ligamentum nuchae and other parts of the body | Most parts of the world | <i>Simulium</i> spp. | No economic significance |
| | Gastro-splenic ligaments | Many parts of the world | <i>Simulium</i> spp. | No economic significance |
| <i>Onchocerca gibsoni</i> | Subcutaneous and intermuscular nodules | Africa, Asia, Australasia | <i>Culicoides</i> spp. | Carcass trimming |
| <i>Onchocerca ochengi</i> (syn. <i>O. dermati</i>) | Scrotum, udder, connective tissue | East and West Africa | Unknown | Blemished hides |
| <i>Onchocerca armillata</i> | Wall of thoracic aorta | Middle East, Africa, India | <i>Culicoides</i> , <i>Simulium</i> | No economic significance |
| <i>Onchocerca dukei</i> | Abdomen, thorax, thighs | West Africa | Unknown <i>Simulium</i> ? | Confused with <i>Cysticercus bovis</i> at meat inspection |
| <i>Onchocerca cebei</i> (syn. <i>O. sweetae</i>) | Abdomen, thorax, thighs | Far East, Australia | <i>Culicoides</i> spp. | Blemished hides |

innocuous nature of the infection there is unlikely to be any demand for control.

Notes: Some consider this parasite to be synonymous with *O. lienalis*.

Onchocerca gibsoni

Predilection site: Connective tissue

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: These slender worms range from 2 to over 20 cm in length and lie tightly coiled in tissue nodules. Males are 3–5 cm and females 14–20 cm, although there have been reports of worms up to 50 cm in length.

Description, microscopic: The tail of the male is curved and bears lateral alae and six to nine papillae at either side. The spicules are unequal in size. Microfilariae are not sheathed and are 240–280 µm long and are found mainly in the brisket area. The cuticle possesses transverse striations.

Final hosts: Cattle, zebu

Intermediate host: Midges (*Culicoides*)

Geographical distribution: Africa, Asia and Australasia

Pathogenesis: Worms occur in groups ('worm nests') and provoke a fibrous reaction around the coiled worms in muscle tissue (nodules can measure up to 5 cm in diameter). The nodules are often in the brisket and can be responsible for economic loss due to carcass trimming.

Clinical signs: Affected animals are not clinically ill and show no presenting signs other than subcutaneous nodules at the predilection sites.

Diagnosis: In active lesions, the presence of worms is readily established on section of the subcutaneous nodules. Microfilariae may also be found in skin biopsy samples taken from affected areas with subcutaneous lymph spaces. The microfilariae are concentrated in the preferred feeding sites of the vectors, which for *Culicoides* spp. are usually the shaded lower parts of the trunk, and it is usually recommended that samples be taken from the region of the linea alba. The piece of skin is placed in warm saline and teased to allow emergence of the microfilariae, and is then incubated for about 8–12 hours. The microfilariae are readily recognised by their sinuous movements in a centrifuged sample of the saline. Another option is to scarify the skin of a predilection site and examine the fluid exudate for microfilariae.

Pathology: A nodule forms around the worms with the head becoming fixed and surrounded by fibroblasts. Successive portions of the worm are drawn into the nodule, where they eventually lie coiled up and surrounded by a fibrous tissue capsule, which increases in thickness as the lesion grows older. In older nodules, degeneration of the tissues and calcification of the worms frequently takes place. The capsule consists of dense fibrous tissue containing blood vessels, leucocytes and lymph spaces. Microfilariae are common and wander in the lymph spaces. Their presence may lead to thickening of the dermis.

Epidemiology: The incidence of infection can be very high in endemic areas.

Treatment: In the past this has consisted of daily administration of diethylcarbamazine over a period as a microfilaricide, but it now appears that a single dose of ivermectin is highly efficient in this respect, although the dying microfilariae may provoke local tissue reactions. Affected carcasses must be trimmed to remove the nodules.

Control: With the ubiquity of the insect vectors there is little possibility of efficient control, though insect repellents will help reduce insect attack. In any case, with the relatively innocuous nature of the infection there is unlikely to be any demand for control.

Onchocerca ochengi

Synonym: *Onchocerca dermatata*

Predilection site: Connective tissue, scrotum and udder

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description: The slender worms range from 2.0 to 6.0 cm in length and lie tightly coiled in tissue nodules. In active lesions the presence of worms is readily established on section of these nodules.

Final host: Cattle

Intermediate hosts: Unknown

Geographical distribution: Parts of East and West Africa

Pathogenesis: *Onchocerca ochengi* in the skin causes some economic loss from blemished hides.

Clinical signs: Affected animals are not clinically ill and show no presenting signs other than subcutaneous nodules at the predilection sites.

Diagnosis: As for *O. gibsoni*

Pathology: Not reported

Epidemiology: The incidence of infection can be very high in endemic areas.

Treatment and control: As for *O. gibsoni*

Parafilaria bovicola

Common names: Summer 'bleeding disease', verminous nodules

Predilection site: Subcutaneous and intermuscular connective tissue

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Slender white worms 3.0–6.0 cm in length. Males are 2–3 cm and females 4–6 cm.

Description, microscopic: Anteriorly, there are numerous papillae and circular ridges in the cuticle. In the female the vulva is situated

anteriorly near the simple mouth opening. Small embryonated eggs, 45 by 30 µm, that have a thin flexible shell are laid on the skin surface where they hatch to release the microfilariae or L₁, which are about 200 µm in length.

Final hosts: Cattle, buffalo

Intermediate hosts: Muscid flies; *Musca autumnalis* in Europe

Geographical distribution: Africa, Asia, southern Europe and Sweden

Pathogenesis: Adult worms in the subcutaneous connective tissue induce small inflammatory lesions and haemorrhagic nodules, usually in the upper body regions. When the gravid female punctures the skin to lay her eggs, there is a haemorrhagic exudate or 'bleeding point' which streaks and mats the surrounding hairs and attracts flies. Individual lesions only bleed for a short time and healing is rapid. There is some evidence that exposure to sunlight is required to initiate bleeding of the nodules.

At the sites of infection, which are predominantly on the shoulders, withers and thoracic areas, there is inflammation and oedema which, at meat inspection, resemble subcutaneous bruising in early lesions and have a gelatinous greenish-yellow appearance with a metallic odour in longer-standing cases. Sometimes the lesions extend into the intermuscular fascia. The affected areas have to be trimmed at marketing and further economic loss is incurred by rejection or downgrading of the hides.

Clinical signs: The signs of parafilariosis, such as 'bleeding points' during the warmer seasons, are pathognomonic. Active bleeding lesions are seen most commonly in warm weather, an apparent adaptation to coincide with the presence of the fly intermediate host. The haemorrhagic exudate often streaks the hair and may lead to focal matting.

Diagnosis: This is normally based on clinical signs, but if laboratory confirmation is required the small embryonated eggs or microfilariae may be found on examination of fresh exudate from bleeding points. The demonstration of eosinophils in smears taken from lesions is also considered a constant diagnostic feature. Serodiagnosis using an ELISA technique has been developed.

Pathology: Nodules formed in the cutaneous and intermuscular connective tissue are 1–2 cm in diameter, enlarge in the summer months, burst open and haemorrhage and heal with scarring.

Epidemiology: In Europe, bovine parafilariosis occurs in spring and summer, disappearing in winter, whereas in tropical areas it is seen mainly after the rainy season. A high prevalence of 36% in cattle has been reported from some endemic areas in South Africa and the disease is now present in Sweden, an area previously free from infection. *Parafilaria* infection may be introduced by the importation of cattle from endemic areas, but its spread will depend on the presence of specific fly vectors. It has been estimated in Sweden that one 'bleeding' cow will act as a source of infection for three other animals.

Treatment: Patent infections in beef and non-lactating dairy cattle may be treated with ivermectin, moxidectin or nitroxylin. The former two drugs are given parenterally as a single dose, whereas two doses of nitroxylin are required at an interval of 3 days. None of these drugs is licensed for use in lactating cattle, when the less effective levamisole may be tried. These drugs produce a marked reduction in bleeding points and, due to resolution of the muscle lesions,

a significant reduction in meat condemnation if slaughter is delayed for 70 days after treatment.

Control: This is difficult because of the long prepatent period during which drugs are thought not to be effective. In Sweden, dairy cattle and particularly heifers at pasture are the main source of infection for *M. autumnalis*, which is an outdoor fly, active in spring and summer. However, infections in young beef cattle are the chief cause of economic loss through carcass damage.

Since neither ivermectin nor nitroxylin is effective against immature worms, treatment is only useful for patent infections recognizable by the clinical signs. However, because of restrictions on the use of ivermectin and nitroxylin in lactating cows, these are rarely treated and instead are kept indoors during the period of fly activity.

In endemic areas, young beef cattle may be treated with an anthelmintic some time before slaughter as described above. In Sweden the use of insecticide-impregnated ear tags has been recommended for vector control.

Notes: The adults of this genus of primitive filarioids live under the skin where they produce inflammatory lesions or nodules and, during egg laying, haemorrhagic exudates or 'bleeding points' on the skin surface.

