Treatment In fat lamb production systems, because of the short period between birth and marketing, treatments for parasitic gastroenteritis (PGE) are generally given preventively rather than as specific therapeutic interventions to treat disease outbreaks. However, when necessary, treatment with any of the benzimidazoles, levamisole, an avermectin/milbemycin or the new drugs monepantel and the dual-active derquantel–abamectin will remove adult worms and developing stages, unless resistance to some of the older drugs is present in the flock. Treatment with these two new compounds should be used strategically and integrated into parasite control options for the farm along with existing anthelmintics where these still possess a reasonably high level of efficacy. Following treatment, lambs can be moved to pasture not grazed by sheep that year, but it is important that these pastures have sufficient levels of larvae *in refugia* to dilute any larvae arising from eggs of worms that have survived treatment. The occasional outbreaks of type II teladorsagiosis (ostertagiosis) in young adult sheep in the spring may be treated with the same anthelmintics. Unlike *O. ostertagi* in calves, the arrested stages of the common sheep nematodes are susceptible to the benzimidazoles and levamisole.

Control Although the control of PGE in sheep is based on the same principles as those described for *O. ostertagi* in cattle, its practice is somewhat different for the following reasons.

- 1 The PPR (periparturient rise in faecal egg counts) is very marked in ewes and is the most important cause of pasture contamination with nematode eggs in the spring.
- 2 PGE in sheep is generally associated with a variety of nematode genera with differing epidemiological characteristics.

- 3 Most sheep graze throughout their lives so that pasture contamination with nematode eggs and the intake of infective larvae is almost continuous and modified only by climatic restrictions.
- 4 Anthelmintic resistance is now widespread throughout many sheep-rearing areas of the world and therefore strategies are required to manage existing resistance and/or to limit the further development of resistant isolates. In Britain, for example, guidelines for the use of anthelmintics in sustainable control strategies for sheep in northern temperate areas have been produced (Sustainable Control of Parasites in Sheep or SCOPS; available at www.scops.org.uk) and are outlined in Table 9.1.

The key factors which define the rate of development of anthelmintic resistance, on which the SCOPS principles are based, are summarized directly from the guidelines:

- the proportion of worms on a farm that carry resistant alleles;
- the frequency of anthelmintic use;
- the efficacy of each treatment;
- the proportion of the total worm population in the animal at the time of treatment;
- the speed with which any surviving parasites are subsequently diluted with unselected parasites *in refugia*.

Summary of guidelines for the control of gastrointestinal nematodes and use of anthelmintics in sheep and goats

Anthelmintic usage

- 1 **Use anthelmintics sparingly.** This will reduce the selection pressure for further development of drug resistance. Effective monitoring of faecal egg counts is integral to this approach. This strategy is discussed more fully under treatment of ewes and lambs.

Table 9.1 SCOPS Guidelines.

|--|
| <ol style="list-style-type: none"> 1 Work out a control strategy with your veterinarian or adviser. The need for specialist consultation is greater now than ever before. Decisions about the judicious use of anthelmintics in worm control programmes are complex, and will require ongoing consultations 2 Use effective quarantine strategies to prevent the importation of resistant worms in introduced sheep and goats. Introduction of resistance alleles is considered a major cause of anthelmintic resistance in UK flocks. The recommended treatments also prevent the importation of <i>Haemonchus contortus</i> 3 Test for anthelmintic resistance on your farm. Knowing which products (chemical groups) are effective in a flock is fundamental to an effective control strategy 4 Administer anthelmintics effectively. Administer the right dose in the correct way, and exploit opportunities to enhance drug efficacy to ensure maximum kill rates 5 Use anthelmintics only when necessary. Understand the trade-off between tolerating some level of parasitism and minimising selection for anthelmintic resistance. Faecal egg count monitoring has an important role 6 Select the appropriate anthelmintic for the task. Consider narrow-spectrum treatments whenever possible. Alternate chemical groups in appropriate ways 7 Adopt strategies to preserve susceptible worms on the farm. Aim to reduce the heavy selection for anthelmintic resistance imposed when treating sheep with strong acquired immunity or when dosing on to low contamination pastures 8 Reduce dependence on anthelmintics. Use alternative control measures when possible. These include grazing management, risk assessment and using rams that have been selected for resistance to nematodes |
|--|

Source: Abbott *et al.* (2012).

- 2 **Use anthelmintics effectively.** It is important to check the dosing equipment regularly and to apply correct techniques to maximise the efficacy of the drug and also to ensure that the drug is stored according to the manufacturer's recommendations. It is important to read the instructions for injectable products as the injection site can vary depending on whether the drug is long-acting or whether it is administered subcutaneously or intramuscularly. Sheep should be dosed at the rate recommended for the heaviest animal in a subgroup to reduce the likelihood of underdosing.
- 3 **Monitor for anthelmintic resistance.** It is essential to ensure that the drug to be administered will be effective. The resistance status of each family of anthelmintic should be assessed on the farm.
- 4 **Use the appropriate anthelmintic.** In some situations it may be possible to target treatment by using a narrow-spectrum drug, for example closantel against a specific infection dominated by *Haemonchus* or a benzimidazole against *Nematodirus*. Avoidance of a broad-spectrum drug in these circumstances will reduce the selection pressure on this family of anthelmintics. Annual rotation of anthelmintic families can be useful, especially where resistance to the macrocyclic lactones is absent or at a very low level. This strategy will have minimal impact where multiple resistance is firmly established.

Control strategies (see also Chapter 6)

- 1 **Use effective quarantine procedures.** It is essential to treat all sheep and goats imported onto the home farm effectively in order to prevent the introduction of anthelmintic-resistant worms. This may involve the introduction of new livestock or it may involve the return of stock that has been temporarily grazed away from the main farm on other pastures. If any resistant worms survive the quarantine treatment, then their numbers should be so low that the emergence of anthelmintic resistance will be greatly delayed. This may be difficult on farms with resistance to all three families of drugs. The recent availability in some countries of the new 4-AD class of anthelmintic (i.e. monepantel) and the new dual-active containing both derquantel (5-SI) and abamectin (3-ML) provide new drug choices for this treatment dose. A narrow-spectrum product may also be useful in some circumstances. In many northern temperate areas, resistance is mainly to the benzimidazoles with some resistance to levamisole and emerging resistance to the macrocyclic lactones. In these circumstances the SCOPS guidelines recommends the treatment of all imported sheep either **sequentially** with a moxidectin anthelmintic (3-ML) and monepantel (4-AD) **or** with a single treatment using the new dual-active product derquantel–abamectin. Treated animals should be held off pasture for 24–48 hours to allow any worm eggs in the alimentary tract to pass out in the faeces.
- 2 **Use strategies to conserve susceptible worms.** The aim is to lower the selection pressure for development of resistance which occurs when sheep are treated and moved on to pasture with low contamination or when immune animals are treated. Two approaches are appropriate. Firstly, do not move treated sheep immediately on to low contamination pasture as any worms which survive treatment will not be diluted by large numbers of more susceptible parasites. Instead, delay moving the sheep from contaminated pasture after dosing to allow them to become lightly reinfected and then move them onto the 'cleaner' grazing. Secondly, leave a proportion (about 10%) of the flock untreated so that some animals will shed eggs on to

the low-contamination pasture. There is inevitably a trade-off between the potential to reduce selection for resistance versus some loss of productivity.

- 3 **Use strategies that reduce the reliance on anthelmintics.** Approaches which integrate grazing management will reduce the exposure to infective larvae, and thus reduce the adverse effects of infection on productivity, while allowing sufficient exposure to induce a measure of acquired immunity. This strategy is considered in more detail in the following sections.

In selecting the best method of prophylaxis, much depends on whether the farm consists primarily of permanent pasture or has pastures which are rotated with crops so that new leys or hay and silage aftermaths are available each year.

Prophylaxis on farms consisting of mainly permanent pasture

On such farms control may be obtained either by anthelmintic prophylaxis or by alternate grazing on an annual basis with cattle and sheep. The former is the only feasible method where the farm stock is primarily sheep, while the latter can be used where cattle and sheep are both present in reasonable proportions.

Prophylaxis by anthelmintics Intensive chemoprophylaxis is not a long-term option for the sustainable control of ovine and caprine PGE.

- 1 **Adult sheep at tupping.** At this time most ewes in good body condition will be carrying low worm burdens as they will have a strong acquired immunity. Treatment at this period can significantly select for anthelmintic resistance. It is therefore recommended that only mature ewes with a low body condition score or immature ewes are dosed around tupping. Use an anthelmintic which is effective against arrested larval stages.
- 2 **Adult sheep at lambing.** The most important source of infection for the lamb crop is undoubtedly the increase in nematode eggs in ewe faeces during the PPR and prophylaxis will only be efficient if this is kept to a minimum. Effective anthelmintic therapy of ewes during the fourth month of pregnancy should eliminate most of the worm burdens present at this time, including arrested larval stages and in the case of ewes on extensive grazing, where nutritional status is frequently low, this treatment often results in improved general body condition. Treatment around lambing or turnout, and again 4–5 weeks later, will significantly reduce the ewe contribution to pasture contamination, but it may also increase the selection for drug resistance. To reduce the selection pressure it has been suggested that ewes are dosed early in the lactation period to allow them to become reinfected before a high level of immunity is re-established. In addition, leaving a proportion of the ewes untreated will allow the pasture to be contaminated with unselected parasites. However, both of these approaches could increase the risk of disease in the lamb crop later in the season. Where ewes are inwintered or housed for a period before lambing, dose them on entry to the shed. Following turnout on to contaminated pasture they may require further treatment in about 4–5 weeks. An alternative to the gathering of ewes for these treatments is to provide anthelmintic incorporated in a feed or energy block during the periparturient period. The results obtained with the latter system appear to be best when the ewes are contained in small paddocks or fields, as the uptake of drug is less consistent under

extensive grazing systems. Rumen boluses designed for the slow release of anthelmintics over a prolonged period are available in some countries for sheep and are recommended for use in ewes during the periparturient period to eliminate worm egg output. Young adults and rams should also be treated at these times.

- 3 **Lambs.** Treatment for *Nematodirus battus* infection is considered separately under the relevant section. In general, lambs should be treated at weaning, and where possible moved to 'safe' pastures, i.e. those not grazed by sheep since the previous year. Where such grazing is not available, prophylactic treatments (using either a levamisole, benzimidazole, pro-benzimidazole or avermectin/milbemycin product) should be repeated until autumn or marketing. Where anthelmintic resistance has been confirmed to one or more of these drugs, their use should either be discontinued or targeted at known specific and susceptible worm populations, and the introduction of the new 4-AD or 5-SI family of anthelmintics should be considered where these drugs are available. The number of treatments will vary depending on the stocking rate, and levels of challenge that the lambs experience between weaning and marketing, for those under more intensive conditions. In order to reduce unnecessary dosing of lambs, it is recommended that faecal egg counts are monitored to predict the need for treatment.

The prophylactic programmes outlined are relatively costly in terms of drugs and labour but are currently the only practicable options available where the enterprise is heavily dependent on one animal species.

Prophylaxis by alternate grazing of sheep and cattle On farms where sheep and cattle are both present in significant numbers, effective control is theoretically possible by alternating the grazing of pasture on an annual basis with each host, due to the relative insusceptibility of cattle to sheep nematodes and vice versa. However, *Nematodirus battus* can infect young susceptible calves and this may inadvertently contaminate pasture which is being prepared for next season's lambs. In practice, control is best achieved by exchanging, in the spring, pastures grazed by sheep and beef cattle over the previous year, preferably combined with anthelmintic treatment at the time of exchange.

Prophylaxis on farms with alternative grazing

In these mostly intensive farms, rotation of crops and grass is often a feature, and therefore new leys and hay and silage aftermaths are available as safe pastures each year and can be reserved for susceptible stock. In such a situation, control should be based on a combination of grazing management and anthelmintic prophylaxis.

- 1 **Prophylaxis by grazing management and anthelmintics.** Good control is possible with only one annual anthelmintic treatment of ewes when they leave the lambing field. This will terminate the PPR in faecal egg counts prior to moving the ewes and lambs to a safe pasture. At weaning, the lambs should be moved to another safe pasture and an anthelmintic treatment of the lambs at this time is good policy. A second system has been devised for farms where arable crops, sheep and cattle are major components and involves a 3-year rotation of cattle, sheep and crops. With this system the aftermath grazing available after cropping may be used for weaned calves and weaned lambs. It has been suggested that anthelmintic prophylaxis can be disposed of completely under this system, but clinical PGE

has sometimes occurred when treatment has been omitted. As anthelmintics may not remove all the worms present and some cattle nematodes can infect sheep and vice versa, and because a few infective larvae on the pasture can survive for beyond 2 years, it is advisable to give at least one annual spring treatment to all stock prior to moving to new pastures, following current advice not to move treated lambs immediately after treatment and to also leave a proportion undosed in order to reduce the pressures on selection for anthelmintic resistance.

- 2 Prophylaxis by grazing management alone.** Systems using strip or creep grazing, which limit the return of sheep to pastures until the contamination has declined to a low level, have been used with some success but are costly in terms of labour and fencing. A system where sheep are rapidly rotated through a series of paddocks has been used for the control of *Haemonchus* in set tropical areas. Sheep only graze a paddock for 3.5–4 days and are then moved to the next paddock. A short grazing time is required to prevent autoinfection. Return to the original paddock must not occur at an interval of less than 5 weeks. Under the hot humid environment the infective larvae are very active and die out rapidly on the herbage.

Ostertagia leptospicularis

Synonyms: *Ostertagia crimensis*, *Skrjabinagia kolchida*, *Grosspiculagia podjapolskyi*

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: Adults are slender reddish-brown worms with a short buccal cavity. Males measure 6–8 mm and females 8–9 mm in length.

Description, microscopic: Distinguished from other ostertagian species by the length of the oesophagus, which is longer than in other species (0.7 mm compared with approximately 0.6 mm). In cattle, the worms are thinner than *O. ostertagi* and male worms are differentiated on spicule morphology (see Table 1.4).

Hosts: Deer (roe deer), cattle, sheep, goat, camel

Geographical distribution: Many parts of the world, particularly Europe and New Zealand

For more details see Chapter 8.

Marshallagia marshalli

Synonyms: *Ostertagia marshalli*, *Ostertagia tricuspis*

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: Similar to *Ostertagia* spp. and can be differentiated by its greater length (males 10–13 mm, females 15–20 mm).

Description, microscopic: Males have a long thin dorsal ray, which bifurcates near the posterior extremity. The end of the spicule is divided into three small processes, surrounded by a transparent membrane. The ellipsoidal eggs are much larger than those of *Ostertagia* spp., measuring 160–200 by 75–100 µm and resemble those of *Nematodirus battus*. The thick-shelled eggs have almost parallel sides and contain a morula in an advanced stage of development when passed in the faeces (see Fig. 4.3). The eggs can be differentiated from those of *Nematodirus* as the morula is more developed and the geographical distribution of the worms is different.

Hosts: Sheep, goat, deer, camel and wild small ruminants

Geographical distribution: The tropics and subtropics including southern Europe, USA, South America, India and Russia

Pathogenesis and clinical signs: Generally *M. marshalli* is not considered to be an important pathogen.

Diagnosis: Adults are readily identified based on the structure of the male spicules. Eggs are recognised in faecal samples by their large size.

Epidemiology: Wild ruminants serve as an important reservoir of infection.

Treatment and control: Anthelmintics used to treat other gastrointestinal nematodes are likely to be effective.

Notes: Other species include *M. mongolica*, which is found in the abomasum of sheep, goats and camels in parts of Mongolia, and *M. schikhobalovi* and *M. dentispicularis*, which occur in sheep in Russia.

Haemonchus contortus

Synonym: *Haemonchus placei* (see Notes)

Common name: Barber's pole worm

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Family: Trichostrongyloidea

Description, gross: The adults are easily identified because of their specific location in the abomasum and their large size (2.0–3.0 cm) (Fig. 9.2). In fresh specimens, the white ovaries winding spirally around the blood-filled intestine produce a 'barber's pole' appearance (see Fig. 1.28).

Description, microscopic: The male has an asymmetrical dorsal lobe and barbed spicules (see Fig. 1.29a); the female usually has a vulval flap. The vulva is situated at the beginning of the posterior third of the body. This is a useful feature for distinguishing *Haemonchus* from *Mecistocirrus*, where the vulva is positioned near to the tip of the tail. In both sexes there are cervical papillae (see Fig. 1.29b) and a tiny lancet inside the buccal capsule. Infective larvae have 16 gut cells, the head is narrow and rounded and the tail of the sheath is offset. The egg is medium-sized (64–95 × 40–50 µm) and is a regular broad ellipse with barrel-shaped side walls and flattened wide poles (see Fig. 4.3). The chitinous shell is thin, slightly light-yellowish in colour, smooth and the egg contains numerous

Fig. 9.2 Adult *Haemonchus contortus* on the surface of the abomasum.

blastomeres which nearly fill the entire volume. The blastomeres are not readily distinguished. Infective larvae measure around 690 µm (see Fig. 4.14).

Hosts: Sheep, goat, cattle, deer, camel, llama

Geographical distribution: Worldwide; most important in tropical and subtropical areas

Pathogenesis: Essentially, the pathogenesis of haemonchosis is that of an acute haemorrhagic anaemia due to the blood-sucking habits of the worms. Each worm removes about 0.05 mL of blood per day by ingestion and seepage from the lesions, so that a sheep with 5000 *H. contortus* may lose about 250 mL daily. In acute haemonchosis, anaemia becomes apparent about 2 weeks after infection and is characterised by a progressive and dramatic fall in the packed red cell volume. During the subsequent weeks the haematocrit usually stabilises at a low level, but only at the expense of a twofold to threefold compensatory expansion of erythropoiesis. However, due to the continual loss of iron and protein into the gastrointestinal tract and increasing inappetence, the marrow eventually becomes exhausted and the haematocrit falls still further before death occurs. When ewes are affected, the consequent agalactia may result in the death of the suckling lambs. Less commonly, in heavier infections of up to 30,000 worms, apparently healthy sheep may die suddenly from severe haemorrhagic gastritis (Fig. 9.3). This is termed hyperacute haemonchosis.

Fig. 9.3 Abomasal haemorrhages in acute haemonchosis.

Perhaps as important as acute haemonchosis in tropical areas is the lesser-known syndrome of chronic haemonchosis. This develops during a prolonged dry season when reinfection is negligible, but the pasture becomes deficient in nutrients. Over such a period the continual loss of blood from small persisting burdens of several hundred worms is sufficient to produce clinical signs associated primarily with loss of weight, weakness and inappetence rather than marked anaemia.

Clinical signs: In hyperacute cases, sheep die suddenly from haemorrhagic gastritis.

Acute haemonchosis is characterised by anaemia (Fig. 9.4), variable degrees of oedema, of which the submandibular form and ascites are most easily recognised, lethargy, dark-coloured faeces and falling wool. Diarrhoea is not generally a feature. Chronic haemonchosis is associated with progressive weight loss and weakness, neither severe anaemia nor gross oedema being present.

Diagnosis: The history and clinical signs are often sufficient for the diagnosis of the acute syndrome especially if supported by faecal worm egg counts. Necropsy, paying attention to both the abomasum and the marrow changes in the long bones, is also useful. Changes are usually evident in both, although in sheep which have just undergone 'self-cure' (see section Epidemiology) or are in a terminal stage of the disease, the bulk of the worm burden may have been lost from the abomasum. In hyperacute haemonchosis, only the abomasum may show changes since death may have occurred so rapidly that marrow changes are minimal. The diagnosis of chronic haemonchosis is more difficult because of the concurrent presence of poor nutrition and confirmation may have to depend on the gradual disappearance of the syndrome after anthelmintic treatment.

Pathology: At necropsy in cases of acute haemonchosis, there may be between 2000 and 20,000 worms present on the abomasal mucosa, which shows numerous small haemorrhagic lesions. The abomasal contents are fluid and dark brown due to the presence of altered blood. The carcass is pale and oedematous and the red marrow has expanded from the epiphyses into the medullary cavity.