Setaria labiato-papillosa

Synonyms: *Setaria cervi*, *Setaria altaica*, *Setaria digitata*

Common name: Bovine abdominal filariosis

Predilection site: Peritoneum, pleural cavity

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Long slender whitish worms, up to 12.0 cm in length, and in which the posterior end is spirally coiled. The site and gross appearance are sufficient for generic identification (Fig. 8.46). Males are 40–60 mm and females 60–120 mm in length.

Description, microscopic: The tail of the female ends in a marked button, which is divided into a number of papillae. Microfilariae are sheathed and measure 240–260 µm.

Figure 8.46 Worms of *Setaria* spp. in the mesentery.

Final hosts: Cattle, buffalo, bison, yak, and various deer and antelope, rarely sheep

Intermediate hosts: Mosquitoes (*Aedes*, *Culex*)

Geographical distribution: Worldwide

Pathogenesis: The worms in their normal site are usually harmless, occasionally inducing a mild fibrinous peritonitis and are only discovered at necropsy. *Setaria labiato-papillosa* may have an erratic migration in sheep and goats and enter the spinal canal causing cerebrospinal setariosis ('lumbar paralysis'), which is irreversible and often fatal; the condition has only been reported in the Middle and Far East.

Clinical signs: There are no clinical signs when the worms are in their normal site, but when nervous tissue is involved there is locomotor disturbance, usually of the hindlimbs, and if the parasites are high in the spinal canal there may be paraplegia.

Diagnosis: Infection with the adult worms is only accidentally discovered in the living animal by the finding of microfilariae in routine blood smears. In cases of cerebrospinal nematodosis, confirmatory diagnosis is only possible by microscopic examination of the spinal cord, since the parasites exist only as larval forms in their aberrant site.

Pathology: A mild fibrinous peritonitis may be found on postmortem. Migrating larvae affecting the CNS may cause areas of damage seen as brown foci or streaks grossly. The lesions show microcavitation and variable haemorrhage. There is loss of myelin and fragmentation of axons locally with eosinophils, neutrophils and macrophages present along with mild meningitis and vascular cuffing.

Epidemiology: Since the worms are usually innocuous, their epidemiology has received little study. The prevalence is higher in warmer countries, where there is longer seasonal activity of the mosquito vectors.

Treatment: There is no treatment for setarial paralysis.

Control: This would depend on control of the mosquito vectors, which is unlikely to be applied specifically for this parasite.

Notes: *Setaria labiato-papillosa* has often been referred to as *S. cervi*, although the latter species is considered a parasite of axis deer (*Cervus axis*). The parasite is also considered to be identical to *S. digitata*, although some consider the latter to be a valid and distinct species.

Setaria digitatus

Common name: Kumri

Predilection site: Peritoneum, pleural cavity

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: As for *S. labiato-papillosa*. The male is 40–50 mm and the female 60–80 mm in length.

Description, microscopic: The tail of the female ends in a simple button.

Final hosts: Cattle, buffalo

Intermediate hosts: Mosquitoes (*Armigeres*, *Aedes*, *Anopheles*, *Culex*)

Geographical distribution: Asia

Pathogenesis: The parasites inhabit the thoracic and peritoneal cavities causing little harm. Immature forms have been reported in the CNS of sheep, goats and horses causing epizootic cerebrospinal nematodosis. Affected animals suffer acute focal encephalo-myelomalacia, which causes acute or subacute tetraplegia or paraplegia of the hindlimbs.

Pathology: In aberrant hosts, migrating larvae affecting the CNS may cause areas of damage seen as brown foci or streaks grossly. Acute malacia occurs along the track of the worm such that the lesions show microcavitation and variable haemorrhage. There is loss of myelin and fragmentation of axons locally with eosinophils, neutrophils and macrophages present along with a mild meningitis and vascular cuffing.

Details on the life cycle, epidemiology, treatment and control are as for *S. labiato-papillosa*.

Parasites of the integument

Stephanofilaria stilesi

Predilection site: Skin

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: These are small nematodes, males measuring 2.6–3.7 mm and females 3.7–6.9 mm in length.

Description, microscopic: There are four to five cephalic spines and 18–19 peribuccal spines. The male spicules are unequal and the female worms have no anus. The thin-shelled eggs are 58–72 by 42–55 µm in size. Microfilariae are 45–60 µm in length and are characterised by a peribuccal elevation with a single spine and a short and rounded tail.

Final host: Cattle

Intermediate hosts: Horn fly (*Haematobia irritans*, *H. titillans*)

Geographical distribution: USA, Japan, Commonwealth of Independent States (CIS)

Pathogenesis: Lesions begin to appear within 2 weeks of infection. In this species, the lesions are usually localised to the preferred biting areas of the vectors on the lower abdomen, commonly along the mid-ventral line between the brisket and navel, but also on the udder, scrotum, flanks and ears. The flies feed predominantly along the mid-ventral line of the host and their bites create lesions that permit microfilariae to invade the skin. These lesions are attractive to both species of horn flies as well as non-biting muscids. Adult nematodes occur in the dermis and microfilariae in the dermal papillae of lesions but not in adjacent healthy tissue.

Clinical signs: In endemic regions, granulomatous and ulcerative lesions may be seen on the skin, particularly in the mid-ventral line between the brisket and navel (Fig. 8.47). The dermatitis can be exudative and haemorrhagic.

Figure 8.47 Granulomatous skin on the lower abdomen associated with *Stephanofilaria stilesi*.

Diagnosis: Though adult worms and microfilariae are present in the lesions, they are often scarce and many scrapings prove negative. Diagnosis is therefore usually presumptive in endemic areas, and is based on the appearance and site of the lesions. Deep skin scrapings macerated in saline will release microfilariae and adult worms. Biopsy sections readily reveal microfilariae and adults.

Pathology: The skin is at first nodular, but later there is papular eruption with an exudate of blood and pus. In the centre of the lesion there may be sloughing of the skin, but at the margin there is often hyperkeratosis and alopecia. The condition is essentially an exudative, often haemorrhagic, dermatitis that attracts the fly vectors. Sometimes the lesions are exacerbated by secondary bacterial infection.

Epidemiology: In endemic areas the incidence of infection may be as high as 90% and the occurrence is to a great extent influenced by the type of herbage. Succulent grazing produces soft moist faeces, which are more suitable breeding sites for the flies than the hard crumbly faeces deposited on sparse dry grazing. Hence, irrigation of pasture may result in an increase in stephanofilariosis. Although the lesions subside in cooler weather, the damage to the hide is permanent and may result in considerable economic loss. Milk yield may be severely diminished from the pain of the lesions and the irritation of cattle by the flies.

Treatment: Organophosphate compounds, such as trichlorphon, applied topically as an ointment have proved effective. Levamisole at 9–12 mg/kg by injection followed by daily application of zinc oxide ointment has also been reported as effective. Avermectins have reported activity against larval stages but have no appreciable effect against adult stages.

Control: Control of horn flies is feasible by the proper handling of manure and the use of insecticides. Macroyclic lactones applied topically give reported protection against horn flies for periods of up to 5 weeks.

Stephanofilaria dedoesi

Predilection site: Skin

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: These are small nematodes, males measuring 2.3–3.2 mm and females 6.1–8.5 mm in length.

Description, microscopic: The oral aperture is surrounded by a protruding cuticular rim with a denticulate edge. The anterior extremity has a circular thickening, which bears a number of small cuticular spines. The male spicules are unequal and the female worms have no anus.

Geographical distribution: Indonesia

Clinical signs: With *S. dedoesi*, lesions occur mainly on the head, legs and teats of cattle. The dermatitis can be exudative and haemorrhagic.

Other filarial species have been reported in cattle and buffalo in India and parts of Asia. The identification of individual species is beyond the scope of this book and interested readers will need to consult a relevant taxonomic specialist.

Stephanofilaria assamensis

Predilection site: Skin

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Geographical distribution: India in *Bos indicus*

Pathogenesis: Infection causes a marked dermatitis ('humpsore'), particularly in the hump, legs and neck.

Stephanofilaria okinawaensis

Predilection site: Skin

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: The parasites are small, rounded, whitish and slender-bodied. Females are 7.0–8.5 mm and males 2.7–3.5 mm in length

Stephanofilaria zaheeri

Predilection site: Skin

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Geographical distribution: India

Final hosts: Cattle, buffalo

Clinical signs: With *S. zaheeri*, lesions occur mainly on the head, legs and teats of cattle and buffalo.

Stephanofilaria kaeli**Predilection site:** Skin**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Filarioidea**Geographical distribution:** India***Parafilaria bovicola***

For more details see Parasites of connective tissue.

Dracunculus medinensis**Common names:** Guinea worm or Medina worm**Predilection site:** Subcutaneous connective tissue**Phylum:** Nematoda**Class:** Secernentea**Family:** Dracunculidae**Description, gross:** Males measure about 2–3 cm and females up to around 100 cm in length.**Description, microscopic:** The female worm has no vulva.**Final hosts:** Human and occasionally cattle, horse, dog, cat and other mammal**Intermediate hosts:** Copepod crustaceans (*Cyclops* spp.)**Geographical distribution:** Africa, the Middle East and parts of Asia**Pathogenesis:** Following initial infection there are virtually no signs of disease until the gravid adult female emerges in the subcutaneous tissues of the extremities. Pathogenesis is associated with the cutaneous ulcer formation.**Clinical signs:** The migration of the worm to the surface of the skin may induce pruritis and urticaria and a blister on an extremity.**Diagnosis:** Symptoms of dracunculosis are pathognomonic.**Pathology:** Secondary bacterial infection of the ulcer lesion or degeneration of worms can cause marked abscessation.**Epidemiology:** A major global eradication programme has reduced the incidence and importance of *D. medinensis*.**Treatment:** The worm may be gradually removed through the lesion by winding it round a small stick at a rate of about 2 cm each day or it may be surgically excised. Treatment with thiabendazole or niridazole, administered over several days, might be effective. Ivermectin or albendazole may be useful but efficacy data are lacking.**Control:** This is best achieved through the provision of clean drinking water or water that has been adequately sieved to remove any copepods.***Besnoitia besnoiti*****Synonym:** *Sarcocystis besnoiti***Predilection site:** Skin, conjunctiva**Phylum:** Apicomplexa**Class:** Conoidasida**Family:** Sarcocystiidae**Description:** The pseudocysts are non-septate and about 100–600 µm in diameter, with a thick wall containing thousands of merozoites but no merozoites.**Intermediate hosts:** Cattle, goat, wild ruminants (wildebeest, impala, kudu)**Final hosts:** Cat, wild cats (lion, cheetah, leopard)**Geographical distribution:** Worldwide, although important in tropical and subtropical countries, especially Africa.**Pathogenesis:** Following infection in cattle there is a systemic phase accompanied by lymphadenopathy and oedematous swellings in dependent parts of the body. Subsequently bradyzoites develop in fibroblasts in the dermis, subcutaneous tissues and fascia and in the nasal and laryngeal mucosa. The developing cysts in the skin result in a severe condition characterised by painful subcutaneous swellings and thickenings of the skin, loss of hair and necrosis. Apart from the clinical manifestations, which in severe cases can result in death, there can be considerable economic losses due to condemnation of hides at slaughter.**Clinical signs:** Affected animals show skin thickening, swelling, hair loss and skin necrosis. Photophobia, excessive lacrimation and hyperaemia of the sclera are present, and the cornea is studded with whitish elevated specks (pseudocysts).**Diagnosis:** Besnoitiosis can be diagnosed by biopsy examination of skin. The spherical encapsulated cysts are pathognomonic. The best method is examination of the scleral conjunctiva where the pseudocysts can be seen macroscopically.**Pathology:** This genus differs from other members of the Sarcocystiidae in that the cysts containing bradyzoites are found mainly in fibroblasts in or under the skin. The host cell enlarges and becomes multinucleate as the *Besnoitia* cyst grows within a parasitophorous vacuole, eventually reaching up to 0.6 mm in diameter (see Fig. 2.26).**Epidemiology:** Although infection of cattle is thought to be mainly by ingestion of sporulated oocysts from cat faeces, there is a suggestion that mechanical spread by biting flies feeding on skin lesions of cattle may be another route of transmission.**Treatment:** There is no known treatment.**Control:** Limiting contact of domestic cattle with cats can help reduce the incidence of infection. In countries where the disease is endemic in wildlife populations, control is difficult or impossible to achieve and may be limited to the elimination of infected animals.***Hypoderma* spp.****Class:** Insecta**Family:** Oestridae

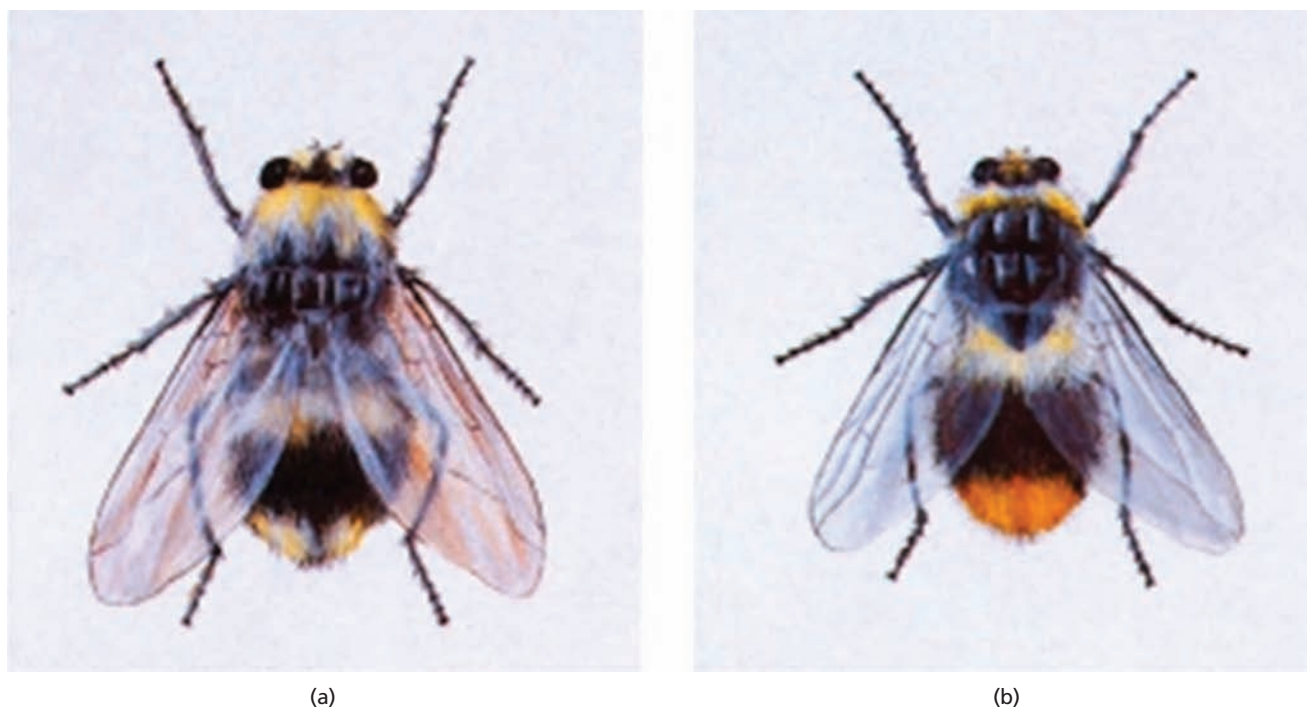

Figure 8.48 (a) *Hypoderma bovis*; (b) *Hypoderma lineatum*.

Description, adults: The adults are large and the abdomen is covered with yellow–orange hairs giving them a bee-like appearance (Fig. 8.48). The adults have no functioning mouthparts.

Description, larvae: The mature larvae are thick and somewhat barrel-shaped, tapering anteriorly. When mature they are 25–30 mm long, and most segments bear short spines. The colour is dirty white when newly emerged from the host, but rapidly turns to dark-brown; the pupa is almost black. The third-stage larvae of the two species of *Hypoderma* that commonly parasitise cattle (*H. bovis* and *H. lineatum*) may be distinguished from other species of *Hypoderma* by examination of the posterior spiracular plate, which is completely surrounded by small spines (Table 8.9). The two *Hypoderma* species in cattle may be distinguished from each other by the fact that in *H. bovis* the posterior spiracular plate surrounding the button has a narrow funnel-like channel, whereas in *H. lineatum* it has a broad channel (see Fig. 3.50).

Hosts: Cattle; the larvae occur erratically in other animals including equines, sheep and, very rarely, humans.

Table 8.9 Summary of differences between the *Hypoderma* species which parasitise cattle.

| Feature | <i>Hypoderma bovis</i> | <i>Hypoderma lineatum</i> |
|--------------------|--|---|
| Adult length | 15 mm | 13 mm |
| Eggs laid | Singly | In batches |
| Larval morphology | Posterior spiracular plate surrounding the button has a narrow funnel-like channel | Posterior spiracular plate surrounding the button has a broad channel |
| Migration path | Along nerves | Between the fascial planes of muscles and along connective tissue |
| Overwintering site | Epidural fat of the spinal cord | Sub mucosa of the oesophagus |

Geographical distribution: Northern hemisphere. However, *Hypoderma* is absent from extreme northern latitudes, including Scandinavia, and it has occasionally been found sparsely south of the equator in Argentina, Chile, Peru and southern Africa following accidental introduction in imported cattle.

Pathogenesis: By far the most important feature of this genus is the economic loss caused by downgrading and condemnation of hides perforated by larvae. The L₃ under the skin damage the adjacent flesh and this necessitates trimming from the carcass the greenish gelatinous tissue called ‘butcher’s jelly’, also seen in the infested oesophageal submucosal tissues. In addition the adult flies themselves are responsible for some loss. When they approach animals to lay their eggs, their characteristic buzzing noise, which appears to be instantly recognisable, causes the animals to panic or ‘gad’, sometimes injuring themselves on posts, barbed wire and other obstacles. Dairy cows show reduced milk yield and beef animals have reduced weight gain as a result of interrupted feeding. This species will pursue animals for some distance making repeated attacks.

Clinical signs: Except for poor growth and decreased milk yield in bad cases, the host animals show no appreciable signs until the larvae appear along the back. The presence of L₃ causes characteristic fluid-filled swellings (‘warbles’) in the dermis of the back, which can be seen and felt (Fig. 8.49).