Epidemiology: The epidemiology of *H. contortus* is best considered separately, depending on whether it occurs in tropical and subtropical or in temperate areas.

Fig. 9.4 Anaemia and submandibular oedema characteristic of haemonchosis.

Tropical and subtropical areas Because larval development of *H. contortus* occurs optimally at relatively high temperatures, haemonchosis is primarily a disease of sheep in warm climates. However, since high humidity, at least in the microclimate of the faeces and the herbage, is also essential for larval development and survival, the frequency and severity of outbreaks of disease is largely dependent on the rainfall in any particular area.

Given these climatic conditions, the sudden occurrence of acute clinical haemonchosis appears to depend on two further factors. First, the high faecal worm egg output of between 2000 and 20,000 epg, even in moderate infections, means that massive pasture populations of L₃ may appear very quickly. Second, in contrast to many other helminth infections, there is little evidence that sheep in endemic areas develop an effective acquired immunity to *Haemonchus*, so that there is continuous contamination of the pasture.

In certain areas of the tropics and subtropics, such as Australia, Brazil, the Middle East and Nigeria, the survival of the parasite is also associated with the ability of *H. contortus* larvae to undergo hypobiosis. Although the trigger for this phenomenon is unknown, hypobiosis occurs at the start of a prolonged dry season and permits the parasite to survive in the host as arrested L₄ instead of maturing and producing eggs, which would inevitably fail to develop on the arid pasture. Resumption of development occurs just before the onset of seasonal rains. In other tropical areas such as East Africa, no significant degree of hypobiosis has been observed and this may be due to more frequent rainfall in these areas making such an evolutionary development unnecessary.

The survival of *H. contortus* infection on tropical pastures is variable depending on the climate and degree of shade, but the infective larvae are relatively resistant to desiccation and some may survive for 1–3 months on pasture or in faeces.

In areas of endemic haemonchosis it has often been observed that after the advent of a period of heavy rain the faecal worm egg counts of sheep infected with *H. contortus* drop sharply to near zero levels due to the expulsion of the major part of the adult worm burden. This event is commonly termed the self-cure phenomenon, and has been reproduced experimentally by superimposing an infection of *H. contortus* larvae on an existing adult infection in the abomasum. The expulsion of the adult worm population is considered to be the consequence of an immediate-type hypersensitivity reaction to antigens derived from the developing larvae. It is thought that a similar mechanism operates in the naturally occurring self-cure when large numbers of larvae mature to the infective stage on pasture after rain. Although this phenomenon has an immunological mechanism, it is not necessarily associated with protection against reinfection since the larval challenge often develops to maturity.

Another explanation of the self-cure phenomenon as it occurs in the field is based on the observation that it may happen in lambs and adults contemporaneously and on pasture with insignificant numbers of infective larvae. This suggests that the phenomenon may also be caused, in some non-specific way, by the ingestion of fresh growing grass. Whatever the cause, self-cure is probably of mutual benefit to both host and parasite. The former gains a temporary respite from persistent blood loss while the ageing parasite population is eventually replaced by a vigorous young generation.

Temperate areas In the British Isles, the Netherlands and presumably in other parts of northern Europe and in Canada, which are among the least favourable areas for the survival of *H. contortus*, the epidemiology is different from that of tropical zones. From the information available, infections seem to develop in two ways.

Perhaps most common is the single annual cycle. Infective larvae, which have developed from eggs deposited by ewes in the spring, are ingested by ewes and lambs in early summer. The majority of this worm population become arrested in the abomasum as EL₄, and does not complete development until the following spring. During the period of maturation of these hypobiotic larvae, clinical signs of acute haemonchosis may occur and in the ewe this often coincides with lambing. The epidemiology is unknown, but is perhaps associated with pasture contamination by that proportion of ingested larvae which did not undergo hypobiosis in early summer.

Treatment: When an acute outbreak has occurred the sheep should be treated with one of the benzimidazoles, levamisole, an avermectin/milbemycin, or a salicylanilide (closantel) and moved to pasture not recently grazed by sheep. When the original pasture is grazed again, prophylactic measures should be undertaken, as enough larvae may have survived to institute a fresh cycle of infection. Chronic haemonchosis is dealt with in a similar fashion. If possible the new pasture should have a good nutritional value; alternatively, some supplementary feeding may be given.

Control: In the tropics and subtropics this varies depending on the duration and number of periods in the year when rainfall and temperature permit high pasture levels of *H. contortus* larvae to develop. At such times it may be necessary to use an anthelmintic at intervals of 2–4 weeks depending on the degree of challenge. Sheep should also be treated at least once at the start of the dry season and preferably also before the start of prolonged rain to remove persisting hypobiotic larvae whose development could pose a future threat. For this purpose, one of the modern benzimidazoles or an avermectin/milbemycin is recommended. In some wool-producing areas where *Haemonchus* is endemic, closantel, which has a residual prophylactic effect, may be used. Because of long withdrawal periods, this is of more limited use in meat-producing animals.

Apart from anthelmintic prophylaxis, some studies, especially in Kenya, have indicated the potential value of some indigenous breeds of sheep, which seem to be naturally highly resistant to *H. contortus* infection. Presumably such breeds could be of value in developing areas of the world where veterinary surveillance is poor. Rapid rotation through a series of paddocks can be effective in certain wet tropical areas (for details see discussion of prophylaxis by grazing management alone in the section Treatment and control of parasitic gastroenteritis in sheep).

In temperate areas, the measures outlined for the control of PGE in sheep are usually sufficient to pre-empt outbreaks of haemonchosis.

Currently, trials are in progress to determine the efficacy of both a recombinant vaccine based on a membrane glycoprotein of intestinal microvilli, and on native antigens, for the control of parasitic stages of *H. contortus*.

Notes: Until recently the sheep species was called *H. contortus* and the cattle species *H. placei*. However, there is now increasing evidence that these are the single species *H. contortus* with only strain adaptations for cattle and sheep.

Trichostrongylus axei

Synonym: *Trichostrongylus extenuatus*

Common name: Stomach hairworm

Predilection site: Abomasum or stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are small, hair-like, light brownish-red and difficult to see with the naked eye. Males measure around 3–6 mm and females 4–8 mm in length.

Description, microscopic: There is no buccal capsule and the anterior of the worm and the vulval area lacks any accessory cuticular structures. The bursa is simple in form and the ventro-ventral ray is positioned well apart from the other rays. The male spicules are dissimilar and unequal in length, the right being shorter than the left (see Table 1.3a and Fig 1.11). The female has double ovejectors. The eggs are medium-sized, an irregular ellipse and measure about 70–106 by 30–45 μm . The poles are dissimilar, one being more rounded, and are not very wide (see Fig. 4.3).

Hosts: Cattle, sheep, goat, deer, horse, donkey, pig and occasionally human

Geographical distribution: Worldwide

Pathogenesis: The extent of the lesions in the abomasum or stomach is dependent on the size of the worm population. Small irregular areas showing diffuse congestion and whitish-grey, raised, circular lesions may be present in the pyloric and fundic regions. These lesions are about 1–2 cm in diameter and have been termed plaques or ringworm lesions (Fig. 9.5). In heavy infections, shallow ulcers may be seen. The changes induced in the gastric mucosa are similar to those of *Ostertagia*, with an increase in pH and increased permeability of the mucosa leading to an increase in plasma pepsinogen concentration and hypoalbuminaemia.

Clinical signs: The principal clinical signs in heavy infections are rapid weight loss and diarrhoea. At lower levels of infection, inappetence and poor growth rates, sometimes accompanied by soft faeces, are the common signs.

Diagnosis: This is based on clinical signs, seasonal occurrence of disease and, if possible, lesions at postmortem examination. Faecal egg counts are a useful aid to diagnosis, although faecal cultures are

Fig. 9.5 Raised plaques in abomasum due to *Trichostrongylus axei*.

necessary for generic identification of larvae. At necropsy, *T. axei* is easily identified from washings and digests of the abomasum or stomach.

Pathology: In sheep, there is often extensive desquamation of the superficial epithelium of the mucosa. A mucoid hyperplasia is seen in the plaques and in longer-established infections there may be shallow ulcers in the neck regions of the glands. Cellular infiltration of the lamina propria occurs, particularly an influx of eosinophils and lymphocytes. In most cases there is not a marked reduction in the number of parietal or zymogen cells. Over time, infection can lead to a chronic proliferative inflammation and shallow depressed ulcers may be present.

Epidemiology: The embryonated eggs and infective L₃ of *T. axei* can survive under adverse conditions. Larval numbers increase on pasture in late summer/autumn, often giving rise to clinical problems during the winter and early spring. Immunity is slowly acquired and age immunity is not well developed.

Treatment and control: See section Treatment and control of parasitic gastroenteritis in sheep.

Parabronema skrjabini

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: The white slender adult worms (up to 3.6 cm long) resemble *Haemonchus* spp. somewhat in gross form and size, but without the red spiral coloration, while the younger worms are closer to *Ostertagia* in appearance. Males measure 15–18 mm with one spicule.

Description, microscopic: The genus is readily distinguished from the other abomasal worms by the presence of large cuticular shields and cordons in the cephalic region. The tail of the male is spiral with four pairs of pre-anal papillae.

Final hosts: Sheep, goat, cattle, camel

Intermediate hosts: Muscid flies of the genera *Stomoxys* and *Lyperosia*

Geographical distribution: Central and East Africa, Asia, and some Mediterranean countries, notably Cyprus

Pathogenesis: *Parabronema* is usually regarded as non-pathogenic, although it can cause nodular lesions in the abomasal wall.

Clinical signs: Usually inapparent

Diagnosis: Abomasal worms may be found in abomasal scrapings on postmortem.

Pathology: Non-specific. An abomasitis may be found and lesions may become nodular.

Epidemiology: The seasonality of infection is related to the activity of the fly vectors.

Treatment: Treatment is normally not required.

Control: Any measures to reduce fly populations will be beneficial.

Notes: This genus in ruminants is equivalent to *Habronema* in equines.

Eimeria gilruthi**Synonym:** *Globidium gilruthi***Predilection site:** Abomasum**Phylum:** Apicomplexa**Class:** Conoidasida**Family:** Eimeriidae**Hosts:** Sheep, goat**Description:** Large meronts measuring up to 800 µm found in the abomasal wall of sheep and goats. Only the meront stage is known.**Notes:** Abomasal coccidiosis attributed to *Eimeria* (*Globidium*) *gilruthi* infection is sporadically reported in sheep and goats from different parts of the world. Infections are generally believed to be incidental and are characterised by the presence of giant meronts within the mucosa of the abomasum and, less commonly, the duodenum. The absence of oocysts and sexual tissue stages suggests that sheep may be abnormal hosts for *E. gilruthi*, with infections resulting in one or more generations of merogony in the abomasum, but without progression to gametogony.**SMALL INTESTINE*****Trichostrongylus***Species of *Trichostrongylus* are small, light brownish-red, hair-like worms, and are difficult to see with the naked eye. Males measure around 4.0–5.5 mm and females 5.5–7.5 mm in length.**Description, microscopic:** The worms have no buccal capsule. A useful generic character is the distinct excretory notch in the oesophageal region. The male bursa has long lateral lobes, while the dorsal lobe is not well defined. Spicules are stout, ridged and pigmented brown, and a gubernaculum is present. Species identification is based on the shape and size of the spicules (see Table 1.3). The female tail is bluntly tapered (see Fig. 1.9) and there is no vulval flap. The eggs are thin-shelled and typically strongyle.**Diagnosis:** This is based on clinical signs, seasonal occurrence of disease and, if possible, lesions at postmortem examination. Faecal egg counts are a useful aid to diagnosis, although faecal cultures are necessary for generic identification of larvae. At necropsy, the small intestine is often inflamed and the mucosa thickened with an increase in mucus. There may be flattened red areas that are demarcated from the surrounding mucosa. Digestion of the gut in warm physiological saline for 2–3 hours will release the small hair-like worms for examination.**Pathology:** Microscopically, there is villous atrophy and fusion of villi with elongation and dilation of the intestinal crypts and an increase in the number of mucus-secreting goblet cells. This is accompanied by marked cellular infiltration of the lamina propria, in particular an increase in eosinophils. Intraepithelial globule leucocytes are numerous, often in the more normal surrounding areas of the mucosa.**Epidemiology:** The embryonated eggs and infective L₃ of *Trichostrongylus* can survive under adverse conditions. In temperate areas the L₃ survive the winter, occasionally in sufficient numbers toprecipitate clinical disease in the spring, but more commonly larval numbers increase on pasture in summer and autumn giving rise to clinical problems during these seasons. Hypobiosis plays an important part in the epidemiology, the seasonal occurrence being similar to that of *Ostertagia* spp. In contrast to other trichostrongyles, hypobiosis occurs at the L₃ stage although their role in outbreaks of disease has not been fully established.In the southern hemisphere larvae accumulate in late winter and outbreaks are usually seen in spring. In Australia and Africa, following a period of drought the advent of rain has been shown to rehydrate large numbers of apparently desiccated L₃ (anhydrobiosis) which then become active and rapidly available to grazing animals. *Trichostrongylus colubriformis* also survives adverse environmental conditions as adult parasites within the host and these can persist for many months.Immunity to *Trichostrongylus*, as in *Ostertagia*, is slowly acquired and in sheep, and probably goats, it wanes during the periparturient period.**Treatment:** This is as described for ostertagiosis and PGE in sheep.**Control:** See section Treatment and control of parasitic gastroenteritis in sheep.**Notes:** *Trichostrongylus* is rarely a primary pathogen in temperate areas, but is usually a component of parasitic gastroenteritis in ruminants. By contrast, in the subtropics it is one of the most important causes of PGE.***Trichostrongylus colubriformis*****Synonym:** *Trichostrongylus instabilis***Common name:** Black scour or bankrupt worm**Predilection site:** Duodenum and anterior small intestine**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Trichostrongyloidea**Description, gross:** Males measure around 4.0–5.5 mm and females 5.5–7.5 mm in length.**Description, microscopic:** There is no buccal capsule and the anterior of the worm and the vulval area lack any accessory cuticular structures. The bursa is simple in form and the ventro-ventral ray is positioned well apart from the other rays. The spicules are thick, brown, unbranched, of equal length and terminate in a barb-like tip (see Table 1.3b and Fig. 1.12). The female has double ovejectors. The thin-shelled eggs are medium-sized, an irregular ellipse and measure about 79–101 by 38–50 µm. The poles are dissimilar, one being more rounded, and are not very wide. The eggs are segmenting when laid.**Hosts:** Sheep, goat, cattle, camel and occasionally pig and human**Geographical distribution:** Worldwide. Although *T. colubriformis* occurs in temperate regions, it is mainly a parasite of subtropical and tropical zones.**Pathogenesis:** Following ingestion, the larvae penetrate the mucosa and developing worms are located in superficial channels sited

Fig. 9.6 Erosions characteristic of intestinal trichostrongylosis.

just beneath the surface epithelium and parallel with the luminal surface, but above the lamina propria. When the subepithelial tunnels containing the developing worms rupture to liberate the young worms about 10–12 days after infection, there is considerable haemorrhage and oedema and plasma proteins are lost into the lumen of the gut leading to hypoalbuminaemia and hypoproteinaemia. Grossly there is an enteritis, particularly in the duodenum; the villi become distorted and flattened and the mucosa is inflamed, oedematous and covered in mucus. However, many areas may superficially appear normal. Where parasites are congregated within a small area, erosion of the mucosal surface is apparent with severe villous atrophy (Fig. 9.6). In heavy infections diarrhoea occurs, and this, together with the loss of plasma protein into the lumen of the intestine and an increase in turnover of the intestinal epithelium, leads to an impairment in protein metabolism for growth and is reflected as weight loss. Reduced deposition of body protein, calcium and phosphorus and efficiency of food utilisation may occur. Heavy infections can induce osteoporosis and osteomalacia of the skeleton.

Clinical signs: The principal clinical signs in heavy infections are rapid weight loss and diarrhoea, often dark-coloured. Deaths can be high, particularly if animals are also malnourished and they receive a high larval challenge over a short period. At lower levels of infection, inappetence and poor growth rates, sometimes accompanied by soft faeces, are the common signs. It is often difficult to distinguish the effects of low infections from malnutrition.

Trichostrongylus vitrinus

Common name: Black scour worm

Predilection site: Duodenum and small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are small, hair-like and light brownish-red when fresh. Males measure around 4–6 mm and females 5–8 mm in length.

Description, microscopic: The spicules are thick, unbranched, of equal length and end in a point (see Table 1.3c and Fig. 1.13). Eggs are slightly 'brazil nut'-shaped and measure 93–118 by 41–52 µm.

Hosts: Sheep, goat, deer, camel, occasionally pig and human

Fig. 9.7 Scanning electron micrograph of small intestine showing villous atrophy in areas where *Trichostrongylus* worms are present.

Geographical distribution: Mainly temperate regions of the world

Pathogenesis: The macroscopic lesions in the intestine are similar to those described for *T. colubriformis*, although they tend not to be as extensive and appear to resolve earlier, possibly being indicative of an earlier expulsion of worms than with *T. colubriformis*. Frequently, shallow red depressed areas, demarcated from the more normal coloured surrounding mucosa, are present on the surface of the intestine. These have been termed 'finger-print' lesions. These affected areas are devoid of villi, or the villi appear as rounded protruberances, and numerous worms are embedded in the surface mucosa (Fig. 9.7). Infection can induce similar adverse effects on protein and mineral metabolism to those described for *T. colubriformis*.

Clinical signs: The principal clinical signs in heavy infections are weight loss and diarrhoea. At lower levels of infection, inappetence and poor growth rates, sometimes accompanied by soft faeces, are the common signs.

Trichostrongylus longispicularis

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are similar in size to *T. colubriformis*.

Description, microscopic: The spicules are stout, brown, unbranched, slightly unequal in length and terminate in a tapering blunt tip that has a small semi-transparent protrusion (see Table 1.3d).

Hosts: Cattle, sheep, goat, deer, camel, llama

Geographical distribution: Ruminants in Australia; and cattle in America and parts of Europe.

There are a number of other species of *Trichostrongylus* found in the small intestine of sheep and goats (*T. rugatus*, *T. falculatus*, *T. probolurus*, *T. drepaniformis* and *T. capricola*). These have a more local distribution. The species in rabbits, *T. retortaeformis* and *T. affinis*, have occasionally been recovered from small ruminants.

Cooperia curticei

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: *Cooperia curticei* is moderately small with a large bursa with fleshy supporting rays. The most notable feature is the 'watch spring'-like posture. Males measure around 4.5–6.0 mm and females 6.0–8.0 mm in length. When fresh they appear pinkish white.

Description, microscopic: The main generic features are the very small cephalic vesicle and the transverse cuticular striations in the oesophageal region. The body possesses longitudinal ridges. Spicules are equal in length and have a central protruberance with a transverse striation and end in a rounded disc-like structure (see Table 1.5b). The females have a long tapering tail. Eggs are oval with nearly similar poles and parallel side walls (see Fig. 4.3). They are thin-shelled with a smooth surface and contain many blastomeres which are hard to distinguish. Infective larvae measure around 780 µm (see Fig. 4.14).

Hosts: Sheep, goat, deer

Geographical distribution: Worldwide

Pathogenesis: *Cooperia curticei* is generally considered to be a mild pathogen in lambs and kids, although in some studies it has been associated with inappetence and poor weight gains. A partial immunity to reinfection develops after about 8–12 months of exposure to infective larvae.

Clinical signs: Low to moderate infections are often asymptomatic but heavy worm burdens can lead to loss of appetite and poor growth rates.

Diagnosis: Eggs of *Cooperia* spp. are all very similar morphologically. Faecal culture will allow identification of infective larvae.

Pathology: *Cooperia* do not tunnel into the epithelium but coil among the intestinal villi, causing adjacent villous atrophy. In heavy infections there is more widespread villous atrophy in the small intestine leading to loss of brush border enzymes and digestive disturbance.