Diagnosis: The presence of the larvae under the skin of the back allows diagnosis of warble flies. The eggs may also be found on the hairs of the animals in the summer. Immunodiagnostic tests may be used to detect animals infected with migrating larvae and hence those needing treatment.

Pathology: Warble larvae induce a pronounced tissue inflammation. The cellular reaction is predominantly eosinophilic and lymphocytic. The presence of the larvae also induces the production of

Figure 8.49 ‘Warble’ larvae of *Hypoderma* spp. on the back of a bovine animal.

a thickened connective tissue-lined cavity surrounding the larva, filled with inflammatory cells, particularly eosinophils. If larvae die in the spinal canal, the release of a highly toxic proteolysin may cause paraplegia. Larval death in other regions may, in very rare cases, lead to anaphylaxis in sensitised animals.

Treatment: *Hypoderma* is highly susceptible to systemically active organophosphate insecticides and to the macrocyclic lactones abamectin, ivermectin, doramectin, eprinomectin and moxidectin. The organophosphate preparations are applied as pour-ons to the backs of cattle and are absorbed systemically; macrocyclic lactones can be given by subcutaneous injection or pour-on.

Control: In control schemes in Europe, a single annual treatment is usually recommended, preferably in September, October or November. This is before the larvae of *H. bovis* have reached the spinal canal, so that there is no risk of spinal damage from disintegration of dead larvae. Treatment in the spring when the larvae have left their resting sites and arrived under the skin of the back, although effective in control, is less desirable since the breathing L₃ has then perforated the hide. However, in some countries such as the UK, such treatment is mandatory if warbles are present on the backs of cattle.

Successful eradication schemes supported by legislation, such as restriction of cattle movement on infected farms and compulsory treatment in the autumn, have been undertaken on islands such as the UK and Eire. For example, in the UK the prevalence of infected cattle was reduced from around 40% in the 1970s to virtually zero in the 1990s. However, evidence of infection is still encountered occasionally in animals imported into the UK. Other areas that have practised successful eradication such as Denmark and the Netherlands are clearly at greater risk of reintroduction.

Epidemiology: The flies occur in the summer, particularly from mid June to early September. They are most active on warm days, when they lay their eggs on cattle. The flies are limited in dispersal ability and can travel for more than 5 km.

Hypoderma bovis

Common names: Warble fly, northern cattle grub

Predilection site: Subcutaneous tissues, spinal canal

Description: Adult female *H. bovis* are about 15 mm in length and bee-like in appearance; the abdomen is covered with yellow–orange hairs with a broad band of black hairs around the middle (Fig. 8.48a). The hairs on the head and the anterior part of the thorax are greenish-yellow.

Hypoderma lineatum

Common names: Warble fly, common cattle grub, heel fly

Predilection site: Subcutaneous tissues, oesophagus

Description: Adult female *H. lineatum* are about 13 mm in length and bee-like in appearance; the abdomen is covered with yellow–orange hairs with a broad band of black hairs around the middle. The hairs on the head and the anterior part of the thorax are yellowish-white (Fig. 8.48b).

Pathogenesis: The panic reaction provoked by the approach of adult warble flies is less pronounced with *H. lineatum* than with *H. bovis*, since it reaches the animals by a series of hops along the ground and remains on the lower limb for a time while it lays its row of eggs, so that the animal may be unaware of its presence. Consequently, in parts of the USA this species is appropriately termed the ‘heel fly’. If larvae of *H. lineatum* die in the oesophageal wall, they may cause bloat through oesophageal stricture and faulty regurgitation. Larval death in other regions may, in very rare cases, lead to anaphylaxis in sensitised animals.

ECTOPARASITES

FLIES

The larval stages, ‘maggots’, of a number of species of fly (Diptera) are found in skin wounds on cattle and are listed in the host–parasite checklist at the end of this chapter. More detailed descriptions of these parasites can be found in Chapters 3 and 17.

LICE

Heavy louse infestation is known as pediculosis. Blood-sucking lice have been implicated in the transmission of disease such as those that transmit rickettsial anaplasmosis; however, lice are predominantly of importance because of the direct damage they cause. This effect is usually a function of their density. A small number of lice may be very common and present no problem. However, louse populations can increase dramatically reaching high densities. Transfer of lice from animal to animal or from herd to herd is usually by direct physical contact. Because lice do not survive for long off their host, the potential for animals to pick up infestations from dirty housing is limited, although it cannot be ignored. Occasionally, lice may also be transferred between animals by attachment to flies (phoresy).

Description: Lice have a segmented body divided into a head, thorax and abdomen. They have three pairs of jointed legs and a pair of short antennae. All lice are dorsoventrally flattened and wingless. The sensory organs are poorly developed; the eyes are vestigial or absent.

Geographical distribution: Worldwide, primarily in cooler areas

Pathogenesis: Light infestations are usually only discovered accidentally and should not be considered of any pathogenic importance, lice being almost normal inhabitants of the dermis and coat of many cattle, especially in winter. Moderate infestations are associated only with a mild chronic dermatitis, and are well tolerated. In heavier infestations there is pruritus, with rubbing and licking, but if sucking lice are present in large numbers there may be anaemia and weakness.

Clinical signs: Light infestations are usually only discovered accidentally. In these infections the lice and eggs are easily found by parting the hair, especially along the back, the lice being next to the skin and the eggs scattered like coarse powder throughout the hair. It is important to remember that a heavy louse infestation may itself be merely a symptom of some other underlying condition such as malnutrition or chronic disease, since debilitated animals do not groom themselves and leave the lice undisturbed. In such animals the shedding of the winter coat may be delayed for many weeks, retaining large numbers of lice.

Diagnosis: The lice may be seen on the skin. Removal and examination under a light microscope will allow species identification. The eggs are also visible and appear as white specks attached to the hairs.

Epidemiology: In warm countries there is no marked seasonality of bovine pediculosis, but in cold and temperate regions the heaviest infestations are in late winter and early spring, when the coat is at its thickest, giving a sheltered, bulky and humid habitat for optimal multiplication. The most rapid annual increase in louse populations is seen when cattle are winter-housed, and lice can build up in numbers very quickly. In late spring, there is usually an abrupt fall in the numbers of lice, most of the parasites and eggs being shed with the winter coat. Numbers generally remain low throughout the summer, partly because the thinness of the coat provides a restricted habitat, but partly also because high skin surface temperatures and direct sunlight limit multiplication and may even be lethal.

Treatment: The organophosphate insecticides (e.g. chlorfenvinphos, coumaphos, chlorpyrifos, crotoxyphos, trichlorphon, phosmet and propetamphos), usually applied as pour-on or spot-on applications, are effective in killing all lice. However, most insecticides registered for use on cattle are not very active against louse eggs. This means that after treatment eggs can still hatch and continue the infestation. A second treatment is therefore recommended 2 weeks later to kill newly emerged lice. Pour-on or spot-on synthetic pyrethroids, such as cypermethrin or permethrin, or pour-on avermectins may also be used, although the latter have only limited activity against chewing lice. Essential oils have been shown to be very effective against chewing lice when groomed into the hair.

Control: The timing and frequency of treatments depends very much on individual circumstances. In many cases treatment in late autumn or early winter will give adequate control of cattle lice. In Europe, louse control is usually undertaken when cattle are housed for the winter. Because a wide variety of chemical classes are effective, louse control is not difficult to achieve. Insecticide resistance is widespread in lice, and its rapid spread may be linked to the facultative parthenogenesis seen in many louse species. Hence, in an attempt to reduce the risk of selection for resistance, rotation of chemical classes is strongly advised. Treatment of all stock on farm and subsequent initial quarantine and treatment of all newly introduced animals will allow a good degree of louse control to be maintained.

Bovicola bovis

Synonym: *Damalinia bovis*

Common names: Red louse, cattle chewing louse

Predilection site: Favours the top of the head, especially the curly hair of the poll and forehead, the neck, shoulders, back and rump, and occasionally the tail switch.

Class: Insecta

Order: Phthiraptera

Suborder: Ischnocera

Family: Trichodectidae

Description: *Bovicola bovis* are a reddish-brown in colour with dark transverse bands on the abdomen. Adults measure up to 2 mm in length and 0.35–0.55 mm in width. The head is relatively large, as wide as the body, and is rounded anteriorly (Fig. 8.50; see also Fig. 3.69). The mouthparts are ventral and are adapted for chewing. The legs are slender and are adapted for moving among the hair. The claws, on each leg, are small.

Hosts: Cattle

Pathogenesis: The mouthparts of *B. bovis* are equipped for biting and chewing, and these lice feed on the outer layers of the hair shafts, dermal scales and blood scabs. If infestations increase, the lice may spread down the sides and may cover the rest of the body. This louse feeds by scraping away scurf and skin debris from the base of the hairs, causing considerable irritation to the host animal. The skin reaction can cause the hair to loosen and the cattle react to the irritation by rubbing or scratching, which will result in patches of hair being pulled or rubbed off. Scratching may produce wounds or bruises and a roughness to the skin. This may lead to secondary skin infections and skin trauma such as spot and fleck grain loss in the hide, reducing its value.

Figure 8.50 Chewing louse, *Bovicola*.

Epidemiology: *Bovicola bovis* is one of the commonest cattle parasites in Europe and it is the only chewing louse found on cattle in the USA. Though it causes less individual damage than sucking lice, it is present in larger numbers and so can be extremely damaging. Infested cattle may show disrupted feeding patterns.