Epidemiology: In temperate areas, this is similar to that of *Teladorsagia*. Hypobiosis at the EL₄ is a regular feature during late autumn and winter in the northern hemisphere, and spring and summer in the southern hemisphere. Generally, first-year grazing animals are most likely to accumulate moderate worm populations. Exposure to infective pasture enables animals to acquire a good level of immunity and as adults they usually show little clinical signs of infection but act as carriers, shedding low numbers of eggs in their faeces. Infective larvae survive well on pasture, being tolerant of cold conditions.

Treatment: The principles are similar to those applied in PGE in sheep. *Cooperia* is one of the dose-limiting species and one should consult the manufacturer's data sheets for efficacy of anthelmintics against adult and L₄ stages.

Control: Similar to that recommended for *Teladorsagia*.

Notes: In temperate areas, members of the genus *Cooperia* usually play a secondary role in the pathogenesis of PGE of small ruminants, although they may be the most numerous trichostrongyle present.

Cooperia surnabada

Synonym: *Cooperia mcmasteri*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The males measure around 7 mm and the females 8 mm in length.

Description, microscopic: The appearance is very similar to *C. oncophora*, although the bursa is larger and the bursal rays tend to be thinner. The spicules are thinner with a posterior bifurcation and the tips possess a small conical appendage; and an internal branch that is shorter and pointed (see Table 1.5c).

Hosts: Cattle, sheep, goat, camel

Geographical distribution: Parts of Europe, North America and Australia

For more details see Chapter 8.

Nematodirus battus

Common name: Thread-necked worm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are long and slender, the males measuring around 11–16 mm and females 15–25 mm in length. The anterior of the worm is thinner than the posterior region and the cuticle possesses longitudinal ridges. The body is usually twisted or coiled so that the worms tend to tangle together.

Description, microscopic: A small but distinct cephalic vesicle is present (see Fig 1.32). Males are characterised by having only one set of divergent rays in each bursal lobe (see Fig. 1.33) and the tips of the spicules are fused into a small, flattened, oval-shaped projection (see Table 1.6a). The female worm has a long pointed tail. The large egg is brownish with parallel sides and measures around 150–180 by 67–80 µm (see Fig. 4.3). The chitinous eggshell is thin-walled, smooth and contains four to eight darkly stained blastomeres when passed in faeces.

Hosts: Sheep, goat, camelids and occasionally cattle (calves)

Geographical distribution: *Nematodirus battus* is most important in the British Isles, but also occurs in a number of European countries (Norway, Sweden, Netherlands) and parts of USA and Canada.

Pathogenesis: Nematodirosis, due to *N. battus* infection, is an example of a parasitic disease where the principal pathogenic effect is attributable to the larval stages. Following ingestion of large numbers of L₃ there is disruption of the intestinal mucosa, particularly in the ileum, although the majority of developing stages are found on the mucosal surface. Development through L₄ to L₅ is complete by 10–12 days from infection and this coincides with severe damage to the villi and erosion of the mucosa leading to villous atrophy. The ability of the intestine to exchange fluids and nutrients is grossly impaired, and with the onset of diarrhoea the lamb rapidly becomes dehydrated.

Clinical signs: In severe infections, yellowy-green diarrhoea is the most prominent clinical sign and can occur during the prepatent period. As dehydration proceeds, the affected animals become thirsty and in infected flocks the ewes continue to graze, apparently unaffected by the larval challenge, while their inappetent and diarrhoeic lambs congregate round drinking places. At necropsy, the carcass has a dehydrated appearance and there is often an acute enteritis. The intertwining of the thin twisted worms in the intestine can produce an appearance similar to that of cottonwool. Mortalities can be high in untreated animals. Concurrent infection with pathogenic species of coccidia can exacerbate the severity of disease.

Diagnosis: Because the clinical signs appear during the prepatent period, faecal egg counts are of little value in early diagnosis which is best made on grazing history, clinical signs and, if possible, a postmortem examination. Nematodirosis should be differentiated from coccidiosis.

Pathology: Gross pathological changes may be limited to fluid mucoid contents in the upper small intestine with occasional hyperaemia of the mucosa of the duodenum with excess mucus on the surface. Worm counts may reveal tangled cottony masses of elongate, coiled nematodes. The presence of large numbers of larvae is associated with villous atrophy and fusion, while crypts may appear elongate and dilated. Local erosions may occur if villous atrophy is severe and on histopathology there is a mixed inflammatory response with large numbers of lymphocytes, plasma cells and eosinophils in the lamina propria.

Epidemiology: The three most important features of the epidemiology of *N. battus* infections are as follows.

- 1 The capacity of the free-living stages, particularly the egg containing the L₃, to survive on pasture, some for up to 2 years.
- 2 The critical hatching requirements of most eggs, which ensure the appearance of large numbers of L₃ on the pasture simultaneously, usually in May and June. Although the flush of larvae on the pasture may be an annual event, the appearance of clinical nematodirosis is not: if the flush of L₃ is early, the suckling lambs may not be consuming sufficient grass to acquire large numbers of L₃; if it is late, the lambs may be old enough to resist the larval challenge. There is some evidence that there is an age resistance to *N. battus*, which commences when lambs are about 3 months old. However, susceptible lambs of 6–7 months can have considerable *N. battus* burdens and it is therefore doubtful if this age immunity is absolute.
- 3 The negligible role played by the ewe in the annual cycling of *N. battus*, which can thus be considered a lamb-to-lamb disease with usually only one generation of parasites each year in the spring, although in some years an autumn generation of parasites may be seen. Adult sheep often have a few *N. battus* eggs

in their faeces, but these are insufficient to precipitate a larval flush, although they are enough to ensure the persistence of infection on the pastures. In management systems that involve both sheep and cattle, young calves can become infected when they graze pasture that carried lambs the previous spring.

Treatment: Several drugs are effective against *Nematodirus* infections: levamisole, an avermectin/milbemycin or one of the modern benzimidazoles. However, *Nematodirus* is one of the dose-limiting species and the manufacturer's data sheet should be consulted as there are differences in efficacy against adults and L₄ stages between oral and parenteral administration for some macrocyclic lactones. The response to treatment is usually rapid and, if diarrhoea persists, coccidiosis should be considered as a complicating factor.

Control: Because of the annual hatching of *N. battus* eggs in spring, the disease can be controlled by avoiding the grazing of successive lamb crops on the same pasture. Where such alternative grazing is not available each year, control can be achieved by anthelmintic prophylaxis, the timing of treatments being based on the knowledge that the peak time for the appearance of *N. battus* L₃ is May to early June. Ideally, dosing should be at 3-week intervals over May and June and it is unwise to await the appearance of clinical signs of diarrhoea before administering the drugs. Forecasting systems are based primarily on soil temperature in the early spring which can predict the likely severity of nematodirosis. In years when the forecast predicts severe disease, three treatments are recommended during May and June; in other years two treatments in May should suffice.

Notes: As anthelmintic resistance is rare in *Nematodirus* species, it may be advisable to use a benzimidazole against specific *Nematodirus* infection and in this way reduce the selection pressure on the other families of drugs.

Nematodirus filicollis

Common name: Thread-necked worm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are long slender worms, males measuring 10–15 mm and females 15–24 mm in length.

Description, microscopic: A small but distinct cephalic vesicle is present. The male has two sets of parallel rays in each of the main bursal lobes (see Fig. 1.34). The spicules are long and slender with fused tips and terminate in a narrow pointed swelling (see Table 1.6b). The female has a truncate blunt tail with a small spine (similar to *N. spathiger*), and the egg is large, ovoid (130–200 × 70–90 μm), thin-shelled and colourless and twice the size of the typical trichostrongyle egg (see Fig. 4.3).

Hosts: Sheep, goat, occasionally cattle and deer

Geographical distribution: Cosmopolitan, but more prevalent in temperate zones

Pathogenesis: Similar to that of *N. battus* but of lesser severity.

Clinical signs: Low to moderate infections may produce no obvious clinical manifestations. In severe infections, diarrhoea can occur during the prepatent period and young animals may become dehydrated.

Diagnosis: Examination of faeces will enable the colourless eggs to be differentiated from the brown eggs of *N. battus*. At necropsy the tips of the male spicules will allow diagnosis from other *Nematodirus* species.

Pathology: Third-stage larvae enter the deep layers of the mucosa, penetrating into the crypts. Larvae emerge as fourth- or fifth-stage larvae and coil among the villi with their posterior ends protruding into the lumen. The presence of large numbers of worms leads to the development of villous atrophy, crypt dilation and elongation. If villous atrophy is severe, the worms may not be able to maintain their position in the intestine.

Epidemiology: The hatch of L₃ from the eggs occurs over a more prolonged period than with *N. battus*, and numbers of infective larvae accumulate on pasture and often peak in late autumn to early winter. More than one annual generation is possible. Although *N. filicollis* has been associated with outbreaks of nematodiosis in small ruminants, it is more common to find it in conjunction with the other trichostrongyles that contribute to ovine PGE.

Treatment: See *Nematodirus battus*

Control: Disease due to monospecific *N. filicollis* infections is rarely seen. They are usually part of the worm burden of trichostrongyloid species that are responsible for the syndrome of PGE in sheep and as such may be controlled by the measures outlined elsewhere.

Nematodirus spathiger

Common name: Thread-necked worm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are slender worms, males measuring around 10–15 mm and females 15–25 mm in length.

Description, microscopic: A small but distinct cephalic vesicle is present. The male has two sets of parallel rays in each of the main bursal lobes. The spicules are long and slender with fused tips and terminate in a spoon-shaped tip (see Table 1.6c). The female has a truncate blunt tail with a small spine (similar to *N. filicollis*), and the egg is large, ovoid, thin-shelled and colourless and twice the size of the typical trichostrongyle egg. The egg measures 175–260 by 106–110 µm and usually contains an embryo of eight cells when passed in the faeces. Infective larvae measure around 1100 µm and have eight gut cells (see Fig. 4.14).

Hosts: Sheep, goat, occasionally cattle and other ruminants

Geographical distribution: Cosmopolitan

Pathogenesis: Similar to that of *N. battus* but of lesser severity.

Clinical signs: Low to moderate infections may produce no obvious clinical manifestations. In severe infections, diarrhoea can

occur during the prepatent period and young animals may become dehydrated.

Diagnosis: Examination of faeces will enable the colourless eggs to be differentiated from the brown eggs of *N. battus*. At necropsy the tips of the male spicules will allow diagnosis from other *Nematodirus* species.

Pathology: As for *N. filicollis*

Epidemiology: The eggs do not usually exhibit delayed hatching, and the pattern of infection is similar to that of *Trichostrongylus* species.

Treatment and control: See *Nematodirus battus*

Bunostomum trigonocephalum

Synonym: *Monodontus trigonocephalum*

Common name: Hookworm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ancylostomatoidea

Description, gross: *Bunostomum* is one of the larger nematodes of the small intestine of ruminants, being around 1.0–3.0 cm long, stout, greyish-white and characteristically hooked at the anterior end with the buccal capsule opening anterodorsally (see Fig. 1.49).

Description, microscopic: The large buccal capsule opens anterodorsally and bears on the ventral margin a pair of chitinous cutting plates and internally a large dorsal cone. Dorsal teeth are absent from the buccal capsule but there is a pair of small subventral lancets at its base. In the male the bursa is well developed and has an asymmetrical dorsal lobe. The right externo-dorsal ray arises higher up on the dorsal stem and is longer than the left. It arises near the bifurcation of the dorsal ray, which divides into two tridigitate branches. The spicules are slender, twisted and relatively short. In the female the vulva opens a short distance in front of the middle of the body.

The infective larva is small with 16 gut cells and a short filamentous tail (see Fig. 4.14). The egg is medium-sized (75–104 × 45–57 µm), an irregular broad ellipse in shape, with similar wide poles, and dissimilar side walls, one being flattened. The thin-shelled egg contains four to eight darkly stained blastomeres.

Hosts: Sheep, goat, camel, deer

Geographical distribution: Worldwide, but of more economic importance in warm climates

Pathogenesis: The adult worms are blood-suckers and infections of 100–500 worms can produce progressive anaemia, hypoalbuminaemia, loss of weight and occasionally diarrhoea. Worm burdens of around 600 may lead to death in sheep.

Clinical signs: The main clinical signs are progressive anaemia, with associated changes in the blood picture, hydraemia and oedema, which show particularly as submandibular oedema ('bottle jaw'). The animals become weak and emaciated and the appetite

usually decreases. The skin is dry and the wool of sheep falls out in irregular patches. Diarrhoea may occur, and the faeces may be dark because of altered blood pigments. Collapse and death may occur.

Diagnosis: The clinical signs of anaemia and perhaps diarrhoea in young sheep are not in themselves pathognomonic of bunostomosis. However, in temperate areas, the epidemiological background may be useful in eliminating the possibility of *Fasciola hepatica* infection. In the tropics, haemonchosis must be considered, possibly originating from hypobiotic larvae. Faecal worm egg counts are useful in that these are lower than in *Haemonchus* infection, while the eggs are more bluntly rounded, with relatively thick sticky shells to which debris is often adherent. For accurate differentiation, larval cultures should be prepared.

Pathology: The carcass is anaemic and cachexic. Oedema and ascites are seen. The liver is light brown and shows fatty changes. The intestinal contents are haemorrhagic and the mucosa is usually swollen, covered with mucus, and shows numerous lesions resulting from the worms feeding. The parasites may be seen still attached to the mucosa or free in the lumen.

Epidemiology: Pathogenic infections are more common in the tropics and subtropics and, in some areas, the highest worm burdens are found at the end of the dry season apparently due to the maturation of hypobiotic larvae. Young animals are most susceptible. In temperate countries, high worm burdens are usually uncommon. The prophylactic dosing regimens adopted for the control of trichostrongyles has contributed to the low prevalence of *Bunostomum*.

Treatment: The prophylactic anthelmintic regimens advocated for other gastrointestinal nematodes are usually sufficient.

Control: A combination of strategic dosing with anthelmintics and pasture management as used in the control of ovine PGE is effective. Larvae are susceptible to desiccation, and the infection is mainly found on permanently or occasionally moist pastures. Avoiding or draining such pastures is an effective control measure. The ground around water troughs should be kept hard and dry, or treated with liberal applications of salt. Housed sheep and goats should be protected by ensuring the floors and bedding are kept dry and that faeces are removed frequently and are not allowed to contaminate food and water.

Gaigeria pachyscalis

Common name: Hookworm

Predilection site: Duodenum and small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ancylostomatoidea

Description, gross: Adult males measure up to 2 cm; females are up to 3 cm in length.

Description, microscopic: The buccal capsule contains a large dorsal cone, but no dorsal tooth, and a pair of subventral lancets, which have several cusps each. The male bursa has small lateral lobes joined together ventrally, and a large dorsal lobe. The anterolateral ray is short and blunt and is separated widely from other lateral

rays. The externo-dorsal rays arise from the main stem of the dorsal ray, which is split for about one-quarter of its length, the two short branches ending in very small digitations. The spicules are slender with recurved barb ends. The eggs measure 105–129 by 50–55 µm and their poles are bluntly rounded.

Hosts: Sheep, goat, wild ruminants

Geographical distribution: South America, South Africa, Indonesia and parts of Asia

Pathogenesis: The parasite is a voracious blood-sucker; as few as 100–200 worms are sufficient to produce death in sheep within a few weeks.

Clinical signs: Causes severe anaemia and death.

Diagnosis: Demonstration of the characteristic large eggs in the faeces.

Pathology: As for *B. trichocephalum*

Epidemiology: As for *B. trichocephalum*

Treatment and control: As for *B. trichocephalum*

Strongyloides papillosus

Common name: Threadworm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Rhabditoidea

Description, gross: Slender hair-like worms generally less than 1.0 cm long.

Description, microscopic: Only females are parasitic. The long oesophagus may occupy up to one-third of the body length and the uterus is intertwined with the intestine giving the appearance of twisted thread (see Fig. 1.51). Unlike other intestinal parasites of similar size the tail has a blunt point. *Strongyloides* eggs are oval with blunt poles and slightly barrel-shaped side walls, thin-shelled and small, being half the size of typical strongyle eggs. These colourless eggs have a smooth shell and measure about 43–60 by 20–25 µm and contain an L₁ larva (see Fig. 4.3). In herbivores it is the larvated egg which is passed out in the faeces, but in other animals it is the hatched L₁. Infective larvae measure about 600 µm.

Hosts: Sheep, goat, cattle, other ruminants, pig and rabbit

Geographical distribution: Worldwide

For more details on pathogenesis, epidemiology, treatment and control see Chapter 8.

Capillaria longipes

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: These are very fine filamentous worms, the narrow stichosome oesophagus occupying about one-third to half the body length. Males measure around 10–13 mm and females up to 20 mm.

Description, microscopic: The males have a long thin single spicule, 1.2 mm long, and often possess a primitive bursa-like structure. The females contain eggs that resemble those of *Trichuris* in possessing bipolar plugs. The eggs are only slightly barrel-shaped, the mid regions of the shell wall being parallel. They measure 45–50 by 22–25 µm and are colourless, and have thick shells that are slightly striated with slightly projecting transparent bipolar plugs (see Fig. 4.3).

Hosts: Sheep, goat, occasionally cattle

Geographical distribution: Worldwide

Pathogenesis: Considered to be of low pathogenicity and of little veterinary significance.

Clinical signs: No clinical signs have been attributed to infection with this parasite.

Diagnosis: Because of the non-specific nature of the clinical signs and the fact that, in heavy infections, these may appear before *Capillaria* eggs are present in the faeces, diagnosis depends on necropsy and careful examination of the small intestine for the presence of the worms. This may be carried out by microscopic examination of mucosal scrapings squeezed between two glass slides; alternatively the contents should be gently washed through a fine sieve and the retained material resuspended in water and examined against a black background.

Pathology: No associated pathology

Epidemiology: Infection is by ingestion of the larvated eggs and is common in sheep though not significant.

Treatment: Not usually required

Control: Not required

Moniezia expansa

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, gross: These are long tapeworms, up to 600 cm or more in length, which are unarmed, possessing four large prominent suckers (see Fig. 1.96).

Description, microscopic: Segments are broader than they are long (up to 1.5 cm wide) and contain two sets of genital organs grossly visible along the lateral margin of each segment (see Table 1.10). There is a row of inter-proglottid glands at the posterior border of each segment, which may be used in species differentiation. In *M. expansa* they extend along the full breadth of the segment; in *Moniezia benedeni* they occupy only the mid-zone of the segment. The irregularly triangular-shaped eggs have a well-defined pyriform apparatus and vary from about 50 to 67 µm in diameter (see Fig. 4.3).

Final hosts: Sheep, goat, occasionally cattle

Intermediate hosts: Free-living forage mites, mainly of the family Oribatidae

Geographical distribution: Worldwide

Pathogenesis: Although generally regarded as of little pathogenic significance, there are several reports, especially from eastern Europe and New Zealand, of heavy infections causing unthriftiness, diarrhoea and even intestinal obstruction. However, *Moniezia* infections are so obvious, both in life, because of the presence of proglottids in the faeces, and at necropsy, that other causes of ill health may be overlooked. It is interesting that experimental studies have failed to demonstrate substantial clinical effects even with fairly heavy worm burdens.

Clinical signs: While a great variety of clinical signs, including unthriftiness, diarrhoea, respiratory signs and even convulsions, have been attributed to *Moniezia*, infections are generally symptomless. Subclinical effects remain to be established.

Diagnosis: This is based largely on the presence of mature proglottids in the faeces and the characteristic shape of *Moniezia* eggs (triangular, *M. expansa*; quadrangular, *M. benedeni*) that contain the oncosphere. The eggs of *M. benedeni* are slightly larger than those of *M. expansa*.

Pathology: Little pathology is associated with the presence of light infections. Heavy infections may produce a solid mass of tapeworms that may occlude the intestinal lumen.

Epidemiology: Infection is common in lambs, kids and calves during their first year of life and less common in older animals. A seasonal fluctuation in the incidence of *Moniezia* infection can apparently be related to active periods of the forage mite vectors during the summer in temperate areas. The cysticercoids can overwinter in the mites.

Treatment: In many countries several drugs, including niclosamide, praziquantel, bunamidine and a number of broad-spectrum benzimidazole compounds, which have the advantage of also being active against gastrointestinal nematodes, are available for the treatment of *Moniezia* infection. If this is carried out in lambs and calves in late spring, in temperate areas, the numbers of newly infected mites on pasture will be reduced.

Control: Ploughing and reseeded, or avoiding the use of the same pastures for young animals in consecutive years, may prove beneficial.

Notes: This genus of cestodes is common in ruminants and resembles, in most respects, *Anoplocephala* of the horse. *Moniezia* spp. are the only tapeworms of ruminants in many countries of western Europe.

Other species of tapeworms are found in the small intestine of sheep and goats. Many of the details are essentially similar to *Moniezia*.

Avitellina centripunctata

Synonym: *Avitellina woodlandi*

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, gross: This tapeworm resembles *Moniezia* on gross inspection except that the segmentation is so poorly marked that it appears somewhat ribbon-like. It can reach 3 m in length by about 3–4 mm in width and the posterior end is almost cylindrical in appearance.

Description, microscopic: Proglottids are short with indistinct segmentation and single genitalia present with the pores alternating irregularly (see Table 1.10). Eggs lack a pyriform apparatus and measure around 20–45 µm. They are contained in capsules in a single paruterine organ in each proglottid.

Final hosts: Sheep, goat, camel and other ruminants

Intermediate hosts: Thought to be oribatid mites or psocid lice

Geographical distribution: Europe, Africa and Asia

Pathogenesis: Of negligible pathogenicity, similar to that of *Moniezia* spp.

Clinical signs: Usually asymptomatic

Notes: Several minor species of *Avitellina* occur: *A. goughi* and *A. chalmersi* are found mainly in sheep in Asia and Africa and *A. tattia* occurs in goats in the Indian subcontinent. These species have more than one paruterine organ in each proglottid.

Stilesia globipunctata

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, gross: Adults measure 45–60 cm in length by 2–4 mm wide.

Description, microscopic: The narrow scolex has four large suckers, but no hooks. Strobila are broader than long. A single set of genital organs is present with genital pores alternating irregularly (see Table 1.10). Two distinct sets of testes are present in each segment, one on each side, but no testes in the median line. Eggs lack a pyriform apparatus and measure around 27 by 15 µm.

Final hosts: Sheep, goat, cattle and other ruminants

Intermediate hosts: Thought to be oribatid mites and psocid lice

Geographical distribution: Southern Europe, Africa and Asia

Pathogenesis: Generally considered to be of low pathogenicity, although severe infection has been reported to cause death.

Clinical signs: Normally asymptomatic

Pathology: Nodules and desquamation may occur in the jejunum where the scoleces of the immature tapeworms penetrate the epithelium. The scolex and anterior proglottids are embedded within the nodule, the posterior proglottids being free in the lumen of the intestine.

Treatment and control: Treatment is rarely called for, but praziquantel administered at 8–15 mg/kg has proved effective.

Thysaniezia ovilla

Synonym: *Thysaniezia giardi*, *Helictometra giardi*

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, gross: Adults reach 200 cm in length, varying in width up to 12 mm.

Description, microscopic: The scolex is small, measuring up to 1 mm in diameter, and the suckers are slit-like in appearance. Segments are short, bulge outwards giving the margin of the worm an irregular appearance, and contain a single set of genital organs, rarely two, with genital pores alternating irregularly. Mature segments have an undulating uterus (see Table 1.10).

The oval eggs (measuring up to 27 × 19 µm) are devoid of a pyriform apparatus and have a thick grey shell and a protruberance at one end. They are found in groups of 10–15 in the numerous elongated paruterine organs (100 µm long) in each proglottid.

Final hosts: Cattle, sheep, goat, camel and wild ruminants

Intermediate hosts: Oribatid mites (*Galuma*, *Schelorbates*) and psocids (bark lice, dust lice)

Geographical distribution: Southern Africa

Pathogenesis: Not considered pathogenic

Diagnosis: The mature segments found in the faeces are readily distinguishable from those of *Moniezia*.

Epidemiology: Infection is very commonly found in adult cattle in southern Africa.

Treatment and control: As for *Moniezia*

Thysanosoma actinoides

Common name: Fringed tapeworm

Predilection site: Small intestine, bile and pancreatic ducts

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, gross: The adult ‘fringed’ tapeworms measure 15–30 cm by 8 mm wide.

Description, microscopic: The scolex is up to 1.5 mm; segments are short and wide and fringed posteriorly. In the distal regions of the tapeworm the ‘fringes’ are as long as the proglottid (see Table 1.10). Each proglottid contains two sets of genital organs with the testes lying medially. Numerous paruterine organs are present in each proglottid and the oval eggs (measuring about 27 × 18 µm) have no pyriform apparatus.

Final hosts: Sheep, cattle, deer

Intermediate hosts: Oribatid mites (*Galuma*, *Schelorbates*) and psocids (bark lice, booklice and dust lice)

Geographical distribution: North and South America

Pathogenesis and clinical signs: Generally not considered pathogenic. Blockage of the bile or pancreatic ducts may occur resulting in digestive disorders and unthriftiness.

Diagnosis: Identification of the mature segments and eggs in the faeces.

Epidemiology: Infection is commonly found in sheep, cattle and deer in the western USA and parts of South America.

Treatment and control: As for *Moniezia*

Cymbiforma indica

Synonym: *Ogmocotyle indica*

Predilection site: Gastrointestinal tract, particularly the duodenum

Phylum: Platyhelminthes

Class: Trematoda

Family: Notocotylidae

Description, gross: Adult flukes are pear-shaped, concave ventrally and measure 0.8–2.7 cm long by 0.3–0.9 mm wide.

Description, microscopic: There is no ventral sucker and the cuticle is armed with fine spines anteriorly and ventrally. The ovary has four marked lobes. The genital opening is sited just anterior to the middle of the body and to the left of the midline. Eggs bear long filaments at both poles and measure 18–27 by 11–13 μm .

Final hosts: Sheep, goat, cattle

Intermediate hosts: Snails

Geographical distribution: India

Pathogenesis and clinical signs: Generally not considered pathogenic, despite heavy infections frequently reported.

Diagnosis: Identification of the flukes on postmortem.

Treatment and control: Not required

Skrjabinotrema ovis

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Brachylaemidae

Description, gross: Adult fluke are small with smooth bodies and measure 1.0 by 0.3–0.7 mm.

Description, microscopic: Eggs measure 24–32 by 16–20 μm and are slightly flattened on one side with a large operculum at one end and a small appendage at the other.

Final host: Sheep

Intermediate hosts: Snails

Geographical distribution: China, Russia, eastern CIS

Pathogenesis and clinical signs: Heavy infections may cause catarrhal enteritis.

Diagnosis: Identification of the flukes on postmortem.

Sheep coccidia

Fifteen species of *Eimeria* have been identified in sheep, of which 11 species are commonly identified based on oocyst morphology (Table 9.2; see also Table 4.8 and Fig. 4.34). Each stage of individual coccidial species has its preferences as to which cells and which parts of the gut it infects. Those infecting the posterior part of the intestine tend to be more harmful.

Although the majority of sheep, particularly those under 1 year old, carry coccidia, only two species (*E. crandallis* and *E. ovinoidalis*) are known to be highly pathogenic. It was thought for many years that the species of *Eimeria* affecting sheep and goats were the same. However, cross-transmission studies have shown that although morphologically similar, coccidia in small ruminants are host-specific and cross-infection between sheep and goats does not occur.

The following general descriptions apply to sheep and goat *Eimeria*.

Pathogenesis: The most pathogenic species of coccidia are those that infect and destroy the crypt cells of the large intestinal mucosa. This is because the ruminant small intestine is very long, providing a large number of host cells and the potential for enormous parasite replication with minimal damage. If the absorption of nutrients is impaired, the large intestine is, to some extent, capable of compensating. Those species that invade the large intestine are more likely to cause pathological changes, particularly if large numbers of oocysts are ingested over a short period of time. Here, the rate of cellular turnover is much lower and there is no compensation effect from other regions of the gut. In lambs or kids that become heavily infected, the mucosa becomes completely denuded resulting in severe haemorrhage (Fig 9.8) and impaired water resorption, leading to diarrhoea, dehydration and death. In lighter infections, the effect on the intestinal mucosa is to impair local absorption. Species that develop more superficially in the small intestine cause a change in villous architecture with a reduction in epithelial cell height and a diminution of the brush border, giving the appearance of a 'flat' mucosa. These changes result in a reduction of the surface area available for absorption and consequently a reduced feed efficiency.

Table 9.2 Predilection sites and prepatent periods of *Eimeria* species in sheep.

| Species | Predilection site | Prepatent period (days) |
|-------------------------------|---------------------------|-------------------------|
| <i>Eimeria ahsata</i> | Small intestine | 18–30 |
| <i>Eimeria bakuensis</i> | Small intestine | 18–29 |
| <i>Eimeria crandallis</i> | Small and large intestine | 15–20 |
| <i>Eimeria faurei</i> | Small and large intestine | 13–15 |
| <i>Eimeria granulosa</i> | Unknown | ? |
| <i>Eimeria intricata</i> | Small and large intestine | 23–27 |
| <i>Eimeria marsica</i> | Unknown | 14–16 |
| <i>Eimeria ovinoidalis</i> | Small and large intestine | 12–15 |
| <i>Eimeria pallida</i> | Unknown | ? |
| <i>Eimeria parva</i> | Small and large intestine | 12–14 |
| <i>Eimeria weybridgeensis</i> | Small intestine | 23–33 |

Fig. 9.8 Haemorrhagic mucosa due to infection with *Eimeria ovinoidalis*.

Clinical signs: Clinical signs vary, from loss of pellet formation to weight loss, anorexia and diarrhoea (with or without blood) (Fig. 9.9).

Pathology: On postmortem, there may be little to see beyond thickening and petechiation of the bowel but mucosal scrapings will reveal masses of gamonts and oocysts. Giant meronts may be seen in the mucosa of the small intestine as pin-point white spots (Fig. 9.10), but unless they are in vast numbers they cause little harm. The most pathogenic stages are the gamonts (Fig. 9.11).

Epidemiology: Coccidia are normally present in animals of all ages and usually cause no clinical signs, as immunity is quickly acquired and maintained by continuous exposure to reinfection. However, intensification may alter the delicate balance between immunity and disease with serious consequences for young

Fig. 9.9 Clinically affected lamb with coccidiosis.

Fig. 9.10 *Eimeria ovinoidalis*. Large intestinal mucosa with ‘giant’ meronts visible as pin-point white spots.

animals. Coccidiosis is one of the most important diseases of lambs, particularly in their first few months of life. While coccidial infection is common, the presence of infection does not necessarily lead to the development of clinical signs of disease and, in many situations, low levels of challenge can actually be beneficial by stimulating protective immune responses in the host. Development of disease is dependent on a number of factors, in particular husbandry and management.

Adult animals are highly resistant to the disease, but not totally resistant to infection. As a result, small numbers of parasites manage to complete their life cycle and usually cause no detectable harm. In the wild or under more natural, extensive systems of management, susceptible animals are exposed to only low numbers of oocysts and acquire a protective immunity. Extensive grazing, as occurs under natural conditions in the wild, limits the level of exposure to infective oocysts. Under modern production systems, however, lambs or kids are born into a potentially heavily contaminated environment, and where the numbers of sporulated oocysts are high, disease often occurs. Three management factors are associated with the development of high levels of infection and the development of disease: pens not cleaned on a regular basis; overcrowding in the pens; pens used to house different age groups.

Fig. 9.11 Macrogamonts of *Eimeria ovinoidalis*.

Adults, although possibly the original source of infective oocysts in the environment, are not usually responsible for the heavy levels of contamination encountered. The source is often the lambs themselves, which following an initial infection in the first few days of life may produce millions of oocysts within their own environment. Growing animals may then face potentially lethal doses of infective oocysts 3 weeks later when their natural resistance is at its lowest. Later-born animals introduced into the same environment are immediately exposed to heavy oocyst challenge. Under unhygienic, overcrowded conditions, the lambs will be exposed to, and ingest a large proportion of, this infection and will develop severe disease and may even die. If conditions are less crowded and more hygienic, the infective dose ingested will be lower, they may show moderate, slight or no clinical signs and develop an immunity to reinfection, but they in turn will have multiplied the infection a million-fold. Stress factors, such as poor milk supply, weaning, cold weather and transport, will reduce any acquired resistance and exacerbate the condition.

Colostrum provides passive immunity to coccidiosis during the first few weeks of life. Thereafter, susceptibility to coccidial infections has been found to increase progressively. Subsequently, animals acquire resistance to coccidia as a result of active immunity. While animals of all ages are susceptible to infection, younger animals are generally more susceptible to disease. The majority of lambs will probably become infected during the first few months of life and may or may not show signs of disease. Those that reach adulthood are highly resistant to the pathogenic effects of the parasites but may continue to harbour small numbers throughout their lives.

Occasionally, acute coccidiosis occurs in adult animals with impaired cellular immunity or in those which have been subjected to stress, such as dietary changes, prolonged travel, extremes of temperature and weather conditions, changes in environment or severe concurrent infection. An animal's nutritional status and mineral and vitamin deficiencies can also influence resistance to infection. Suckling animals, in addition to benefiting from colostrum intake, may forage less and hence pick up fewer oocysts from pasture. Well-nourished animals may simply be able to fight off infection more readily.

Diagnosis: Diagnosis should be based on history, clinical signs (severe diarrhoea in young animals), postmortem findings (inflammation, hyperaemia and thickening of the caecum with masses of gamonts and oocysts in scrapings) supported by oocyst counts and speciation to identify pathogenic species. Counts of faecal oocysts identified to species can help to complete the picture, but oocyst numbers may be grossly misleading when considered in isolation. Healthy animals may pass more than a million oocysts per gram of faeces, whereas in animals dying of coccidiosis the count may be less than 10,000 oocysts per gram of faeces. High counts of non-pathogenic species could mask significant numbers of the more pathogenic species, for instance, and give the impression that the abundant species was the cause.

Treatment: Outbreaks of clinical coccidiosis can appear suddenly and may prove troublesome to resolve as they often occur on heavily stocked farms, particularly where good husbandry and management are lacking. If deaths are occurring, early confirmation of the diagnosis is vital and should be based on history, postmortem examination and intestinal smears. Affected animals

should be medicated and moved to uncontaminated pens or pasture as soon as possible.

Normally, all lambs in a group should be treated, as even those showing no symptoms are likely to be infected. Appearance of clinical symptoms will require treatment with an appropriate anti-coccidial product. This would normally be in the form of a single oral drench with either diclazuril or toltrazuril, in countries where these products are both available and licensed for use. Decoquinate can be administered in feed, bearing in mind that not all lambs may consume the feed, especially severely affected animals that may be off their feed and dehydrated. Where these products are not available or licensed, then treatment with a sulphonamide such as sulphadimidine or sulphamethoxyypyridazine can be considered.

Severely infected animals that are diarrhoeic and dehydrated may require oral or intravenous rehydration. Where non-specific symptoms of weight loss or ill-thrift are present, it is important to investigate all potential causes and seek laboratory confirmation. If coccidiosis is considered significant, much can be done through advice on management and instigation of preventive measures outlined earlier. Batch rearing of animals of similar ages limits the build-up and spread of oocysts and allows targeting of treatment to susceptible age groups during the danger periods.

Control: Animals particularly at risk from coccidiosis are those kept indoors on damp bedding, or those on contaminated heavily stocked pastures, particularly in cold wet weather. The incidence of disease can be reduced through avoidance of overcrowding and stress, and attention to hygiene. Regularly moving food and water troughs, and raising or covering them to prevent faecal contamination, can help reduce the levels of infection. It is good practice to clean and disinfect all buildings between groups of sheep or provide clean pasture for animals turned out to grass. Steam cleaning or pressure washing helps remove faecal debris and it is important to use a disinfectant that claims activity against coccidial oocysts, as not all disinfectants will kill oocysts. Ammonia-based disinfectants are normally used, although other disinfectants containing chlorophenol (chloro-m-cresol) are also effective.

Young animals should be kept off heavily contaminated pastures when they are most susceptible. Good feeding of dams prior to parturition and creep feeding of their progeny will also help to boost resistance to coccidiosis.

Coccidiosis in young lambs at pasture has become a significant problem, particularly with increased stocking densities and reduced availability of pasture for sheep. In early weaning lamb flocks kept indoors, then disease can be anticipated in housed lambs aged 2–3 weeks post weaning. Strategic treatments in these situations usually comprise in-feed decoquinate, or diclazuril or toltrazuril, administered prior to identified periods of risk. The timing of such treatments should be based on the farm history, prevailing management and husbandry systems, and knowledge of the epidemiology of the disease. Intervention treatments should aim to limit disease signs but not prevent sufficient exposure to coccidial oocysts that lead to the development of protective immunity.

Eimeria crandallis

Predilection site: Small and large intestine

Eimeria ovinoidalis

Predilection site: Small and large intestine

For more details on these species see section Large intestine.

Eimeria ahsata

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Sheep

Description: The oocysts are ellipsoidal to ovoid, yellowish-brown, 29–37 by 17–28 μm (mean $33.4 \times 22.6 \mu\text{m}$) with a micropyle and a micropylar cap and have one or occasionally more polar granules, without a residuum (Fig. 9.12; see also Fig. 4.34). Sporocysts are 12–22 by 6–10 μm without a Stieda body and with a residuum. The sporozoites are elongate, and lie lengthways head to tail in the sporocysts, and have one to three clear globules each.

First-generation meronts average 184 by 165 μm and may reach 265 by 162 μm by 15 days post infection and contain several thousand merozoites. Second-generation meronts measure 52 by 39 μm and contain approximately 50 merozoites. Intranuclear stages have been observed in small intestinal epithelial cells, 15, 18 and 19 days after experimental infection. The developing parasites are 1.6–5 μm in size and are mostly localised within a tiny cavity of the nucleus. Each intranuclear parasite is surrounded by a halo, and most contain two to four dark-staining and probably dividing nuclei and appear to be second-generation merozoites. The macrogamonts are 35–45 μm in diameter and the microgamonts are 6.5 by 26 μm .

Life cycle: First-generation meronts are localised along the length of the small intestine, but mainly in the jejunum. Second-generation meronts appear in the cytoplasm of epithelial cells 15–20 days after infection. The gamonts appear at 11 days post infection, suggesting that merogony and gametogony run parallel for a time. Most sexual stages develop in epithelial cells of the crypts (Fig. 9.13). The prepatent period is 18–21 days and the patent period 10–12 days. Sporulation time is 2–3 days.

Fig. 9.12 Oocyst of *Eimeria ahsata*: sheep.

Fig. 9.13 Gamonts of *Eimeria ahsata* within epithelial crypt cells.

Geographical distribution: Worldwide

Pathogenesis: Not considered to be pathogenic, although there have been some reports of *E. ahsata* causing diarrhoea, inappetence, weight loss and even death.

Pathology: Thickening of the wall of the ileum, especially anteriorly, with inflammation of Peyer's patches has been reported.

Eimeria bakuensis

Synonym: *Eimeria ovina*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Sheep

Description: Oocysts are ellipsoidal, pale yellowish-brown, and measure 23–36 by 15–24 μm . There is a micropyle and micropylar cap, one or more polar granules and no residuum (Fig. 9.14;

Fig. 9.14 Oocyst of *Eimeria bakuensis*: sheep.

see also Fig. 4.34). The sporocysts are elongate ovoid, 11–17 by 6–9 μm , and contain a residuum and sometimes an inconspicuous Stieda body. Sporozoites are elongate and lie lengthwise head to tail in the sporocysts and have a large clear globule at the broad end and a smaller one at the narrow end. Meronts when mature are 122–146 μm in diameter and contain hundreds of thousands of merozoites ($9 \times 2 \mu\text{m}$).

Life cycle: There appears to be only one asexual generation. The meronts are found in the endothelial cells lining the central lacteals of the small intestinal villi and mature 13–21 days after infection. The sexual stages are found in the epithelial cells of the small intestinal villi. Synchronous division of the parasites occurs. The microgamonts contain a large residual mass. The sporulation time is 2–4 days. The prepatent period is 19–29 days and the patent period around 10 days.