Haematopinus eurysternus

Common name: Short-nosed louse

Predilection site: Skin, poll and at the base of the horns, in the ears, and around the eyes and nostrils and even in mild infestations it is found in the tail switch.

Class: Insecta

Order: Phthiraptera

Suborder: Anoplura

Family: Haematopinidae

Description: *Haematopinus eurysternus* is one of the largest lice of domestic mammals, measuring 3.4–4.8 mm in length. The louse is broad in shape, with a short pointed head (Fig. 8.51; see also Fig. 3.53). The head and thorax are yellow or greyish-brown, and the abdomen blue–grey with a dark stripe on each side. The hard-shelled eggs are opaque and white and are pointed at their base.

Hosts: Cattle

Pathogenesis: In severe infestations, the entire region from the base of the horns, over the face (Fig. 8.52) to the base of the tail can be infested.

Notes: This species is more commonly found infesting mature cattle than young animals. In North America, *Haematopinus eurysternus* is more prevalent in the Great Plains and Rocky Mountain regions.

Figure 8.51 Sucking louse, *Haematopinus eurysternus*.

Figure 8.52 Severe bovine pediculosis due to *Haematopinus eurysternus*.

Haematopinus quadripertusus

Common name: Tail louse

Predilection site: Tail and perineum

Class: Insecta

Order: Phthiraptera

Suborder: Anoplura

Family: Haematopinidae

Description: *Haematopinus quadripertusus* is a large eyeless louse about 4–5 mm in length. It has a dark well-developed thoracic sternal plate. Behind the antennae are prominent angular processes, known as ocular points or temporal angles. The legs are of similar sizes, each terminating in a single large claw that opposes the tibial spur. Distinct sclerotised paratergal plates are visible on abdominal segments 2 or 3 to 8.

Hosts: Cattle, commonly zebu cattle (*Bos indicus*)

Pathogenesis: *Haematopinus quadripertusus* feeds on host blood using its piercing mouthparts. In severe infestations, the entire region from the base of the horns to the base of the tail can be infested.

Epidemiology: This species is most commonly found among the long tail hairs at the base of the tail. Unlike other cattle lice, *Haematopinus quadripertusus* is most abundant during the summer and in warmer climates. The lice are transmitted through direct contact between hosts.

Haematopinus tuberculatus

Common name: Buffalo louse

Class: Insecta

Order: Phthiraptera

Suborder: Anoplura

Family: Haematopinidae

Description: A large louse measuring about 5.5 mm in length, with prominent ocular points but without eyes.

Hosts: Cattle, buffalo

Pathogenesis: Populations build up during the winter when the animal's coat is longer and thicker but it is not generally considered of any great clinical importance.

Notes: Known originally to infest buffalo but now found to infest cattle in Africa.

Linognathus vituli

Common name: Long-nosed cattle louse

Predilection site: Skin, preferring the head, neck and dewlap

Class: Insecta

Order: Phthiraptera

Suborder: Anoplura

Family: Linognathidae

Description: Bluish-black medium-sized louse with an elongated pointed head and body, approximately 2.5 mm in length (see Fig. 3.55). There are no eyes or ocular points. Forelegs are small. Mid-legs and hindlegs are larger, with a large claw and tibial spur. There are two rows of setae on each segment. The thoracic sternal plate is weakly developed or absent. The eggs may be dark in colour, and are less easy to see on hair. These lice are gregarious in habit, forming dense isolated clusters. While feeding they extend their bodies in an upright position.

Hosts: Cattle

Pathogenesis: This species is capable of transmitting bovine anaplasmosis, dermatomycosis (ringworm) and theileriosis.

Epidemiology: Heaviest infestation occurs in late winter and early spring, commonly on the head and around the eyes (Fig. 8.53).

Solenopotes capillatus

Common name: Little blue cattle louse

Predilection site: Skin of neck, head, shoulders, dewlap, back and tail

Figure 8.53 Heavy louse infestation of *Linognathus vituli*.

Class: Insecta

Order: Phthiraptera

Suborder: Anoplura

Family: Linognathidae

Description: Small bluish lice which tend to occur in clusters on the neck, head, shoulders, dewlap, back and tail. These lice may be distinguished from the genus *Linognathus* by the presence of abdominal spiracles set on slightly sclerotised tubercles, which project slightly from each abdominal segment (see Fig. 3.56). At 1.2–1.5 mm in length, *S. capillatus* is the smallest of the anopluran lice found on cattle. Eyes and ocular points are absent, and the louse has a short rostrum. There are no paratergal plates on the abdomen. The second and third pairs of legs are larger than the first pair and end in stout claws. In contrast to species of *Linognathus*, the thoracic sternal plate is distinct. The eggs of this louse species are small, short and dark blue.

Hosts: Cattle

MITES

The ectoparasitic mites of cattle feed on blood, lymph, skin debris or sebaceous secretions, which they ingest by puncturing the skin, scavenge from the skin surface or imbibe from epidermal lesions. Most ectoparasitic mites spend their entire lives in intimate contact with their host, so that transmission from host to host is primarily by physical contact. Infestation by mites is called acariosis and can result in severe dermatitis, known as mange, which may cause significant welfare problems and economic losses.

Demodex bovis

Predilection site: Hair follicles and sebaceous glands

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Demodicidae

Description: Species of *Demodex* have an elongate tapering body, up to 0.1–0.4 mm in length, with four pairs of stumpy legs ending in small blunt claws in the adult (see Fig. 3.100). Setae are absent from the legs and body. The legs are located at the front of the body, and as such the striated opisthosoma forms at least half the body length.

Hosts: Cattle

Geographical distribution: Worldwide

Pathogenesis: The most important effect of bovine demodicosis is the formation of many pea-sized nodules, each containing caseous material and several thousand mites, which cause hide damage and economic loss. Although these nodules can be easily seen in smooth-coated animals, they are often undetected in rough-coated cattle until the hide has been dressed. Problems caused by demodicosis in cattle are primarily a result of the damage caused to the hides. In some rare cases demodicosis may become generalised and fatal.

Clinical signs: Pea-sized nodules containing caseous material and mites, particularly on the withers, lateral neck, back and flanks. Concurrent pyoderma may occur, leading to furunculosis with ulceration and crust formation.

Diagnosis: For confirmatory diagnosis, deep scrapings are necessary to reach the mites deep in the follicles and glands. This is best achieved by taking a fold of skin, applying a drop of liquid paraffin, and scraping until capillary blood appears.

Pathology: In cattle cutaneous nodules consist of follicular cysts lined with squamous epithelium and filled with waxy keratin squames and mites. Eruption of the cysts on to the skin may form a thick crust; rupture within the dermis may form an abscess or granulomatous reaction.

Epidemiology: Probably because of its location deep in the dermis, it is almost impossible to transmit *Demodex* between animals unless there is prolonged contact. Such contact usually only occurs during suckling, and as such it is thought that most infections are acquired in the early weeks of life. The muzzle, neck, withers and back are all common sites of infestation.

Treatment: In many cases demodicosis spontaneously resolves and treatment is unnecessary. The organophosphate trichlorphon, used on three occasions 2 days apart, and systemic macrocyclic lactones may be effective.

Control: Control is rarely applied since there is little incentive for farmers to treat their animals, as the cost of damage is borne by the hide merchant.

Notes: Species of the genus *Demodex* are highly specialised mites that live in the hair follicles and sebaceous glands of a wide range of wild and domestic animals, including humans. They are believed to form a group of closely related sibling species that are highly specific to particular hosts: *Demodex phylloides* (pig), *Demodex canis* (dog), *Demodex bovis* (cattle), *Demodex equi* (horse), *Demodex musculi* (mouse), *Demodex rattii* (rat), *Demodex caviae* (guinea-pig), *Demodex cati* (cat) and *Demodex folliculorum* and *Demodex brevis* on humans.

In some parts of Australia 95% of hides are damaged, and surveys in the USA have shown one-quarter of the hides to be affected. In Britain 17% of hides have been found to have *Demodex* nodules.

Psorobia bovis

Synonym: *Psorergates bos*

Common name: Cattle itch mite

Predilection site: Skin, all over the body

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Psorergatidae

Description: *Psorobia bovis* is a small mite, roughly circular in form and less than 0.2 mm in diameter. The legs are arranged more or less equidistantly around the body circumference, giving the mite a crude star shape (see Fig. 3.103). Larvae of *P. bovis* have short stubby legs. The legs become progressively

longer during the nymphal stages until, in the adult, the legs are well developed and the mites become mobile. Adults are about 190 µm long and 160 µm wide. The tarsal claws are simple and the empodium is pad-like. The femur of each leg bears a large, inwardly directed, curved spine. In the adult female, two pairs of long whip-like setae are present posteriorly; in the male there is only a single pair.

Hosts: Cattle

Geographical distribution: Australia, New Zealand, southern Africa, North and South America. It has not been reported in Europe.

Pathogenesis: Little or no pathogenic effect

Clinical signs: There are few clinical signs associated with infestations of this mite. Mites may occur on apparently normal skin without causing itching of the host animal.