Geographical distribution: Worldwide

Pathogenesis: Papilloma-like lesions may occur in the small intestine, usually as a sequela to gametocyte formation, but these are not of great pathogenic significance.

Pathology: A few small, slightly haemorrhagic areas are seen scattered throughout the lining of the small intestine and thick white opaque patches, composed of groups of heavily parasitised villi, are present leading to the formation of polyps (Fig. 9.15).

Diagnosis: The presence of polyps containing large numbers of gamonts and oocysts is indicative of *E. bakuensis* infection. Oocysts are prevalent in the faeces of sheep of all ages, and coccidiosis cannot be diagnosed solely by finding oocysts. Peak oocyst counts above 1 million per gram of faeces have been reported in clinically healthy lambs.

Eimeria faurei

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Sheep

Fig. 9.15 *Eimeria bakuensis* polyps in the small intestine.

Fig. 9.16 Oocyst of *Eimeria faurei*: sheep.

Description: The oocyst is ovoid, pale yellow–brown and measures 28–37 by 21–27 μm (mean $32 \times 23 \mu\text{m}$). There is a conspicuous micropyle 2–3 μm in diameter, without a micropylar cap. There is a polar granule but no oocyst residuum (Fig. 9.16; see also Fig. 4.34). The sporocysts are ovoid or pyriform, 11–17 by 7–9 μm with a sporocyst residuum. The Stieda body is absent or inconspicuous. The sporozoites are elongate and lie lengthwise head to tail in the sporocysts and have one to two large clear globules each.

Life cycle: Details of the life cycle are not known. The prepatent period is 13–15 days and sporulation time is 1–3 days.

Geographical distribution: Worldwide

Eimeria granulosa

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Sheep

Description: Oocysts are urn-shaped, 22–35 by 17–25 μm (mean $29.4 \times 20.9 \mu\text{m}$), with a large micropyle and micropylar cap at the broad end (Fig. 9.17; see also Fig. 4.34). There is no residuum but polar granules may be present. The sporocysts are ovoid or elongate ovoid, 1–16 by 8–9 μm , with a slight Stieda body and a residuum. The sporozoites are elongate, lie lengthwise head to tail in the sporocysts and have one to three clear globules.

Life cycle: Details of the life cycle are not known.

Geographical distribution: Worldwide

Eimeria intricata

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Fig. 9.17 Oocyst of *Eimeria granulosa*: sheep.

Family: Eimeriidae

Host: Sheep

Description: Oocysts are ellipsoidal or slightly ovoid, 40–56 by 30–41 μm (mean $48 \times 34 \mu\text{m}$), with a thick wall that is granular and transversely striated, brownish-yellow to dark brown in colour and 2–3 μm thick. There is a micropyle in the outer wall layer only, and usually a micropylar cap (Fig. 9.18; see also Fig. 4.34). There are one or more polar granules, but no residuum. The sporocysts are elongate ovoid, 17–22 by 9–14 μm , with a residuum. The Stieda body is very small or absent. Sporozoites are elongate, lie lengthwise head to tail in the sporocysts and have two to three clear globules. Meronts are up to 65 by 45 μm in size and contain large merozoites (19.5 \times 4 μm). The mature macrogametes are 32–54 by 25–36 μm , and mature microgamonts are 61–250 by 36–71 μm and contain many slender flagellated microgametes.

Life cycle: The meronts are mostly in the cells lining the lower small intestine crypts. The gamonts, gametes and oocysts are in the epithelial cells of the crypts of the large and small intestines. The prepatent period is 23–27 days and sporulation time is 3–7 days.

Geographical distribution: Worldwide

Fig. 9.18 Oocyst of *Eimeria intricata*: sheep.

Eimeria marsica

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Sheep

Description: Oocysts are ellipsoidal, 15–22 by 11–14 μm (mean $19 \times 13 \mu\text{m}$), colourless to slightly greyish or pale yellow, with a micropyle, which may have an inconspicuous micropylar cap (Fig. 9.19; see also Fig. 4.34). There is no oocyst residuum. The sporocysts are elongate ovoid, 7–11 by 4–7 μm . The Stieda body, if present, is small, and each has a sporocyst residuum. Sporozoites are elongate and lie lengthwise head to tail in the sporocysts and each has a single small clear globule.

Life cycle: Details of the life cycle are unknown. The prepatent period is 14–16 days and sporulation time is 3 days.

Geographical distribution: Worldwide

Eimeria pallida

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Sheep

Description: Oocysts are ellipsoidal, colourless to very pale yellow or yellowish-green, 12–20 by 8–15 μm (mean $14 \times 10 \mu\text{m}$) with no micropyle or micropylar cap (Fig. 9.20; see also Fig. 4.34). A polar granule may be present. There is no oocyst residuum. Sporocysts are elongate ovoid, 6–9 by 4–6 μm . Each has a residuum but no Stieda body. The sporozoites are elongate and usually lie lengthwise, head to tail, although they may lie crosswise in the sporocysts. Each has a single clear globule.

Fig. 9.19 Oocyst of *Eimeria marsica*: sheep.

Fig. 9.20 Oocyst of *Eimeria pallida*: sheep.

Life cycle: Details of the life cycle are unknown. The sporulation time is 1–3 days.

Geographical distribution: Worldwide

Notes: *Eimeria pallida* has also been reported in the goat, but given the host specificity of other coccidia species, it is likely this name refers to different species in sheep and goats.

Eimeria parva

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Sheep

Description: Oocysts are subspherical to spherical, smooth, colourless to pale yellow, 13–22 by 11–18 μm (mean 16.5 \times 14 μm). There is no micropyle or micropylar cap, but there is a polar granule (Fig. 9.21; see also Fig. 4.34). There is no oocyst residuum. Sporocysts are ovoid, 6–13 by 5–8 μm . Each has a residuum composed of a few fine granules. The Stieda body is absent or small. The sporozoites each have one clear globule.

Fig. 9.21 Oocyst of *Eimeria parva*: sheep.

Life cycle: The life cycle is typically coccidian, with meronts found in the small intestine and the gamonts mainly in the caecum and colon, and to a lesser extent in the small intestine. Sporulation time is 3–5 days.

Geographical distribution: Worldwide

Eimeria weybridgensis

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Sheep

Description: Oocysts are ellipsoidal to subspherical, colourless or pale yellow, 17–30 by 14–19 μm (mean 24 \times 17 μm). There is a micropyle with a micropylar cap and a polar granule is present (Fig. 9.22; see also Fig. 4.34). There is no oocyst residuum. The sporocysts are elongate ovoid, 13–15 by 6–8 μm and each has a residuum but no Stieda body. The sporozoites are elongate, and lie lengthwise head to tail in the sporocysts. A clear globule is present at each end.

Life cycle: The life cycle is typically coccidian, with a prepatent period of 23–33 days and a patent period of 9–12 days. The sporulation time is 1–3 days.

Geographical distribution: Worldwide

Eimeria punctata

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Hosts: Sheep, occasionally goat

Description: Oocysts are ellipsoidal to ovoid with a thickened pitted wall and measure 24 by 18 μm ; there is a micropyle, with or

Fig. 9.22 Oocyst of *Eimeria weybridgensis*: sheep.

without a polar cap, and an oocyst residuum. The sporocysts are elongate ovoid with a sporocyst residuum.

Geographical distribution: Worldwide although uncommon

Goat coccidia

Fourteen species of coccidia have been identified in goats, of which nine species are commonly identified based on oocyst morphology and predilection site (Table 9.3; see also Table 4.9 and Fig. 4.35). *Eimeria ninakohlyakimovae* and *E. caprina* cause widespread denudation of the mucosa in the upper and lower large intestine in young kids. *Eimeria arloingi* is probably the most commonly encountered coccidia causing polyp formation and focal hyperplasia of the mucosa. Other species that are considered pathogenic in goats are *E. christenseni* and *E. hirci*.

Clinical signs: Clinical signs for *E. christenseni*, *E. hirci*, *E. ninakohlyakimovae* and *E. caprina* (see details in section Large intestine) are similar. Infection leads to loss of appetite, unthriftiness and profuse diarrhoea, often containing streaks of blood. If left untreated, these animals may continue to scour and eventually die of dehydration.

Epidemiology: Management factors associated with the development of high levels of infection and the development of disease are overcrowding, dirty conditions and repeat use of rearing pens for different age groups of young goats. If the same pens are used constantly for successive batches, or if young goats are added to a pen already housing older animals, then the later-born animals are immediately exposed to heavy challenge and can show severe coccidiosis in the first few weeks of life. On heavily stocked and overgrazed pastures, levels of contamination may be high, leading to disease.

A major problem in milking goat herds is that, in an attempt to ensure a constant year-round milk supply, births often take place over an extended period of time. If the same pens are used constantly for successive batches, or if young kids are added to a pen already housing older animals, then the later born kids are immediately exposed to heavy challenge and can show severe coccidiosis in the first few weeks of life.

Diagnosis: Diagnosis is based on history, age, postmortem lesions and faecal examination for oocysts. The latter may be present in very large numbers in both healthy and diseased animals so that postmortem or oocyst differentiation is advisable.

Treatment: While the same compounds used for the treatment and control of coccidiosis in sheep should be effective in goats, little data or information is available on the efficacy of these compounds in

goats. Sulphonamides, decoquinate or diclazuril may be effective if disease is suspected.

Control: Good management and hygiene practices (regular moving of feed and water troughs), avoidance of overcrowding and stress, batch rearing and feeding of dams prior to parturition can all help to reduce the incidence of infection.

Eimeria ninakohlyakimovae

Predilection site: Small and large intestine

Eimeria caprina

Predilection site: Small and large intestine

For more details on these species see section Large intestine.

Eimeria christenseni

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Goat

Description: The oocysts are ovoid or ellipsoidal, 27–44 by 17–31 μm (mean 38 \times 25 μm), colourless to pale yellow, with a micropyle and micropylar cap (Fig. 9.23; see also Fig. 4.35). One or more polar granules are present but there is no oocyst residuum. Sporocysts are broadly ovoid, 12–18 by 8–11 μm . Each has a residuum and the Stieda body is either vestigial or absent. The sporozoites are elongate and lie lengthwise head to tail in the sporocysts. Each has one or more clear globules. First-generation meronts when mature are ellipsoidal, 100–277 by 81–130 μm and contain thousands of straight merozoites about 6–8 by 1–2 μm . Second-generation meronts are 9–20 by 8–12 μm and contain 8–24 merozoites, and sometimes a residuum. Mature macrogametes are 19–35 by 13–25 μm and mature microgamonts are 19–50 by 12–40 μm and contain hundreds of comma-shaped microgametes (3 \times 0.5 μm) and a residuum.

Fig. 9.23 Oocyst of *Eimeria christenseni*: goat.

Table 9.3 Predilection sites and prepatent periods of *Eimeria* species in goats.

| Species | Predilection site | Prepatent period (days) |
|----------------------------------|---------------------------|-------------------------|
| <i>Eimeria alijevi</i> | Small and large intestine | 7–12 |
| <i>Eimeria aspheronica</i> | Unknown | 14–17 |
| <i>Eimeria arloingi</i> | Small intestine | 14–17 |
| <i>Eimeria caprina</i> | Small and large intestine | 17–20 |
| <i>Eimeria caprovina</i> | Unknown | 14–20 |
| <i>Eimeria christenseni</i> | Small intestine | 14–23 |
| <i>Eimeria hirci</i> | Unknown | 13–16 |
| <i>Eimeria jolchijevi</i> | Unknown | 14–17 |
| <i>Eimeria ninakohlyakimovae</i> | Small and large intestine | 10–13 |

Life cycle: First-generation meronts are situated in the endothelial cells of the lacteals of the jejunum and ileum, and in the lamina propria and lymph vessels of the submucosa and mesenteric lymph nodes. Second-generation meronts occur 16 days after infection, mostly in epithelial cells of the crypts, and less often in those of the villi in the small intestine and also in the sinuses of the mesenteric lymph nodes. Gamonts are present in the epithelial cells of the villi and the crypts of the small intestine from 16 days after infection. The prepatent period is 14–23 days and the patent period is 3–30+ days. The sporulation time is 3–6 days.

Geographical distribution: Worldwide

Pathogenesis: This species is one of the more pathogenic in young goats, infection causing desquamation of the mucosa and superficial necrosis.

Pathology: Focal aggregates of coccidia, particularly gamonts and oocysts, occur in the jejunum and ileum and are associated with local infiltration by lymphocytes and plasma cells, epithelial necrosis and submucosal oedema. Superficial desquamation of the mucosa and superficial necrosis are also present. The capillaries are congested and there are petechial haemorrhages. The cellular reaction in the submucosa consists of lymphocytes, macrophages, plasma cells, neutrophils and eosinophils. In the lymph nodes there is oedema and perivascular infiltration by lymphocytes. There are white foci in the intestine consisting essentially of masses of macrogametes, microgamonts and oocysts in the epithelial cells of the tips and sides of the villi and in the crypts.

Eimeria hirci

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Goat

Description: Oocysts are ellipsoidal to subspherical, light brown to brownish-yellow, 18–23 by 14–19 μm (mean 20.7 \times 16.2 μm), with a micropyle and micropylar cap, one or more polar granules, but no oocyst residuum (Fig. 9.24; see also Fig. 4.35). Sporocysts are ovoid, 8–14 by 4–9 μm with a tiny Stieda body and a residuum. The

Fig. 9.24 Oocyst of *Eimeria hirci*: goat.

sporozoites lie lengthwise, at an angle, or even at the ends of the sporocysts and have one to two clear globules.

Life cycle: Details of the life cycle are not known. The prepatent period is 13–16 days and the patent period is 5–14 days. The sporulation time is 1–3 days.

Geographical distribution: Presumed to be worldwide

Pathogenesis: This species is considered pathogenic but lesions and pathology have not been described in detail.

Eimeria alijevei

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Goat

Description: Oocysts are ovoid or ellipsoidal, pale yellowish to colourless, 15–23 by 12–22 μm (mean 17 \times 15 μm), with an inconspicuous micropyle without a micropylar cap or residuum, and one polar granule (Fig. 9.25; see also Fig. 4.35). Sporocysts are elongate to ovoid, 7–13 by 4–9 μm , with or without a Stieda body, and with a sporocyst residuum. The sporozoites are elongate, and lie at an angle or lengthwise head to tail in the sporocysts and usually have one to two clear globules. First-generation meronts are 260 by 180 μm and can be seen grossly as whitish bodies. Second-generation meronts are 15–18 by 9–12 μm . The macrogamonts are 14–18 by 9–14 μm , and the microgamonts 22–25 by 15–20 μm .

Life cycle: The life cycle is typically coccidian with first-generation meronts sited in the epithelial cells of the villi in the middle part of the small intestine. Smaller second-generation meronts occur within crypts of the small intestine. Gamonts and oocysts are in the epithelial cells of the colon, caecum and posterior small intestine. The prepatent period is 7–12 days and the patent period 6–18 days. Sporulation time is 1–5 days.

Geographical distribution: Worldwide

Pathogenesis: Not considered pathogenic, although inappetence, weakness and weight loss have been reported.

Fig. 9.25 Oocyst of *Eimeria alijevei*: goat.

Eimeria arloingi**Predilection site:** Small intestine**Phylum:** Apicomplexa**Class:** Conoidasida**Family:** Eimeriidae**Host:** Goat

Description: Oocysts are ellipsoidal or slightly ovoid, 17–42 by 14–19 μm (mean $27 \times 18 \mu\text{m}$), with a thick wall and a micropyle and micropylar cap present (Fig. 9.26; see also Fig. 4.35). There are one or more polar granules but no oocyst residuum. Sporocysts are ovoid, 10–17 by 5–10 μm with a sporocyst residuum, but the Stieda body is either vestigial or not present. The sporozoites are elongate and lie lengthwise head to tail in the sporocysts and usually have a large clear globule at the large end and a small one at the small end. First-generation meronts are 130–350 by 65–240 μm and contain many thousands of merozoites 9–12 by 1–2 μm . Second-generation meronts are 11–44 by 9–20 μm and contain 8–24 merozoites, which are 4–10 μm long. The microgamonts are 19–34 by 13–29 μm and contain a large residuum and several hundred microgametes. The macrogametes are similarly sited and are 19–28 by 14–20 μm .

Life cycle: There are two generations of meronts, with the mature first-generation meronts occurring in the endothelial cells of the lacteals of the villi, in Peyer's patches in the duodenum, jejunum and ileum, and also in the sinuses of the mesenteric lymph nodes draining these regions. These mature 9–12 days after infection. Second-generation meronts lie in the epithelial cells of the villi and the crypts of the small intestine and are mature at about 12 days post infection. Gamonts are found 11–26 days after infection in the epithelial cells lining the crypts and the villi of the jejunum and ileum. The prepatent period is 14–17 days and the patent period 14–15 days. Sporulation time is 1–4 days.

Geographical distribution: Worldwide

Pathogenesis: Papilloma-like lesions or polyps may occur in the small intestine, usually as a sequela to gametocyte formation, but these are not of great pathogenic significance.

Pathology: A few, small, slightly haemorrhagic areas are seen scattered throughout the lining of the small intestine and thick white

**Fig. 9.26** Oocyst of *Eimeria arloingi*: goat.

opaque patches composed of groups of heavily parasitised villi are present leading to the formation of polyps.

Eimeria aspheronica**Predilection site:** Unknown**Phylum:** Apicomplexa**Class:** Conoidasida**Family:** Eimeriidae**Host:** Goat

Description: Oocysts are ovoid, greenish to yellow–brown, 24–37 by 18–26 μm (mean $31 \times 23 \mu\text{m}$), with a micropyle but without a micropylar cap (Fig. 9.27; see also Fig. 4.35). There is a polar granule but no residuum. Sporocysts are pyriform or ellipsoidal, 11–17 by 7–11 μm , with a sporocyst residuum and a Stieda body that is either vestigial or absent. The sporozoites are elongate and lie lengthwise head to tail in the sporocysts and usually have one to two large clear globules.

Life cycle: Details of the life cycle are not known. The prepatent period is 14–17 days and patent period is 4–9 days. Sporulation time is 1–2 days.

Geographical distribution: Worldwide***Eimeria caprovina*****Predilection site:** Unknown**Phylum:** Apicomplexa**Class:** Conoidasida**Family:** Eimeriidae**Host:** Goat

Description: Oocysts are ellipsoidal to subspherical, 26–36 by 21–28 μm (mean $30 \times 24 \mu\text{m}$), colourless, with a micropyle but without a micropylar cap (Fig. 9.28; see also Fig. 4.35). One or more polar granules are present. There is no oocyst residuum. Sporocysts are

**Fig. 9.27** Oocyst of *Eimeria aspheronica*: goat.

Fig. 9.28 Oocyst of *Eimeria caprovina*: goat. (Courtesy of Professor Antonio Ruiz Reyes, Universidad de Las Palmas, Gran Canaria.)

elongate ovoid, 13–17 by 8–9 μm , and each has a Stieda body and a residuum. The sporozoites are elongate, lie lengthwise head to tail in the sporocysts and have a large clear globule at each end.

Life cycle: Details of the life cycle are not known. The prepatent period is 14–20 days and patent period is 4–9 days. Sporulation time is 2–3 days.

Geographical distribution: North America, Europe

Eimeria jolchijevi

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Goat

Fig. 9.29 Oocyst of *Eimeria jolchijevi*: goat.

Description: Oocysts are ellipsoidal or ovoid, pale yellow, 26–37 by 18–26 μm (mean 31 \times 22 μm), with a micropyle at the broad end and a prominent micropylar cap (Fig. 9.29; see also Fig. 4.35). There is no oocyst residuum. Sporocysts are ovoid, 12–18 by 6–10 μm , with a small Stieda body and a residuum. The sporozoites are elongate and lie lengthwise head to tail in the sporocysts and have one or more large clear globules.

Life cycle: Details of the life cycle are not known. The prepatent period is 14–17 days and patent period is 3–10 days. Sporulation time is 2–4 days.

Geographical distribution: Presumed worldwide

The following three species of coccidia have been reported in goats in New Zealand.

Eimeria capralis

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Goat

Description: Oocysts are ellipsoidal with a distinct micropylar cap, with Stieda body and sporocyst residuum and measure 29 by 20 μm (Fig. 9.30).

Geographical distribution: New Zealand

Eimeria masseyensis

Predilection site: Unknown

Phylum: Apicomplexa

Fig. 9.30 Oocyst of *Eimeria capralis*: goat. (Redrawn from Soe and Pomroy, 1992. Reproduced with permission from Springer Science and Business Media.)

Fig. 9.31 Oocyst of *Eimeria masseyensis*: goat. (Redrawn from Soe and Pomroy, 1992. Reproduced with permission from Springer Science and Business Media.)

Fig. 9.32 Oocyst of *Eimeria charlestoni*: goat. (Redrawn from Soe and Pomroy, 1992. Reproduced with permission from Springer Science and Business Media.)

Class: Conoidasida

Family: Eimeriidae

Host: Goat

Description: Oocysts are ellipsoidal to ovoid, with Stieda body and distinct micropylar cap, and measure 22 by 17 μm (Fig. 9.31).

Geographical distribution: New Zealand

Eimeria charlestoni

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Goat

Description: Oocysts are ellipsoidal with no micropylar cap, and measure 23 by 17 μm . The sporocysts are distinctly elongate and contain prominent refractile bodies (Fig. 9.32).

Geographical distribution: New Zealand

Other protozoa

Cryptosporidium parvum

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Description: Mature oocysts are ovoidal or spheroidal, 5.0 by 4.5 μm in size (range 4.6–5.4 \times 3.8–4.7 μm); length/width ratio 1.19.

Hosts: Cattle, sheep, goat, horse, deer, human

Geographical distribution: Worldwide

Epidemiology: A variety of mammals act as hosts to *C. parvum* but little is known of the importance of their involvement in transmitting infection to, or maintaining infection in, domestic livestock. In young lambs infection appears to be age related, with seasonal peaks of disease reported to coincide with birth peaks in spring and autumn. The primary route of infection is mainly direct animal to animal via the faecal–oral route. In lambs, chilling due to adverse weather conditions in the neonatal period, intercurrent infections or nutritional or mineral deficiencies could exacerbate or increase the likelihood of disease. Infection in these cases is likely to occur through grooming, nuzzling, coprophagy, or by faecal soiling by direct contact with infected animals. Infection may also occur indirectly through consumption of contaminated foods or environmental sources including pasture and water.

For more details see Chapter 8.

Cryptosporidium xiaoi

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Description: Oocysts are 3.94 by 3.44 μm (range 2.94–4.41 \times 2.94–4.41 μm); length/width shape index 1.15.

Hosts: Sheep, goat

Geographical distribution: Unknown

Giardia intestinalis

Synonyms: *Giardia duodenalis*, *Giardia lamblia*, *Lamblia lamblia*

Predilection site: Small intestine

Phylum: Fornicata

Class: Trepomonadea

Family: Giardiidae

Description: The trophozoite has a pyriform to ellipsoidal, bilaterally symmetrical body, 12–15 µm long by 5–9 µm wide. The dorsal side is convex and there is a large sucking disc on the ventral side. There are two anterior nuclei, two slender axostyles, eight flagellae in four pairs and a pair of darkly staining median bodies (see Figs 2.21 and 8.12). The median bodies are curved bars resembling the claws of a hammer. Cysts are ovoid, 8–12 by 7–10 µm, and contain four nuclei (see Fig. 8.13).

Hosts: Human, cattle, sheep, goat, pig, horse, alpaca, dog, cat, guinea pig, chinchilla

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Infections in sheep are considered non-pathogenic.

For more details see Chapter 8.

LARGE INTESTINE

Oesophagostomum columbianum

Common name: Nodular worm

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: Adults are slender worms (male 12–17 mm, female 15–22 mm) with large cervical alae, which produce a marked dorsal curvature of the anterior part of the body.

Description, microscopic: The cuticle forms a high mouth collar shaped like a truncate cone, and separated from the rest of the body by a constriction. The cephalic vesicle is anterior to a cervical groove behind which arise the cervical alae pierced by cervical papillae. External leaf crowns consist of 20–24 elements and the internal has two small elements to each external element. The male bursa is well developed with two equal alate spicules.

The smooth, colourless, thin-shelled egg is a medium-sized (70–89 × 36–45 µm), regular broad ellipse with barrel-shaped walls and round wide poles, and contains 8–16 blastomeres when passed in the faeces (see Fig. 4.3). The L₃ have long filamentous tails, 32 gut cells and a rounded head and measure around 790 µm.

Hosts: Sheep, goat, camel and wild ruminants

Geographical distribution: Worldwide; more important in tropical and subtropical areas

Pathogenesis: In the intestine, *O. columbianum* L₃ migrate deep into the mucosa, provoking an inflammatory response with the formation of nodules, which are visible to the naked eye. On reinfection, this response is more marked, the nodules reaching 2.0 cm in diameter and containing greenish eosinophilic pus and an L₄. When the L₄ emerge there may be ulceration of the mucosa. Diarrhoea occurs coincident with emergence about a week after primary infection and from several months to a year after reinfection. In heavy infections, there may be ulcerative colitis and the disease runs a chronic debilitating course with effects on the production of wool and mutton. The nodules in the gut wall also render the intestines useless for processing as sausage skins and surgical suture material.

Clinical signs: In acute infections, severe dark-green fetid diarrhoea is the main clinical sign and there is usually a rapid loss of weight, emaciation, prostration and death in young animals. In chronic infections, there is inappetence and emaciation with intermittent diarrhoea and anaemia.

Diagnosis: This is based on clinical signs and postmortem examination. Since the acute disease occurs within the prepatent period, eggs of *Oesophagostomum* spp. are not usually present in the faeces. In the chronic disease eggs are present and L₃ can be identified following faecal culture.

Pathology: On postmortem, the carcass is emaciated, the mesenteric lymph nodes are enlarged, and the colonic mucosa is thickened, congested and covered by a layer of mucus in which the worms are scattered. There is hyperplasia of goblet cells, and the lamina propria contains a heavy mixed inflammatory infiltrate with eosinophils, lymphocytes and plasma cells. Nodules caused by histotropic L₄, mainly in the large intestine, are 0.5–3 cm in diameter and comprise a central caseous or mineralised core surrounded by a thin, fibrous, encapsulating stroma. Microscopically, the nematode or its remnants are present among a mass of necrotic debris in which eosinophils are prominent. Giant cells and macrophages may surround the necrotic material. Similar nodules may be found in liver, lungs, mesentery and mesenteric lymph nodes. Those in the deeper layers of the gut project from the serosal surface ('pimply gut') and may cause adhesion to adjacent loops of gut or to other organs, and rarely may incite intussusception or peritonitis. In most cases, however, nodules are incidental findings at necropsy. They are probably the response to histotropic L₄ in hosts sensitised by L₃, or the result of prior infection. The nodules caused by the histotropic L₃ consist of small concentrations of suppurative exudate, which resolve as minor foci of granulomatous inflammation after evacuation of the larvae.

Epidemiology: In tropical and subtropical areas, *O. columbianum* in sheep is especially important. The prolonged survival of the L₄ within the nodules in the gut wall and the lack of an effective immunity made control difficult until the advent of effective anthelmintics.

Treatment: Anthelmintic therapy with broad-spectrum anthelmintics (benzimidazoles, levamisole and avermectins/milbemycins) is highly effective.

Control: A combination of strategic dosing with anthelmintics and pasture management, as used in the control of other nematodes, will also help to control *O. columbianum*.

Notes: The more pathogenic species in sheep occur in the subtropics and tropics and are associated with nodule formation in the intestine.

Oesophagostomum venulosum

Synonym: *Oesophagostomum virginimembrum*

Common name: Large bowel worm

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: Adult worms are slender, with males 11–16 mm and females 13–24 mm long (see Fig. 1.41).

Description, microscopic: The head has a shallow buccal capsule with an external leaf crown of 18 elements. The external crown is compressed so there is only a narrow opening into the buccal capsule. There are no lateral cervical alae and the cervical papillae are posterior to the oesophagus. Around the anterior oesophagus there is an inflated cuticular cephalic vesicle (see Fig. 1.42). This terminates in a cervical groove, which is followed in some species by broad cervical alae. In the male the bursa is well developed. The smooth, colourless, thin-shelled egg is a medium-sized (85–120 × 45–60 µm), regular broad ellipse with barrel-shaped walls, and contains 16–32 blastomeres when passed in the faeces. The L₃ have long filamentous tails, 32 gut cells and a rounded head.

Hosts: Sheep, goat, deer, camel

Geographical distribution: Worldwide

Pathogenesis: Generally considered non-pathogenic.

Clinical signs: Not associated with clinical signs.

Diagnosis: Diagnosis of gastrointestinal nematodes is generally based on clinical signs, grazing history, postmortem findings and faecal egg counts. Faecal worm egg counts are not that useful, as the eggs of *O. venulosum* are difficult to differentiate from other trichostrongyle eggs. For accurate differentiation, larval cultures should be prepared.

Pathology: *Oesophagostomum venulosum* seldom causes significant nodule formation (cf. *O. columbianum*) and when it does the nodules are small and mainly confined to the caecum and colon.

Epidemiology: The basic epidemiology of *O. venulosum* is similar to that of other trichostrongylid infections of sheep and further details on the life cycle and epidemiology are given in Chapters 1 and 6. In temperate areas, there is evidence that *O. venulosum* undergoes hypobiosis at the L₄ stage in sheep during autumn and winter, and that this is the principal manner in which this species survives until the next spring. The species is also capable of overwintering on pasture as L₃.

Treatment and control: As for *O. columbianum*

Notes: *Oesophagostomum virginimembrum* is specific to the dromedary camel but is considered synonymous with *O. venulosum*.

Other species of *Oesophagostomum* have been reported in sheep and goats. Little is known of their pathogenesis and treatment is not usually indicated.

Oesophagostomum multifoliatum

Common name: Nodular worm

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Hosts: Sheep, goat

Geographical distribution: Eastern Africa

Oesophagostomum asperum

Common name: Nodular worm

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Hosts: Sheep, goat

Geographical distribution: Asia, Central America

Chabertia ovina

Common name: Large-mouthed bowel worm

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: The adults range from about 1.3 to 2.0 cm in length and are the largest nematodes found in the colon of ruminants. They are white and stout with a markedly truncated and enlarged anterior end due to the presence of the very large buccal capsule (see Fig. 1.40).

Description, microscopic: The huge buccal capsule, which is bell-shaped, has a double row of small papillae around the rim. There are no teeth. There is a shallow ventral cervical groove, and anterior to it a slightly inflated cephalic vesicle. In the male, the bursa is well developed and the spicules are 1.3–1.7 mm long, with a gubernaculum. In the female, the vulva opens about 0.4 mm from the posterior extremity. The egg is a thin-shelled, smooth, medium-sized (90–100 × 45–55 µm), regular broad ellipse with wide slightly flattened poles (see Fig. 4.3). It contains 16–32 blastomeres. Infective larvae have a rounded head, 32 gut cells and a long filamentous tail and measure around 730 µm (see Fig. 4.14).

Hosts: Sheep, goat, occasionally deer, cattle and other ruminants

Geographical distribution: Worldwide but more prevalent in temperate regions

Pathogenesis: *Chabertia ovina* is present, usually in low numbers, in the majority of sheep and goats. It contributes to the syndrome

of PGE and only occasionally occurs in sufficient numbers to cause clinical disease on its own. The major pathogenic effect is caused by the L₅ and by mature adults; these attach to the mucosa of the colon via their buccal capsules and then feed by ingesting large plugs of tissue, resulting in local haemorrhage and loss of protein through the damaged mucosa. A burden of around 300 worms is considered pathogenic and in severe outbreaks the effects become evident during the late prepatent period. The wall of the colon becomes oedematous, congested and thickened with small haemorrhages at the sites of worm attachment.

Clinical signs: Moderate infections are usually asymptomatic. In severe infections, diarrhoea, which may contain blood and mucus and in which worms may be found, is the most common clinical sign. The sheep become anaemic and hypoalbuminaemic and can suffer severe weight loss.

Diagnosis: Since much of the pathogenic effect occurs within the prepatent period, the faecal egg count may be very low. However, during the diarrhoeic phase, the worms may be expelled and they are easily recognised. At necropsy, diagnosis is generally based on the lesions since the worm burden may be negligible following the expulsion of worms in the faeces, although in some cases worms may be observed attached to the mucosa of the colon.

Pathology: There are petechial haemorrhages in the mucosa of the colon due to immatures, and immature and adult worms are found in the gut lumen.

Epidemiology: In temperate areas, L₃ are capable of surviving the winter. The parasite may also overwinter in the host as hypobiotic L₄ in the wall of the intestine, emerging in the late winter and early spring. Although outbreaks of chabertiosis have been recorded in goats and sheep in Europe, the disease is more important in the winter rainfall areas of Australasia and South Africa.

Treatment: Anthelmintic therapy with broad-spectrum anthelmintics (benzimidazoles, levamisole and avermectins/milbemycins) is highly effective.

Control: Similar to other strongylid intestinal nematodes.

Skrjabinema ovis

Synonym: *Oxyuris ovis*

Common name: Pinworms

Predilection site: Caecum, colon

Phylum: Nematoda

Class: Secernentea

Superfamily: Oxyuroidea

Description, gross: Small worms, up to 7 mm in size; male are 3 mm and females 6–7 mm. There are three large complicated lips and three small intermediate lips. The oesophagus is cylindrical and terminates in a large spherical bulb.

Description, microscopic: The male worm has a single spicule. The tail is bluntly rounded with a cuticular expansion supported by two pairs of processes. Eggs are asymmetrically flattened, larvated and measure 55–60 by 32–35 µm.

Hosts: Sheep, goat

Geographical distribution: Worldwide

Pathogenesis: The pinworms cause negligible pathological disturbance.

Clinical signs: These pinworms have rarely been incriminated as a cause of disease and are usually recognised only at necropsy.

Diagnosis: Identification of the worms on postmortem, or the larvated eggs in faeces.

Pathology: No associated pathology

Epidemiology: Infection occurs by ingestion, either through nuzzling or suckling, or through intake of the larvated eggs in grass, hay or bedding.

Treatment: Not usually required

Control: Not required

Skrjabinema alata

Common name: Pinworms

Predilection site: Caecum, colon

Phylum: Nematoda

Class: Secernentea

Superfamily: Oxyuroidea

Host: Sheep

Geographical distribution: South Africa

Skrjabinema caprae

Common name: Pinworms

Predilection site: Caecum, colon

Phylum: Nematoda

Class: Secernentea

Superfamily: Oxyuroidea

Host: Goat

Geographical distribution: USA, Mexico

Other details of these two species are essentially similar to *Skrjabinema ovis*.

Trichuris ovis

Synonym: *Trichocephalus ovis*

Common name: Whipworms

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: The adults are long white worms, the males measuring 5–8 cm and the females 3.5–7 cm in length with a thick broad posterior end tapering rapidly to a long filamentous anterior end that is characteristically embedded in the mucosa.

Description, microscopic: The male tail is coiled and possesses a single spicule in a protrusible sheath. The sheath bears an oblong swelling a short distance from its distal extremity and is covered with minute spines, which decrease in size towards the distal end. The female tail is merely curved. The characteristic eggs are lemon-shaped, with a thick smooth shell and a conspicuous protruding transparent polar plug (operculum) at both ends (see Fig. 4.3). In the faeces these eggs appear yellow or brown in colour. They measure around 70–80 by 30–42 µm and when laid they contain an unsegmented embryo.

Hosts: Sheep, goat, occasionally cattle and other ruminants

Geographical distribution: Worldwide

Pathogenesis: Most infections are light and asymptomatic. Occasionally when large numbers of worms are present, they cause a haemorrhagic colitis and/or a diphtheritic inflammation of the caecal mucosa. This results from the subepithelial location and continuous movement of the anterior end to the whipworm as it searches for blood and fluid.

Clinical signs: Despite the fact that ruminants have a high incidence of light infections, the clinical significance of this genus, especially in ruminants, is generally negligible although isolated outbreaks have been recorded.

Diagnosis: Since the clinical signs are not pathognomonic, diagnosis may depend on finding numbers of lemon-shaped *Trichuris* eggs in the faeces. Egg output is often low in *Trichuris* infections. However, since clinical signs may occur during the prepatent period, diagnosis in food animals may depend on necropsy.

Pathology: In heavy infections there may be a mucohaemorrhagic typhlitis.

Epidemiology: The most important feature is the longevity of the eggs, which may survive for 3 or 4 years. On pasture, this is less likely since the eggs tend to be washed into the soil.

Treatment: In ruminants, the benzimidazoles, the avermectins/milbemycins or levamisole by injection are very effective against adult *Trichuris*, but less so against larval stages.

Control: Prophylaxis is rarely necessary in ruminants.

Notes: The adults are usually found in the caecum but are only occasionally present in sufficient numbers to be clinically significant.

Other species of *Trichuris* are found less commonly in sheep and goats.

Trichuris skrjabini

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Geographical distribution: Europe, Asia, USA

Trichuris discolor

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Geographical distribution: Europe, Asia, USA

Details of these two species are essentially similar to *Trichuris ovis*.

Eimeria crandallis

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Sheep

Description: Oocysts are subspherical to broadly ellipsoidal, 17–23 by 17–22 µm (mean 21.9 × 19.4 µm), with a micropyle, which may be distinct or indistinct, and a micropylar cap (Fig. 9.33; see also Fig. 4.34). One or more polar granules may be present and there is no residuum. The sporocysts are broadly ovoid, 8–13 by 6–9 µm. There is no Stieda body but a residuum may be present. The sporozoites lie transversely at the ends of the sporocysts and have one to two clear globules. Mature first-generation meronts are 250 µm in diameter and are visible to the naked eye as pin-point white spots, occurring most frequently in the lower jejunum. They contain an average of 253,000 first-generation merozoites measuring 10 by 1.7 µm.

Life cycle: First-generation meronts appear on day 3 after infection and are mature by day 10. Second-generation meronts appear at day 10–12 after infection in the cytoplasm of epithelial cells of the small intestine and the caecum. Most lie at the base of the crypts and contain five to nine merozoites. Progamonts appear in the nuclei

Fig. 9.33 Oocysts of *Eimeria crandallis*: sheep.

of the epithelial cells in the crypts and villi of the jejunum, ileum and caecum at 11–16 days after infection. The progamonts divide synchronously. By day 16, the progamonts on the villi mature into gamonts, and enlarge and move into the cytoplasm above the nucleus where they differentiate into macrogamonts and microgamonts. The progamonts in the crypts mature from day 18. The prepatent period is 13–20 days and sporulation time is 1–3 days.

Geographical distribution: Worldwide

Pathogenesis: The pathogenic lesions are mainly in the ileum, caecum and colon where gametogony of *E. crandallii* occurs. Large numbers of gamonts cause local haemorrhage and oedema, and villous atrophy may be a sequela resulting in malabsorption. Infection is particularly a problem in very young lambs, especially if their immune status is poor or they have been colostrum deprived. Light infections produce a very strong immunity.

Pathology: In heavily infected lambs at around 10 days after infection there is whitish discoloration of the mucosa due to masses of first-generation meronts, and this is apparent through the serosa (Fig. 9.34). From the onset of diarrhoea there is hyperaemia and thickening of the wall of the small intestine, increasing in severity towards the caecum. Gamonts are found in scrapings from these areas. In heavy infections, the caecum and colon may be similarly affected. Histologically, there is leucocyte infiltration with loss of villous epithelium associated with first- and second-generation meronts in the small intestine. There is resulting villous atrophy, and the crypt epithelium is also affected resulting in loss of crypts (Fig. 9.35). From day 11 after infection, progamonts can be detected in the small intestine and the large intestine. Infected crypts are hyperplastic with large basophilic enterocytes and reduced goblet cell numbers. Damage to the mucosa and epithelial sloughing may lead to the presence of intestinal ‘casts’ in the faeces (Fig. 9.36).