Diagnosis: To obtain mites it is necessary, having clipped away a patch of hair, to apply a drop of mineral oil and scrape the skin down to the blood capillary level. The mites themselves are easily identified.

Pathology: Rarely the mite may cause alopecia and desquamation, but in the majority of cases there appears to be no recognisable lesion associated with the infection.

Epidemiology: This mite is not normally considered to be of clinical significance.

Treatment: *Psorobia* is relatively unsusceptible to most acaricides, although the formamidine amitraz has recently been shown to be of considerable value. Otherwise, the older arsenic–sulphur preparations may be used. Macrocyclic lactones may be effective.

Control: Regular checks of livestock and treatments will keep infection rate under control.

Psoroptes ovis

Synonyms: *Psoroptes communis* var. *ovis*, *Psoroptes cuniculi*, *Psoroptes cervinus*, *Psoroptes bovis*, *Psoroptes equi*

Predilection site: Skin, particularly the legs, feet, base of tail and upper rear surface of the udder

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Psoroptidae

Description: *Psoroptes* mites are up to 0.75 mm in length and oval in shape (see Fig. 3.92). All the legs project beyond the body margin. Its most important recognition features are the pointed mouthparts and the three-jointed pretarsi (pedicels) bearing funnel-shaped suckers (pulvilli) (see Fig. 3.87). Adult females have jointed pretarsi and pulvilli on the first, second and fourth pairs of legs and long whip-like setae on the third pair. In contrast, the smaller adult males, which are recognisable by their copulatory suckers and paired posterior lobes, have pulvilli on the first three pairs of legs and setae on the fourth pair. The legs of adult females are approximately the same length, whereas in males the fourth pair is extremely short.

Figure 8.54 Bovine psoroptic mange.

Pathogenesis: In cattle these mites cause intense pruritus, papules, crusts, excoriation and lichenification (Fig. 8.54). Lesions may cover almost the entire body; secondary bacterial infections are common in severe cases. Death in untreated calves, weight loss, decreased milk production and increased susceptibility to other diseases can occur.

Treatment: In cattle, dipping and topical application of non-systemic acaricides, such as the organophosphates (diazinon, coumaphos or phosmet), amitraz or a lime-sulphur dip, may be effective. Dippings should be repeated at 2-week intervals. The topical application of flumethrin is also used in some parts of the world. Most treatments are not licensed for use in dairy cattle. Injectable formulations of avermectins (ivermectin and doramectin) and milbemycins (moxidectin) may be effective, although following treatment with ivermectin the isolation of treated animals for 2–3 weeks after treatment is required to prevent reinfestation. Eprinomectin is available as a pour-on formulation, and is the only macrocyclic lactone that may be used in dairy cattle.

Following diagnosis, the treatment of all animals on infected premises and subsequent treatment of all incoming stock is recommended.

For a more detailed description see Chapter 9.

Psoroptes natalensis

Predilection site: Skin, particularly the legs, feet, base of tail and upper rear surface of the udder

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Psoroptidae

Description: Very similar to *P. ovis* but it is believed that *P. natalensis* can be distinguished morphologically by the length and spatulate shape of the fourth outer opisthosomal seta of the male. However, the precise species status of *P. natalensis* has yet to be confirmed.

Hosts: Primarily buffalo but it has been reported on cattle.

For treatment and pathogenesis see *P. ovis*.

Chorioptes bovis

Synonyms: *Chorioptes ovis*, *Chorioptes equi*, *Chorioptes caprae*, *Chorioptes cuniculi*

Predilection site: Skin, particularly the legs, feet, base of tail and upper rear surface of the udder

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Psoroptidae

Description: Adult female *Chorioptes bovis* are about 300 µm in length (see Fig. 3.93), considerably smaller than *Psoroptes ovis*. *Chorioptes* do not have jointed pretarsi; their pretarsi are shorter than in *Psoroptes* and the sucker-like pulvillus is more cup-shaped, as opposed to trumpet-shaped in *Psoroptes* (see Fig. 3.87). In the adult female, tarsi I, II and IV have short-stalked pretarsi and tarsi III have a pair of long, terminal, whip-like setae. The first and second pairs of legs are stronger than the others and the fourth pair has long slender tarsi. In the male, all legs possess short-stalked pretarsi and pulvilli. However, the fourth pair is extremely short, not extending beyond the body margin. Male *C. bovis* have two broad flat setae and three normal setae on well-developed posterior lobes. The mouthparts are distinctly rounder, and the abdominal tubercles of the male are noticeably more truncate than those of *Psoroptes* (see Fig. 3.87).

Hosts: Cattle, sheep, horse, goat, rabbit

Geographical distribution: Worldwide

Pathogenesis: In cattle, chorioptic mange occurs most often in housed animals, particularly dairy animals, affecting mainly the neck, tail head, udder and legs. Usually only a few animals in a group are clinically affected. The mites are found more commonly on the hindleg than on the foreleg. It is a mild condition, and lesions tend to remain localised, with slow spread. Its importance is economic, the pruritus caused by the mites resulting in rubbing and scratching, with damage to the hide. High infestations have been associated with decreased milk production. The treatment is the same as for sarcoptic mange in cattle.

Clinical signs: Hosts can be asymptomatic with low densities of mites present and thus act as carriers that transfer the mite to other animals. Host reactions are normally only induced when the numbers increase to thousands of mites per host. Scabs or scales develop on the skin of the lower parts of the body. There is some exudation and crust formation on the legs and lower body, but in most cases this does not spread over a wide area. Infected animals may stamp and scratch infected areas. The majority of the mites are likely to be found on the lower leg, particularly the pastern and foot. However, in some animals the infestation may become acute and generalised, and closely resemble infestation with *Psoroptes*.

Diagnosis: Skin scrapings from the suspect lesions should be taken for microscopic examination.

Pathology: The pathology is highly variable depending on the intensity and duration of infection; subclinical infections are common. Clinically affected animals may have pustular, crusted, scaly and lichenified lesions and alopecia.

Epidemiology: Mite populations are highest in the winter and may regress over summer. It is the most common type of mange in cattle in the USA.

Treatment: The dips used for psoroptic mange in cattle are also effective against *Chorioptes*. They should be repeated at 2-week intervals. Ivermectin, doramectin, eprinomectin and moxidectin applied topically as a pour-on are also effective against chorioptic mange.

Control: Regular checks of livestock and quarantining of infected animals will help to control the frequency and extent of infestations.

Notes: The names *Chorioptes ovis*, *Chorioptes equi*, *Chorioptes caprae* and *Chorioptes cuniculi* used to describe the chorioptic mites found on sheep, horses, goats and rabbits, respectively, are now all thought to be synonyms of *Chorioptes bovis*.

Sarcoptes scabiei

Common name: Scabies

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Sarcoptidae

Description: Adult mites have a round, ventrally flattened, dorsally convex body (see Fig. 3.89). Adult females are 0.3–0.6 mm long and 0.25–0.4 mm wide, while males are smaller, typically up to 0.3 mm long and 0.1–0.2 mm wide. The posterior two pairs of limbs do not extend beyond the body margin. In both sexes, the pretarsi of the first two pairs of legs bear empodial claws and a sucker-like pulvillus, borne on a long stalk-like pretarsus. The sucker-like pulvilli help the mite grip the substrate as it moves. The third and fourth pairs of legs in the female and the third pair of legs in the male end in long setae and lack stalked pulvilli. The mouthparts have a rounded appearance. These mites have no eyes or stigmata. The dorsal surface of the body of *S. scabiei* is covered with transverse ridges, but also bears a central patch of triangular scales. The dorsal setae are strong and spine-like. The anus is terminal and only slightly dorsal. There are a number of host-adapted varieties of *S. scabiei* that differ subtly in their morphology.

Pathogenesis: Sarcoptic mange is potentially the most severe of the cattle manges, although many cases are mild. Nevertheless, it is being increasingly diagnosed in Britain and in some areas, including Canada and parts of the USA, the disease is notifiable and the entry of cattle carrying *Sarcoptes*, whether clinically affected or not, is not permitted. The mite has partial site preferences, which have given it, in the USA, the common name of ‘neck and tail mange’, but it may occur on any part of the body. Mild infections merely show scaly skin with little hair loss, but in severe cases the skin becomes thickened, there is marked loss of hair and crusts form on the less well haired parts of the body (Fig. 8.55), such as the escutcheon

Figure 8.55 Characteristic lesions of bovine sarcoptic mange.

of cows. There is intense pruritus leading to loss of meat and milk production and to hides being downgraded because of damage by scratching and rubbing.

Treatment and control: Treatment has largely depended on the use of repeated washes or sprays usually organochlorine insecticides such as gamma-hexachlorocyclohexane. However, organochlorine insecticides are not now available in most countries. Systemic macrocyclic lactones may give good results. Alternatively, the application of a pour-on organophosphate such as phosmet, on two occasions at an interval of 14 days, is also effective. Neither macrocyclic lactones nor phosmet are licensed for use in lactating animals whose milk is used for human consumption. The formamidine amitraz is effective against sarcoptic mange in cattle and has withdrawal periods of 24 and 48 hours, respectively, for meat and milk.

For further details see Chapter 11.

A number of non-obligate ectoparasites are found on cattle and are listed in the host–parasite checklist at the end of this chapter. More detailed descriptions of these parasites can be found in Chapters 3 and 17.