Eimeria ovinoidalis

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Fig. 9.34 Section of small intestine with numerous first-generation meronts of *Eimeria crandallii* visible through the serosal surface.

Fig. 9.35 *Eimeria crandallii* infection of the intestinal mucosa showing inflammatory response and villous atrophy.

Family: Eimeriidae

Host: Sheep

Description: Oocysts are ellipsoidal, colourless or pale-yellow, 17–30 by 14–19 μm (mean $19 \times 13 \mu\text{m}$). There is an inconspicuous micropyle without a micropylar cap (Fig. 9.37; see also Fig. 4.34). Two or more polar granules are present and there is no residuum. Sporocysts are elongate ovoid, 10–14 by 4–8 μm . Each has a Stieda body and a residuum. The sporozoites are elongate, 11–14 by 2–4 μm and lie lengthwise head to tail in the sporocysts. Each has one large and one small globule. First-generation meronts, at 10 days, average 290 μm in diameter and contain many thousands of merozoites (Fig. 9.38). Second-generation meronts mature at about 10–11 days and have a mean diameter of 12 μm , each containing an average of 24 merozoites. The mature microgamonts average 15 by 12 μm and contain many microgametes arranged peripherally around a central residuum, while mature macrogamonts average 16 by 12 μm .

Life cycle: Following ingestion of sporulated oocysts, eight sporozoites emerge from each oocyst into the small intestine and penetrate cells in the intestinal mucosa. The parasites undergo at

Fig. 9.36 Lamb faeces containing mucus and fragments of sloughed mucosa.

Fig. 9.37 Oocyst of *Eimeria ovinoidalis*: sheep.

least one asexual multiplication within the mucosa, giving rise to merozoites within meronts. The first-generation meronts are very large (100–300 µm) and may be visible to the naked eye as pinpoint white spots on the mucosa. These mature in the small intestine lamina propria 9 days after infection, and give rise to a second generation of meronts that are much smaller than the first. Second-generation meronts lie in epithelial cells lining the crypts of the large intestine, maturing 10–11 days after infection. From this last meront generation, merozoites emerge which give rise to the sexual forms (gamonts), which in turn form oocysts that pass out in the faeces. Once outside, the oocysts sporulate, i.e. they undergo two divisions to produce four sporocysts, each containing two sporozoites. Only the sporulated oocysts are infective. If ingested by a susceptible host, the sporozoites emerge and start the cycle again. The prepatent period is 12–15 days and the patent period is 7–28 days. Sporulation time is 1–3 days.

Geographical distribution: Worldwide

Pathogenesis: The pathogenic lesions are mainly in the caecum and colon where second-stage merogony and gametogony of *E. ovinoidalis* occur. Petechial haemorrhages appear in the small intestine 3–7 days after infection. The small intestine may become

Fig. 9.38 First-generation ('giant') meront of *Eimeria ovinoidalis*. Each meront contains thousands of merozoites.

thickened and inflamed. The giant first-generation meronts which form in the mucosa of the small intestine 10 days after infection cause leucocyte and macrophage infiltration, crypt hyperplasia and epithelial loss. There is extensive haemorrhage in the posterior small intestine of severely affected lambs by day 15 after infection. The caecum and upper part of the small intestine become thickened and oedematous, and are haemorrhagic by day 19. The gamonts result in loss of crypt and surface epithelium leading to a denuded mucosa. The lesions cause local haemorrhage and oedema, and villous atrophy may be a sequela resulting in malabsorption.

Pathology: On postmortem examination, the caecum is usually inflamed, empty and contracted, with a hyperaemic, oedematous and thickened wall. In some cases the mucosa may be haemorrhagic. Other lesions are more specific but are not usually associated with clinical signs.

Clinical signs: Clinical signs for both *E. crandallii* and *E. ovinoidalis* are similar. The first sign that coccidiosis may be affecting a flock is that lambs may not be thriving as expected. Several lambs may have a tucked-up and open-fleeced appearance with a few showing faecal staining around the hindquarters due to diarrhoea (see Fig. 9.9). Lambs eventually lose their appetite and become weak and unthrifty. As the disease progresses, some lambs show profuse watery diarrhoea, often containing streaks of blood. If left untreated, these animals may continue to scour and eventually die of dehydration.

Diagnosis: Diagnosis is based on the management history, the age of the lambs, postmortem lesions, faecal examination for oocysts and oocyst speciation. Oocysts may be present in very large numbers in both healthy and diseased lambs so that a necropsy is always advisable.

Epidemiology: In spring-lambing flocks in western Europe, infection of lambs results both from oocysts which have survived the winter and from those produced by earlier born lambs. Lambs are usually affected between 4 and 8 weeks of age, with peak infection around 6 weeks. The outbreaks reported have occurred where ewes and lambs were housed in unhygienic conditions or grazed intensively. The feeding of concentrates in stationary troughs, around which heavy contamination with oocysts has occurred, can also be a precipitating factor. In the USA, coccidiosis occurs when older lambs are confined in feedlots after weaning.

Treatment and control: Decoquinate, diclazuril or toltrazuril are the drugs generally used for the prevention and treatment of these infections. Monensin and amprolium have also been used in some countries for coccidiosis prevention but their use has declined. Several sulphonamides, such as sulphadimidine, sulphamethoxy-pyridazine, sulphadiazine, sulphadoxine and sulphatroxazole, were used for the treatment of infected animals but in many countries are no longer licensed for treatment of coccidial infections in ruminants. All animals in a group should be treated and dehydrated animals may require oral or intravenous rehydration. Where non-specific symptoms of weight loss or ill-thrift are present, it is important to investigate all potential causes and seek laboratory confirmation. Good management and hygiene practices, by regular moving of feed and water troughs, avoidance of overcrowding and stress, batch rearing, feeding of dams prior to parturition, and creep feeding will reduce the incidence of infection. Further details on control are provided in the section Sheep coccidia.

Eimeria ninakohlyakimovae

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Goat

Description: Oocysts are ellipsoidal, thin-walled, colourless, 20–22 by 14–16 μm (mean $20.7 \times 14.8 \mu\text{m}$), without micropyle or micropylar cap and with no oocyst residuum (Fig. 9.39; see also Fig. 4.35). Sporocysts are ovoid, 9–15 by 4–10 μm , each with a Stieda body and a sporocyst residuum. The sporozoites are elongate and lie lengthwise head to tail in the sporocysts, each with two clear globules.

Life cycle: The meronts, gamonts and oocysts are in the epithelial cells of the ileum, caecum and upper large intestine. The prepatent period is 10–13 days. The sporulation time is 1–4 days.

Geographical distribution: Worldwide

Pathogenesis: As for *E. ovinoidalis* in sheep.

Eimeria caprina

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Goat

Description: Oocysts are ellipsoidal or slightly ovoid, dark brown to brownish-yellow in colour, 27–40 by 19–26 μm with a smooth wall. There is a micropyle but no micropylar cap or oocyst residuum (Fig. 9.40; see also Fig. 4.35). One or more polar granules are present. Sporocysts are elongate ovoid, 13–17 by 7–10 μm , with a small Stieda body and a residuum. The sporozoites are elongate, lie lengthwise head to tail in the sporocysts and usually have a large clear globule at the large end and a smaller one at the small end.

Fig. 9.39 Oocyst of *Eimeria ninakohlyakimovae*: goat.

Fig. 9.40 Oocyst of *Eimeria caprina*: goat.

Life cycle: Details of the life cycle are not known. The prepatent period is 17–20 days and the patent period 3–6 days. Sporulation time is 2–3 days.

Geographical distribution: Worldwide

Pathogenesis: This species is considered pathogenic but lesions and pathology have not been described in detail.

Clinical signs: The clinical signs for *E. ninakohlyakimovae* and *E. caprina* are generally similar. Infection leads to loss of appetite, unthriftiness and profuse diarrhoea, often containing streaks of blood. If left untreated, these animals may continue to scour and eventually die of dehydration.

Flagellate protozoa

The life cycle of flagellate protozoa is similar for all species found in sheep and goats. The trophozoites reproduce by longitudinal binary fission. No sexual stages are known and there are no cysts. Transmission is thought to occur by ingestion of trophozoites from faeces. All are considered to be non-pathogenic and are generally only identified from smears taken from the large intestine of fresh carcasses.

Retortamonas ovis

Predilection site: Large intestine

Phylum: Fornicata

Class: Retortamonadea

Family: Retortamonadorididae

Hosts: Sheep, cattle

Description: Trophozoites are pyriform and average 5.2 by 3.4 μm . There is a large cytostome near the anterior end, containing a cytostomal fibril that extends across the anterior end and posteriorly along each side. An anterior flagellum and a posterior trailing flagellum emerge from the cytostomal groove. Cysts are pyriform and ovoid, containing one or two nuclei and retain the cytostomal fibril.

Geographical distribution: Worldwide

Tetratrichomonas ovis

Synonyms: *Trichomonas ovis*, *Ditrichomonas ovis*

Predilection site: Caecum, rumen

Phylum: Parabasalia

Class: Zoomastigophorasida

Family: Trichomonadidae

Host: Sheep

Description: The body is pyriform, 6–9 by 4–8 µm (mean 7 × 6 µm), and the four anterior flagella are of unequal length. There is a slender hyaline axostyle which extends approximately 5 µm beyond the body and gradually tapers to a point. There is no chromatic ring at the point at which the axostyle leaves the body. There is an anterior nucleus, and a prominent pelta at the anterior end. There is a prominent undulating membrane which extends 75–100% the length of the body, and which continues as a free posterior flagellum. The costa is prominent and there are several irregular rows of paracostal granules, and an ovoid or club-shaped parabasal body (approximately 2 × 1 µm), containing an intensely chromophilic body and a parabasal filament.

Geographical distribution: Unknown

Entamoeba ovis

Synonym: *Entamoeba deblicieki*

Predilection site: Small intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites are 13–14 by 11–12 µm in diameter. The nucleus contains a large pale central endosome composed of several granules, a ring of peripheral chromatin and numerous granules of varying sizes around its periphery. The cysts are 4–13 µm in diameter and each contains a single nucleus when mature, with numerous chromatoid bodies of various sizes and abundance, and a cytoplasmic glycogen granule.

Hosts: Sheep, goat

Geographical distribution: Worldwide

Pathogenicity: Non-pathogenic

Diagnosis: Identification of trophozoites, or cysts in large intestinal contents of faeces.

Treatment and control: Not required

Entamoeba wenyoni

Predilection site: Small intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites are 12 by 9 µm with granular protoplasm. The cysts are spherical, 7 µm in diameter, and contain eight nuclei.

Hosts: Goat, camel

Geographical distribution: Unknown

Parasites of the respiratory system***Mammomonogamus nasicola***

Synonym: *Syngamus nasicola*

Predilection site: Nasal cavities

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: The worms are reddish in appearance and about 1–2 cm long. Males are 4–6 mm and females 11–23 mm long and found in permanent copulation. The buccal capsule lacks a cuticular crown.

Description, microscopic: Eggs are ellipsoid, 54–98 µm, with no operculum at either end.

Hosts: Sheep, goat, cattle, deer

Geographical distribution: Central and South America, Central Africa, Caribbean islands

Pathogenesis: Heavy infections cause irritation of the nasal mucosa, sneezing and nasal discharges.

Clinical signs: Infections are usually asymptomatic but affected animals may sneeze and have a nasal discharge.

Diagnosis: This is based on clinical signs and the finding of eggs in the faeces or adult worms on postmortem.

Pathology: Not described

Epidemiology: Unknown

Treatment: Successful treatment has not been reported. Benzimidazoles and macrocyclic lactones are likely to be effective.

Control: No preventive or control measures have been described.

Notes: This genus, closely related to *Syngamus*, is parasitic in the respiratory passages of mammals. Infection has been reported in human and causes a laryngo-pharyngeal syndrome.

Mammomonogamus laryngeus

Synonym: *Syngamus laryngeus*

Common name: Gapeworm

Predilection site: Larynx

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: The worms are reddish in appearance and about 1–2 cm long. The females and males are found in permanent copulation. The buccal capsule lacks a cuticular crown.

Description, microscopic: Eggs are ellipsoid, 42–45 by 75–85 μm , with no operculum at either end.

Hosts: Cattle, buffalo, goat, sheep, deer, rarely human

Geographical distribution: Asia, Central Africa, South America and Caribbean islands

For more details of this species see Chapter 8.

Oestrus ovis

Common name: Sheep nasal bot

Predilection site: Nasal passages

Class: Insecta

Order: Diptera

Family: Oestridae

Description, adults: Greyish-brown flies about 12 mm long, with small black spots on the abdomen and a covering of short brown hairs (Fig. 9.41; see also Fig. 3.44). The head is broad, with small eyes, and the frons, scutellum and dorsal thorax bear small wart-like protruberances. The segments of the antennae are small and the arista bare. The mouthparts are reduced to small knobs.

Description, larvae: Mature larvae in the nasal passages are about 30 mm long, yellow–white and taper anteriorly. Each segment has a dark transverse band dorsally. They have large black oral hooks, connected to an internal cephalopharyngeal skeleton. The ventral surface bears rows of small spines (see Fig. 3.45).

Hosts: Primarily sheep and goat, but also ibex, camel and, occasionally, human

Fig. 9.41 *Oestrus ovis*.

Geographical distribution: Although originally Palaearctic, it is now found in all sheep-farming areas of the world, having been spread with sheep as they were transported worldwide.

Pathogenesis: Most infections are light, with only an average of 2–20 larvae being present in the frontal sinus of infested animals at any one time. Sheep show nasal discharge and sneezing, and rub their noses on fixed objects. In the rare heavier infections, there is unthriftiness and sheep may circle and show lack of coordination, these signs being termed ‘false gid’. If a larva dies in the sinuses, there may be secondary bacterial invasion and cerebral involvement. This may occur if larvae crawl into small cavities and are unable to leave when fully grown. Occasionally the larvae may penetrate the bones of the skull and enter the cerebral cavity. The larvae and the thickening of the nasal mucosa may impair respiration. Changes in the nasal tissues of infected sheep include catarrh, infiltration of inflammatory cells and squamous metaplasia, characterised by conversion of secretory epithelium to stratified squamous type. Immune responses by the host to infestation by *O. ovis* have been recorded.

However, the most important effects are due to the activity of the adult flies. When they approach sheep to deposit larvae, the animals panic, stamp their feet, bunch together and press their nostrils into each other’s fleeces and against the ground. There may be several attacks each day, so that feeding is interrupted and animals may fail to gain weight.

Oestrus can occasionally also infect humans. Larvae are usually deposited near the eyes, where a catarrhal conjunctivitis may result, or around the lips, leading to a stomatitis. Such larvae never fully develop.

Clinical signs: Nasal discharge, rubbing, sneezing, unthriftiness, circling and lack of coordination. Secondary bacterial infections are common.

Diagnosis: Although the clinical signs may assist in diagnosis, infestations of *O. ovis* must be differentiated from other conditions with similar symptoms. Occasionally a larva may be found on the ground after a severe sneezing attack, but often a positive diagnosis can only be made at necropsy.

Pathology: In addition to mechanical damage to the tissues, infestation induces a marked hypersensitivity reaction in which there is an increase in the numbers of serous mast cells and eosinophils and increased production of IgE. Interstitial pneumonia may develop during the course of ovine oestrosis, marked by increases in the numbers of eosinophils and mast cells in the lung parenchyma, mainly in the peribronchial region. This pathology is probably caused by permanent antigenic stimulation during infection, aspirated larval antigen inducing pulmonary sensitisation.

Epidemiology: The adult flies occur from spring to autumn and are particularly active during the summer months. However, in warm climates they may even be active in winter. In southern Europe, three generation peaks in *O. ovis* populations have been recorded in March–April, June–July and September–October. More commonly, however, there are only two generations per year, with adults present in late spring and late summer. Geographically, infestation prevalence tends to be highly localised. The flies hide in warm corners and crevices and in the early morning can be seen sitting on walls and objects in the sun.

Treatment: Where the numbers of larvae are small, it may not be economically viable to treat. However, in heavy infections closantel,

nitroxylin, and the endectocides ivermectin, doramectin and moxidectin are highly effective, as are the organophosphates trichlorophon and dichlorvos.

Control: Should a control scheme be necessary, it has been suggested by South African workers that flock treatment should be given twice a year, the first at the beginning of summer to kill newly acquired larvae, and the second in midwinter to kill any overwintering larvae. Fly repellents may be used but so far these have shown limited success.

***Gedoelestia* spp.**

Predilection site: Nasopharynx

Class: Insecta

Order: Diptera

Family: Oestridae

Description, adults: These are large robust flies of up to 18 mm in length. The head of the adult is reddish-yellow with dark-brown spots. The thorax is rusty brown in colour with a pattern of glossy black lines. The abdomen is brown with large black lateral patches and a series of large tubercles with sharply pointed tips.

Description, larvae: The third-stage larvae are ovoid, up to 20 mm in length, and may be distinguished from all other oestrids by a vertical slit in the posterior peritremes or a vertical suture if the spiracle is closed.

Hosts: Sheep, occasionally cattle, horse and antelope

Geographical distribution: Southern Africa

Pathogenesis: In the normal wildlife hosts, larvae appear to cause little pathological damage, although there are reports of loss of coordination. The infection becomes of veterinary importance when domestic ruminants are grazed close to, or among, the wild hosts. In sheep the larvae usually penetrate through the eye or enter via the nose. The larvae then migrate, arresting eventually in the brain, ocular tissues, nasal cavities or heart. It is in the eye that the signs are most prominent, with glaucoma, extrusion and even rupture of the eyeball.

Clinical signs: In southern Africa this oestrid fly is responsible for an oculo-vascular myiasis, causing extrusion of the eyeball in sheep and, rarely, cattle.

Diagnosis: First-stage larvae may occasionally be observed on the cornea, but often a positive diagnosis can only be made at necropsy.

Pathology: In domestic hosts three main forms of infestation are distinguished: ophthalmic, encephalitic and cardiac, characterised by thrombo-endophlebitis and thrombo-encarditis with encephalomalacia, from vascular thrombosis. Myocardial, pulmonary and renal infarction may also occur.

Epidemiology: Flocks may have a 30% morbidity, of which one-third will die, and in some areas sheep farming has had to be abandoned and replaced by cattle farming because of this parasite.

Treatment: Organophosphates such as trichlorophon are effective against the larvae, and flock treatment will reduce the blindness and mortality. Topical application of 0.25% cypermethrin spray to the eye has been used effectively to kill first-stage larvae.

Control: Domestic stock can safely graze with antelope during winter, when the flies are inactive (June–August). They should be removed from such areas in early spring when flies begin to emerge from puparia with the rising temperature.

Dictyocaulus filaria

Common name: Sheep lungworm

Predilection site: Lungs

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The worms are white with the intestine visible as a dark band. Males measure around 4–8 cm and the females 6–10 cm in length.

Description, microscopic: The eggs measure 112–138 by 69–90 µm and contain a fully formed first-stage larvae when laid. The L₁ resembles that of *D. viviparus* but has a characteristic small protruding cuticular knob at the anterior extremity (see Fig. 4.12b). The larva measures 550–580 µm in length; has a blunt tail and its intestinal cells contain numerous dark food granules.

Hosts: Sheep, goat and a few wild ruminants

Geographical distribution: Worldwide

Pathogenesis: Similar to that of *D. viviparus*, infection leading to a catarrhal bronchitis (Fig. 9.42). However, since the number of lungworms in individual animals is generally low, the widespread lesions associated with the bovine infection are not common.

Clinical signs: The most common signs are coughing and unthriftiness which, in endemic areas, are usually confined to young animals. In more severe cases, dyspnoea, tachypnoea and a tenacious nasal discharge are also present. These signs may be accompanied by diarrhoea or anaemia due to concurrent gastrointestinal trichostrongylosis or fasciolosis.