HOST–PARASITE CHECKLIST

In the following checklists, the codes listed below apply:

Helminths

N, nematode; T, trematode; C, cestode; A, acanthocephalan.

Arthropods

F, fly; L, louse; S, flea; M, mite; Mx, maxillopod; Ti, tick.

Protozoa

Co, coccidia; Bs, blood sporozoa; Am, amoeba; Fl, flagellate; Ci, ciliate.

Miscellaneous ‘protozoal organisms’

B, blastocyst; Mi, microsporidian; My, Mycoplasma; P, Pneumocystidomycete; R, Rickettsia.

Parasites of sheep and goats

ENDOPARASITES

Parasites of the digestive system

OESOPHAGUS

Gongylonema pulchrum

Synonym: *Gongylonema scutatum*

Common name: Gullet worm

Predilection site: Oesophagus, rumen

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: A long, slender whitish worm, the males being about 5.0 cm and the females up to about 14.0 cm in length.

Description, microscopic: Worms are easily distinguished microscopically by the presence of longitudinal rows of cuticular bosses in the anterior region of the body. Asymmetrical cervical alae are prominent. The egg is thick-shelled and possesses two opercula. It measures 50–70 by 25–37 µm and contains an L₁ when passed in faeces.

Final hosts: Sheep, goat, cattle, pig, buffalo, horse, donkey, deer, camel, human, primates

Intermediate hosts: Coprophagous beetles, cockroaches

Geographical distribution: Probably worldwide

Pathogenesis: Infection is usually regarded as non-pathogenic, though infection has been associated with a mild chronic oesophagitis in ruminants. *Gongylonema pulchrum* in humans presents as a painful tumour-like area in the oral epithelium or subcutaneous tissues that contains coiled worms.

Clinical signs: Usually asymptomatic in ruminants

Diagnosis: Usually an incidental finding on postmortem

Pathology: Adult worms bury in the epithelium of the forestomachs producing white or red, blood-filled zig-zag tracts in the mucosa.

Epidemiology: Infection is very much dependent on the presence and abundance of the intermediate hosts, principally coprophagous beetles of the genera *Aphodius*, *Onthophagus*, *Blaps*, *Caccobius* and *Onthophagus*. Humans can acquire infection through direct ingestion

of the intermediate host. Also water can contain infective larvae that have emerged from infected cockroaches in the water source.

Treatment: Not reported

Control: Control is not practical, nor necessary.

RUMEN AND RETICULUM

Gongylonema verrucosum

Common name: Rumen gullet worm

Predilection site: Rumen, reticulum, omasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Long slender worms, reddish when fresh. The males are about 3.5 cm and the females 7.0–9.5 cm in length.

Description, microscopic: The adult parasites have a festooned cervical ala and cuticular bosses only on the left side of the body. The males' spicules are unequal in length with the left spicule longer than the right.

Final hosts: Cattle, sheep, goat, deer

Intermediate hosts: Coprophagous beetles and cockroaches

Geographical distribution: India, South Africa, USA

For additional details see Chapter 8.

Gongylonema monnigi

Common name: Rumen gullet worm

Predilection site: Rumen, reticulum, omasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: A long, slender, whitish worm, the males being about 4 cm and the females up to about 11 cm in length.

Description, microscopic: Similar to *G. verrucosum* except the cervical alae are not festooned.

Final hosts: Sheep, goat

Intermediate hosts: Coprophagous beetles, cockroaches

Geographical distribution: South Africa

Paramphistomum and other rumen fluke

Rumen flukes are mainly parasitic in the forestomachs of ruminants. Their shape is not typical of the trematodes, being conical and thick and fleshy rather than flat. All require a water snail as an intermediate host. There are several genera: *Paramphistomum*, *Cotylophoron*, *Bothriophoron*, *Orthocoelium* and *Giganocotyle*, of which *Paramphistomum* is the most common and widespread in ruminants.

The taxonomy of the paramphistomes is complex and unresolved and many of the species described may be synonymous, being differentiated mainly on size and shape of the suckers.

Details on the pathogenesis, treatment and control of rumen fluke are provided in Chapter 8.

Paramphistomum cervi

Synonym: *Paramphistomum explanatum*

Common name: Rumen fluke

Predilection site: Rumen

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Description, gross: The adults are small conical (pear-shaped) maggot-like flukes about 1.0 cm long and light red in colour when fresh (see Fig. 8.2).

Description, microscopic: One sucker is visible at the tip of the cone and the other well-developed sucker is at the base. The tegument has no spines. The larval stages are less than 5.0 mm, fresh specimens having a pink colour. The egg resembles that of *Fasciola hepatica*, being large (about 115–175 × 75–100 μm), and operculate, but is transparent or slightly greenish rather than yellowish-brown and slightly smaller than eggs of *F. hepatica* (Fig. 9.1). In the early

Fig. 9.1 Rumen fluke eggs (Paramphistomatidae) (arrowed) with yellowish-brown egg of *Fasciola hepatica*.

stages of segmentation the egg contains four to eight blastomeres surrounded by yolk cells.

Final hosts: Cattle, sheep, goat, deer, buffalo, antelope

Intermediate hosts: Water snails, principally *Planorbis* and *Bulinus* spp.

Paramphistomum microbothrium

Common name: Rumen fluke

Predilection site: Rumen

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Final hosts: Cattle, sheep, goat, deer, buffalo, antelope

Intermediate hosts: Freshwater snails (*Fossaria* spp., *Bulinus* spp.)

Geographical distribution: Africa

Paramphistomum streptocoelium

Synonyms: *Ceylonocotyle streptocoelium*, *Orthocoelium streptocoelium*

Common name: Rumen fluke

Predilection site: Rumen

Phylum: Platyhelminthes

Class: Trematoda

Superfamily: Paramphistomatidae

Final hosts: Cattle, sheep, goat and wild ruminants

Intermediate hosts: Freshwater snails (*Glyptaniscus* spp.)

Geographical distribution: Africa

Paramphistomum ichikawa

Common name: Rumen fluke

Predilection site: Rumen

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Final hosts: Sheep, cattle

Intermediate hosts: Planorbid snails (*Gyraulus*, *Helicorbis*, *Segnetilia*)

Geographical distribution: Southeast Asia

Calicophoron daubneyi

Synonyms: *Paramphistomum daubnei*, *Paramphistomum daubneyi*

Common name: Rumen fluke

Predilection site: Rumen

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Description: Resembles *P. cervi*, but there is a genital sucker surrounding the genital pore.

Final hosts: Cattle, goat

Intermediate hosts: Freshwater snails (*Omphiscola* spp.)

Geographical distribution: Europe (mainly Mediterranean areas but also recorded in the UK), parts of Asia

Cotylophoron cotylophorum

Synonym: *Paramphistomum cotylophorum*

Common name: Rumens fluke

Predilection site: Rumens, reticulum

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Description, microscopic: The fluke is very similar to *Paramphistomum cervi* but the genital pore is surrounded by a genital sucker. The egg measures 125–135 by 60–68 µm.

Final hosts: Cattle, sheep, goat and wild ruminants

Intermediate hosts: Freshwater snails (*Bulinus* spp.).

Geographical distribution: India, Australia

Calicophoron calicophorum

Synonym: *Paramphistomum calicophorum*

Common name: Rumens fluke

Predilection site: Rumens, reticulum

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Description, microscopic: The body measures 7.5–14.8 by 3–4 mm, and the genital pore is post-bifurcal. Eggs are 110–150 by 60–90 µm.

Final hosts: Sheep, cattle and wild ruminants

Geographical distribution: India, Australasia and South Africa

Gastrothylax crumenifer

Common name: Rumens fluke

Predilection site: Rumens, reticulum

Phylum: Platyhelminthes

Class: Trematoda

Family: Gastrothylacidae

Description, gross: This is an elongated fluke, being circular in transverse section and reddish in colour when fresh. The body measures 10–16 by 5–8 mm.

Description, microscopic: These flukes differ in having an extremely large ventral pouch that opens anteriorly and which covers the ventral surface of the fluke as far as the large ventral sucker. The ventral pouch is normally triangular in cross-section with a dorsally directed apex. The terminal genitalium opens into the ventral pouch about halfway between the intestinal bifurcation and the pharynx. The terminal oval sucker is small. Eggs are 115–135 by 66–70 µm.

Final hosts: Cattle, buffalo, zebu, sheep and many other ruminants

Geographical distribution: Indian subcontinent, China, Middle East, Africa and parts of Asiatic Russia and Europe

Pathogenesis: The fluke mainly causes anaemia.

Fischoederius elongatus

Predilection site: Rumens, duodenum or anterior small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Gastrothylacidae

Description, gross: The flukes are reddish when fresh. The body measures 10–20 by 3–5 mm.

Description, microscopic: The terminal genitalium is within the ventral pouch. The uterus is situated along the midline. The testes are lobed and one is sited dorsally to the other. Eggs measure 125–150 by 65–75 µm.

Final hosts: Cattle, buffalo, zebu, sheep and many other ruminants. It can accidentally infect humans.

Geographical distribution: Asia

Pathogenesis: Flukes in the rumens usually cause only mild congestion but flukes attached to the duodenum can result in thickening of the mucosa.

Fischoederius cobboldi

Predilection site: Rumens, duodenum or anterior small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Gastrothylacidae

Description, gross: The flukes are reddish in colour when fresh. The body measures 8–10 mm in length.

Description, microscopic: Eggs measure 110–120 by 60–75 µm.

Final hosts: Cattle, buffalo, zebu, sheep and many other ruminants

Geographical distribution: Asia

Pathogenesis: Similar to that of *F. elongatus*.

Monocercomonas ruminantium

Synonyms: *Trichomonas ruminantium*, *Tritrichomonas ruminantium*

Predilection site: Rumen

Phylum: Preaxostyla

Class: Tritrichomonadea

Family: Monocercomonadidae

Description: The trophozoite is subspherical, 3–8 by 3–7 μm , with a rounded anterior end. The axostyle is curved and may or may not extend beyond the body. A pelta and parabasal body are present. The cytostome and anterior nucleus are anterior. There are three anterior flagella and a trailing one (see Fig. 2.18).

Hosts: Cattle, sheep

Geographical distribution: Worldwide

Pathogenesis: Not considered to be pathogenic.

Diagnosis: Identification of trophozoites based on morphological examination.

Epidemiology: Transmission presumably occurs by ingestion of trophozoites from faeces or rumen contents.

Treatment and control: Not required

Monocercomonoides caprae

Synonyms: *Monocercomonas caprae*, *Monocercomonoides sayeedi*

Predilection site: Caecum

Phylum: Preaxostyla

Class: Anaeromonadea

Family: Polymastigidae

Description: Trophozoites are ovoid, 6–12 μm long by 4–8 μm wide.

Host: Goats

ABOMASUM

Teladorsagia circumcincta

Synonym: *Ostertagia circumcincta*

Morph species: *Ostertagia trifurcata*, *Teladorsagia davtiani*

Common name: Brown stomach worm

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: Adults are slender reddish-brown worms with a short buccal cavity. Males measure 6–8 mm and females 8–10 mm.

Description, microscopic:

- *Teladorsagia circumcincta*. The lateral lobes of the bursa are well developed but the dorsal lobe is small; a telamon is present in the genital cone; the accessory bursal membrane is small and is supported by two divergent rays (see Fig. 1.23). Spicules are variable in length but normally long and thin (see Table 1.4e and Fig. 1.24a). The posterior end is split into two branches of equal length. A third short offshoot, not readily seen, arises in front of the bifurcation. The gubernaculum is racket-shaped. The vulva is usually covered with a large flap. The tail tapers gradually and ends in a slender rounded tip that has four to five transverse striations. Eggs are medium-sized (about 80–100 \times 40–55 μm) and are a regular ellipse with not very wide poles (see Fig. 4.3). The shell is thin and smooth and contains many blastomeres which totally fill the egg and which are often hard to distinguish.
- *Ostertagia trifurcata*. The bursa is longer than in *T. circumcincta*. The lateral lobes of the bursa are well developed and the dorsal lobe is small; a well-developed telamon is present in the genital cone. The accessory bursal membrane is modified to form Sjoberg's organ supported by two rays. Spicules are short and broad (see Table 1.4f and Fig. 1.25); the posterior end is divided into three processes, one long and thick with a truncated end, and two short slender branches each tapering to a point. The gubernaculum is somewhat spindle-shaped.
- *Teladorsagia davtiani*. Adult male worms are similar in appearance to *O. trifurcata*. The accessory bursal membrane is modified to form Sjoberg's organ and resembles a pair of sessile papillae on the posterior extremity of the genital cone (see Fig. 1.26).

Hosts: Sheep, goat, deer

Geographical distribution: Worldwide

Pathogenesis: In clinical infections, this resembles the situation in cattle and similar lesions are present at necropsy, although the morocco leather appearance of the abomasal surface seen in cattle is not common in sheep and goats. In subclinical infections, it has been shown under both experimental and natural conditions that *T. circumcincta* causes a marked depression in appetite and this, together with loss of plasma protein into the gastrointestinal tract and sloughed intestinal epithelium, results in interference with the post-absorptive metabolism of protein. In lambs with moderate infections of *T. circumcincta*, carcass evaluation can show poor protein and fat deposition. Skeletal growth can also be impaired.

Clinical signs: The most frequent clinical sign is a marked loss of weight. Diarrhoea is intermittent and although stained hindquarters are common, the fluid faeces that characterise bovine ostertagiosis are less frequently seen.

Diagnosis: This is based on clinical signs, seasonality of infection and faecal egg counts and, if possible, postmortem examination, when the characteristic lesions can be seen in the abomasum. Plasma pepsinogen levels are above the normal of about 0.8 iu tyrosine and usually exceed 2.0 iu in sheep with heavy infections.

Pathology: The pathology is similar to that described for *O. ostertagi* in cattle. The developing parasites cause distension of parasitised gastric glands, leading to a thickened hyperplastic gastric mucosa similar to that seen in cattle (see Fig. 8.6). In heavy infections these nodules coalesce and the abomasal folds are often very oedematous and hyperaemic.

Epidemiology: In sheep, *T. circumcincta* and *O. trifurcata* are responsible for outbreaks of clinical disease, particularly in lambs. In Europe a clinical syndrome analogous to type I bovine ostertagiosis occurs from August to October; thereafter arrested development of many ingested larvae occurs and a type II syndrome has been occasionally reported in late winter and early spring, especially in young adults. In subtropical areas with winter rainfall outbreaks of disease occur primarily in late winter.

Temperate regions In Europe, the herbage numbers of *T. circumcincta* L₃ increase markedly from midsummer onwards and this is when most disease appears. These larvae are derived mainly from eggs passed in the faeces of ewes during the periparturient period, from about 2 weeks prior to lambing until about 6 weeks after lambing. Eggs passed by lambs, from worm burdens which have accrued from the ingestion of overwintered larvae, also contribute to pasture contamination. It is these eggs deposited in the first half of the grazing season from April to June which give rise to the potentially dangerous populations of L₃ from July to October. If ingested prior to October, the majority of these larvae mature in 3 weeks; thereafter, many become arrested in development for several months and may precipitate type II disease when they mature.

Immunity is acquired slowly and usually requires exposure over two grazing seasons before significant resistance to infection develops. Subsequently, adult ewes harbour only very low populations of *Teladorsagia* except during the annual periparturient rise (PPR).

Subtropical regions The epidemiology in subtropical areas is basically similar to that in temperate zones, except that the seasonal timing of events is different. In many of these areas lambing is geared to an increase in the growth of pasture, which occurs with the onset of rain in late autumn or winter. This coincides with conditions which are favourable to the development of the free-living stages of *Teladorsagia* and so infective larvae accumulate during the winter to cause clinical problems or production loss in the second half of the winter; arrested larval development occurs at the end of the winter or early spring. The sources of pasture contamination are again the ewes, during the PPR, and the lambs, following ingestion of larvae that have survived the summer. The relative importance of these sources in any country varies according to the conditions during the adverse period for larval survival. Where the summer is very dry and hot, the longevity of L₃ is reduced, except in areas with shade and these can act as reservoirs of infection until the following winter. Although L₃ can persist in sheep faeces during adverse weather conditions, the protection is probably less than that afforded by the more abundant bovine faecal pat.

Ostertagia trifurcata In temperate regions this is similar to *T. circumcincta*. In tropical and subtropical zones where the summer is very dry and hot, the longevity of L₃ is reduced except in areas with shade and these can act as reservoirs of infection until the following winter. Although L₃ can persist in sheep faeces during adverse weather conditions, the protection is probably less than that afforded by the more abundant bovine faecal pat. In winter rainfall areas the numbers of *Ostertagia* and *Teladorsagia* larvae on pasture reach a maximum in late winter and decline markedly through spring into summer as the pastures dry out.

Treatment: Ovine teladorsagiosis often responds well to treatment with any of the modern benzimidazoles or pro-benzimidazoles, levamisole (which in sheep is effective against arrested larvae), the

avermectins/milbemycins or the recently introduced monepantel and derquantel (in combination with abamectin). However, the widespread prevalence of isolates of *T. circumcincta* that are resistant to the benzimidazoles, and increasingly resistant to levamisole and macrocyclic lactones, dictates that farmers must monitor the resistance status of their flocks to ensure that an effective anthelmintic is used. Treated lambs should preferably be moved to safer pasture, but one which contains infective larvae *in refugia*; if this is not possible, treatment may have to be repeated at 6-weekly intervals until the pasture larval levels decrease in late autumn.

Many of the anthelmintics recommended for sheep are not registered for use in goats. Where goat milk or milk products are used for human consumption, milk-withholding periods for different drugs should be observed. Thiabendazole has antifungal properties and should not be used when milk is processed for cheese.

Control: See section Treatment and control of parasitic gastroenteritis in sheep.

Notes: Considered to be a polymorphic species with at least two male morphs, *Teladorsagia circumcincta* and *Ostertagia trifurcata*, and possibly a third, *Teladorsagia davtiani*. The females cannot be differentiated but are distinguishable from other ostertagian females.

Treatment and control of parasitic gastroenteritis in sheep

The recommendations outlined here are applicable to temperate areas of the northern hemisphere, but the principles can be adapted to local conditions in other regions.