Diagnosis: This is based on history and clinical signs, but should be confirmed by examination of fresh faeces taken from a large proportion of the flock. The L₁ resembles that of *D. viviparus*, but has

Fig. 9.42 *Dictyocaulus filaria* in the bronchus of an infected sheep.

Fig. 9.43 Comparison of the posterior region of the first-stage larvae of (a) *Dictyocaulus filaria*, (b) *Protostrongylus rufescens*, (c) *Muellerius capillaris*, (d) *Cystocaulus ocreatus* and (e) *Neostrongylus linearis*.

a characteristic cuticular knob at the anterior extremity and dark granulation of the intestinal cells. It is differentiated from other ovine lungworms by its larger size and blunt-ended tail (Fig. 9.43a).

Pathology: In severe cases, pulmonary oedema and emphysema may occur and the lung surface may be studded with purulent areas of secondary bacterial infection.

Epidemiology: Although this parasite is prevalent worldwide, it is only responsible for sporadic outbreaks of disease in temperate countries such as the UK and North America. It occurs more frequently as a clinical problem in eastern Europe and some Mediterranean countries, the Middle East and India.

In temperate areas the epidemiology is similar to that of *D. viviparus* in that both the survival of overwintered larvae on pasture and the role of the ewe and doe as carriers are significant factors in the persistence of infection on pasture from year to year in endemic areas. In ewes it is likely that the parasites are present largely as hypobiotic larvae in the lungs during each winter and mature in the spring. Development to the L₃ only occurs during the period from spring to autumn. In lambs and kids, patent infections first occur in early summer, but the heaviest infections are usually seen in autumn. The prevalence of infection is lower in adult animals and their larval output smaller. Infective L₃ can migrate from the faeces without the need for fungal dispersion. It is likely that only two cycles of the parasite occur during each grazing season.

In warmer climates, where conditions are often unsuitable for larval survival, the carrier animal is probably a more important source of pasture contamination and outbreaks of disease in young susceptible animals are most likely to occur after a period of prolonged rain around weaning. Goats are often more susceptible to infection than sheep and can disseminate infection when both are grazed together.

Treatment: Where sporadic outbreaks occur, the affected animals, or preferably the whole flock, should be gathered, treated with a suitable anthelmintic (see *Dictyocaulus viviparus*) and then, if possible, moved to fresh pasture. The prophylactic regimens of control currently recommended for the control of gastrointestinal nematodes in sheep will, in normal years, be effective to a large extent in suppressing *D. filaria* infection.

Control: Where it is necessary to apply specific control measures, it is suggested that the flock should be annually treated with a suitable anthelmintic in late pregnancy. The ewes and lambs should then be grazed on pasture which, in temperate areas at least, should not have been used by sheep during the previous year.

Notes: This species, the most important lungworm of sheep and goats, is commonly associated with a chronic syndrome of coughing and unthriftiness, which usually affects lambs and kids.

Protostrongylus rufescens

Common name: Red lungworm

Predilection site: Small bronchioles

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description, gross: Adult worms are slender reddish worms; males measure up to 4.5 cm and females up to 6.5 cm.

Description, microscopic: In the male, the bursa is well developed but small. The dorsal ray is globular in shape with six papillae on the ventral side. The spicules are almost straight; the distal ends bear two membraneous alae. The male worms can be differentiated from *D. filaria* by these long comb-like spicules. The gubernaculum has two boot-shaped prolongations bearing several knobs posteriorly. In the female, the vulva is close to the anus and the conoid tail. Both horns of the uterus extend anteriorly (prodelphic). This differs from *D. filaria* where the vulva is situated near the middle of the body and where the two horns of the uterus extend in opposite directions (amphidelphic). The eggs measure around 75–120 by 45–82 µm and are unsegmented when laid. The first-stage larva has a wavy outline with a pointed tail but is devoid of a dorsal spine (Fig. 9.43b). It measures 320–400 µm and contains fine granules.

Final hosts: Sheep, goat, deer and wild small ruminants

Intermediate hosts: Snails (*Helicella*, *Theba*, *Abida*, *Zebrina*, *Arianta*)

Geographical distribution: Europe, Africa, Australia, North America

Pathogenesis: The worms live in the small bronchioles where they produce irritation, and local areas of inflammation develop leading to small foci of lobular pneumonia. The number of nodules on the lung surface may relate to the intensity of infection.

Clinical signs: Pneumonic signs have rarely been observed, and infections are almost always inapparent, being identified only at necropsy.

Diagnosis: The presence of infection is usually noted only during routine faecal examination. The L₁ are first differentiated from those of *Dictyocaulus filaria* by the absence of an anterior protoplasmic knob and then on the individual characters of the larval tail.

Pathology: In *Protostrongylus* infection there is a somewhat larger area of lung involvement than with *Muellerius* infection; occlusion of the small bronchioles by worms causes the lesser branches that occur toward the lung surface to be filled with eggs, larvae and cellular debris. The affected alveolar and bronchial epithelium is desquamated, blood vessels are occluded and cellular infiltration and proliferation of connective tissue occurs. This results in a small area of lobular pneumonia and the grey-yellowish lesion has a roughly conical form, with the base on the surface of the lung.

Epidemiology: *Protostrongylus*, whose intermediate host range is restricted to certain species of snail, has a lower prevalence than *Muellerius* though its geographic range is just as wide. Additional factors which play a part in ensuring the endemicity of these worms are, first, the ability of the L₁ to survive for months in faecal pellets and, secondly, the persistence of the L₃ in the intermediate host for the lifetime of the mollusc. Also important in this respect are the long periods of patency and the apparent inability of the final host to develop acquired immunity, so that adult sheep have the heaviest infections and the highest prevalence.

Treatment: The modern benzimidazoles, levamisole, ivermectin and moxidectin have been shown to be effective. However, higher dose rates or repeated treatments may be necessary for high efficacy.

Control: Because of the ubiquity of the molluscan intermediate hosts, and the fact that the L₃ can survive as long as the molluscs, specific control is difficult but fortunately rarely necessary. In some enterprises it may be practical to reduce snail numbers through the liming of pastures.

Other *Protostrongylus* species reported in sheep are shown in Table 9.4.

Muellerius capillaris

Common name: Nodular lungworms

Predilection site: Lung

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description, gross: These are grey–reddish, slender, hair-like worms about 1.0–2.5 cm long; although large, they are often difficult to discern with the naked eye as they are deeply embedded in lung tissue. Males are 12–24 mm and females 19–25 mm long.

Description, microscopic: The posterior end of adult male *Muellerius* is spirally coiled and the bursa is very small and folded inwards. The spicules consist of a proximal alate region and two distal serrated arms. Two sclerotised rods represent the gubernaculum. Eggs measure about 100 by 20 µm and are unsegmented when laid and develop in the lungs before being passed as L₁ larvae in the faeces. The first-stage larva has an S-shaped wavy tail (see Fig. 4.12c) and a small dorsal spine adjacent to the tip (Fig. 9.43c). It measures 300–320 µm and contains fine granules.

Final hosts: Sheep, goat, deer and wild small ruminants

Intermediate hosts: Snails (*Helix*, *Succinea*) and slugs (*Limax*, *Agriolimax*, *Arion*)

Table 9.4 Other protostrongylid species in sheep.

| Species | Distribution |
|--------------------------------------|---------------------------|
| <i>Protostrongylus skrjabini</i> | Eastern Europe and Russia |
| <i>Protostrongylus stilesi</i> | USA |
| <i>Protostrongylus rushi</i> | USA |
| <i>Protostrongylus brevispiculum</i> | USA |
| <i>Protostrongylus davtiani</i> | USA |

Geographical distribution: Worldwide except for arctic and sub-arctic regions

Pathogenesis: Although there can be extensive emphysemic nodules, pneumonic signs have rarely been observed and infections are usually inapparent, being identified only at necropsy. Sometimes mild infections are accompanied by sporadic coughing. Heavy infections may predispose the lungs to secondary bacterial infection. In goats, heavy infection with *M. capillaris* can induce coughing and dyspnoea and occasionally pneumonia.

Clinical signs: Generally asymptomatic but occasional coughing and dyspnoea in heavy infections.

Diagnosis: The presence of infection is usually noted only during routine faecal examination. The L₁ are first differentiated from those of *Dictyocaulus filaria* by the absence of an anterior protoplasmic knob and then on the individual characters of the larval tail. Frequently, several species of small nodular lungworms may be present.

Pathology: *Muellerius* is frequently associated with small, spherical, nodular, focal lesions that occur most commonly near, or on, the lung surface, and on palpation have the feel and size of lead shot. Nodules containing single worms are almost imperceptible, and the visible ones enclose several of the tiny worms as well as eggs and larvae. Occasionally larger greyish nodules, up to 2 cm in diameter, are apparent and sometimes the nodules are calcified. The nodules consist of necrotic masses, resulting from the degeneration of accumulated leucocytes and pulmonary tissue, and they are surrounded by connective tissue and occasional giant cells. Adjoining pulmonary tissue may be hyperaemic and the alveoli become filled with cells and debris.

Epidemiology: *Muellerius* is by far the commonest genus of sheep lungworm, and in many temperate areas such as Britain, the eastern states of the USA and the winter rainfall regions of Australia almost all sheep carry the infection; the extensive distribution and high prevalence are partly attributable to its wide range of intermediate hosts and the ability of larvae to overwinter in the molluscs. Prevalence of infection tends to increase with age. Additional factors which play a part in ensuring the endemicity of these worms are, first, the ability of the L₁ to survive for months in faecal pellets and, secondly, the persistence of the L₃ in the intermediate host for the lifetime of the mollusc. Also important in this respect are the long periods of patency and the apparent inability of the final host to develop acquired immunity, so that adult sheep have the heaviest infections and the highest prevalence. Wild small ruminants are frequently heavily infected and could transmit protostrongylids to grazing sheep and goats under some management systems.

Treatment and control: As for *Protostrongylus rufescens*

The following metastrongylid worms all inhabit the lungs, but none is a major pathogen and, though common, they are of little economic importance compared with the other helminth parasites of sheep and goats. Although there are several different genera and species, they are sufficiently similar in behaviour to be considered together.

Cystocaulus ocreatus

Common name: Small lungworm

Predilection site: Lung

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description, gross: Adults are slender dark-brown worms, males measuring up to 4–5 cm and females up to 9 cm in length.

Description, microscopic: In the male, the bursa is small; the spicules consist of a proximal cylindrical region joined distinctly to a distal lance-shaped region. The gubernaculum has a complex structure, with the posterior part consisting of two pointed boot-shaped structures. In the female, the vulva is protected by a bell-shaped expansion of the cuticle. The first-stage larva has a kinked tail and dorsal and ventral spine (Fig. 9.43d).

Final hosts: Sheep, goat, deer and wild small ruminants

Intermediate hosts: Snails (*Helicella*, *Helix*, *Theba*, *Cepaea*, *Monacha*)

Geographical distribution: Worldwide

Pathogenesis: The worms live in the small bronchioles where they produce irritation, and local areas of inflammation develop leading to small foci of lobular pneumonia; the number of nodules on the lung surface may relate to the intensity of infection.

Clinical signs: Pneumonic signs have rarely been observed, and infections are almost always inapparent, being identified only at necropsy.

Diagnosis: The presence of infection is usually noted only during routine faecal examination. The L₁ are first differentiated from those of *Dictyocaulus filaria* by the absence of an anterior protoplasmic knob and then on the individual characters of the larval tail.

Pathology: In *Cystocaulus* infections, occlusion of the small bronchioles by worms causes the lesser branches that occur toward the lung surface to be filled with eggs, larvae and cellular debris. The affected alveolar and bronchial epithelium is desquamated, blood vessels are occluded and cellular infiltration and proliferation of connective tissue occurs. This results in a small area of lobular pneumonia and the dark-brown to black lesion has a roughly conical form, with the base on the surface of the lung.

Epidemiology: *Cystocaulus*, whose intermediate host range is restricted to certain species of snail, has a lower prevalence than *Muellerius* though its geographic range is just as wide. Additional factors which play a part in ensuring the endemicity of these worms are, first, the ability of the L₁ to survive for months in faecal pellets and, secondly, the persistence of the L₃ in the intermediate host for the lifetime of the mollusc. Also important in this respect are the long periods of patency and the apparent inability of the final host to develop acquired immunity, so that adult sheep have the heaviest infections and the highest prevalence.

Treatment and control: As for *Protostrongylus rufescens*

Notes: A second species, *C. nigrescens*, is found in eastern Russia and Europe.

Neoststrongylus linearis

Common name: Small lungworm

Predilection site: Lung

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description, gross: Adults are slender small worms; males are 5–8 mm and females 13–15 mm long.

Description, microscopic: In the male, the spicules are unequal in size. The first-stage larva has a straight tail with a small dorsal and two small lateral spines (Fig. 9.43e).

Geographical distribution: Central Europe, Middle East

Treatment and control: As for *Protostrongylus rufescens*

Spiculocaulus austriacus

Common name: Small lungworm

Predilection site: Lung

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description, gross: Adult worms are slender and small.

Geographical distribution: Europe

Varestrongylus schulzi

Synonym: *Bicaulus schulzi*

Common name: Small lungworm

Predilection site: Lung

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description, gross: Adults are slender small worms; males are 12–15 mm and females 22–25 mm long.

Geographical distribution: Europe

Echinococcus granulosus

Common name: Dwarf dog tapeworm, hydatidosis

Predilection site: Mainly liver and lungs (intermediate hosts); small intestine (definitive host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: 'Hydatid' cysts are large fluid-filled vesicles, 5–10 cm in diameter, with a thick concentrically laminated cuticle and an internal germinal layer.

Description, microscopic: The germinal layer produces numerous small vesicles or brood capsules each containing up to 40 scolices, invaginated into their neck portions and attached to the wall by stalks. Brood capsules may become detached from the wall of the vesicle and float freely in the vesicular fluid and form 'hydatid sand'.

Fig. 9.44 Hydatid cysts of *Echinococcus granulosus* in the lung.

Final hosts: Dog and many wild canids

Intermediate hosts: Domestic and wild ruminants, human and primates, pig and lagomorphs; horses and donkeys are resistant

Geographical distribution: Worldwide

Pathogenesis: In domestic animals the hydatid in the liver or lungs (Figs 9.44 and 9.45) is usually tolerated without any clinical signs, and the majority of infections are only revealed at the abattoir. Where oncospheres have been carried in the circulation to other sites, such as the kidney, pancreas, central nervous system (CNS) or marrow cavity of long bones, pressure by the growing cyst may cause a variety of clinical signs.

In contrast, when humans are involved as intermediate hosts, the hydatid in its pulmonary or hepatic site is often of pathogenic significance. One or both lungs may be affected causing respiratory symptoms, and if several hydatids are present in the liver there may be gross abdominal distension. If a cyst should rupture, there is a risk of death from anaphylaxis; if the person survives, released daughter cysts may resume development in other regions of the body.

Fig. 9.45 Hydatid cyst of *Echinococcus granulosus* in the liver.

Clinical signs: Infection in cattle or sheep is generally not associated with clinical signs. Human infection can result in respiratory distress or abdominal enlargement depending on whether the lungs or liver are infected.

Diagnosis: The presence of hydatids as a clinical entity is rarely suspected in domestic animals, and specific diagnosis is never necessary.

Pathology: In sheep, about 70% of hydatids occur in the lungs, about 25% in the liver, and the remainder in other organs.

Epidemiology: Only a few countries, notably Iceland and Eire, are free from *E. granulosus*. It is customary to consider the epidemiology as being based on two cycles, pastoral and sylvatic.

In the pastoral cycle the dog is always involved, being infected by feeding on ruminant offal containing hydatid cysts. The domestic intermediate host will vary according to the local husbandry but the most important is the sheep, which appears to be the natural intermediate host, scolices from these animals being the most highly infective for dogs. In parts of the Middle East the camel is the main reservoir of hydatids, while in northern Europe and northern Russia it is the reindeer. The pastoral cycle is the primary source of hydatidosis in humans, infection being by accidental ingestion of oncospheres from the coats of dogs, or from vegetables and other foodstuffs contaminated by dog faeces.

The sylvatic cycle occurs in wild canids and ruminants and is based on predation or carrion feeding. It is less important as a source of human infection, except in hunting communities where the infection may be introduced to domestic dogs by the feeding of viscera of wild ruminants.

Treatment: No treatment in sheep

Control: This is based on the regular treatment of dogs to eliminate the adult tapeworms and on the prevention of infection in dogs by exclusion from their diet of animal material containing hydatids. This is achieved by denying dogs access to abattoirs and, where possible, by proper disposal of sheep carcasses on farms. In some countries these measures have been supported by legislation, with penalties when they are disregarded. In countries where no specific measures for hydatid control exist, it has been found that an incidental benefit from the destruction of stray dogs for rabies control has been a great reduction in the incidence of hydatid infection in humans.

A recombinant DNA vaccine has been developed for *E. granulosus* but it requires further refinement for practical application and it is currently not available commercially.

Notes: Considerable phenotypic and genetic variability has been observed within the species *E. granulosus* and several strains have been identified based on molecular genotyping. New data demonstrate that '*E. granulosus*' is an assembly of several, rather diverse strains and genotypes (designated G1–G10) that show fundamental differences not only in their epidemiology but also in their pathogenicity to humans.

Parasites of the liver

Fasciola hepatica

Common name: Liver fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Superfamily: Fasciolidae

Description, gross: The young fluke at the time of entry into the liver is 1.0–2.0 mm in length and lancet-like. When it has become fully mature in the bile ducts it is leaf-shaped, grey–brown in colour and is around 2.5–3.5 cm in length and 1.0 cm in width (see Fig. 1.70a).

Description, microscopic: The anterior end is conical and marked off by distinct shoulders from the body. The tegument is covered with backwardly projecting spines. An oral and ventral sucker may be readily seen. The egg is thin-shelled, oval with almost similar poles and barrel-shaped side walls, operculate, brownish-yellow and large (130–145 × 65–90 µm), and about twice the size of a trichostrongyle egg (see Fig. 4.3). The contents are granular and almost fill the egg. There are no blastomeres.

Final hosts: Sheep, cattle, goat, horse, deer, human and other mammals

Intermediate hosts: Snails of the genus *Galba* (formerly *Lymnaea*). The most common, *Galba* (syn. *Lymnaea*) *truncatula* is an amphibious snail with a wide distribution throughout the world. Other important vectors of *F. hepatica* outside Europe are:

| | |
|----------------------|---|
| <i>L. tomentosa</i> | Australia, New Zealand |
| <i>L. columella</i> | Central and North America, Australia, New Zealand |
| <i>L. bulimoides</i> | Northern and southern USA and the Caribbean |
| <i>L. humilis</i> | North America |
| <i>L. viator</i> | South America |
| <i>L. diaphena</i> | South America |
| <i>L. cubensis</i> | South America |
| <i>L. viridis</i> | China, Papua New Guinea |

Geographical distribution: Worldwide, although discontinuous

Pathogenesis: This varies according to the number of metacercariae ingested, the phase of parasitic development in the liver and the species of host involved. Essentially the pathogenesis is twofold. The first phase occurs during migration in the liver parenchyma and is associated with liver damage and haemorrhage. The second occurs when the parasite is in the bile ducts, and results from the haematophagic activity of the adult flukes and from damage to the biliary mucosa by their cuticular spines. Most studies have been in sheep and the disease in this host is discussed in detail. The seasonality of outbreaks is that which occurs in western Europe.

Fasciolosis in sheep may be **acute**, **subacute** or **chronic**. The **acute** disease is the less common type of fasciolosis and occurs 2–6 weeks after the ingestion of large numbers of metacercariae, usually over 2000, and is due to extensive destruction of the liver parenchyma and the severe haemorrhage which results when the young flukes, simultaneously migrating in the liver parenchyma, rupture blood vessels. Damage to the liver parenchyma is also severe. Outbreaks of acute fasciolosis may be complicated by concurrent infections with *Clostridium novyi* resulting in clostridial necrotic hepatitis ('black disease'), although this is less common nowadays because of widespread vaccination against clostridial diseases.

In the **subacute** disease, metacercariae are ingested over a longer period and while some have reached the bile ducts, where they cause a cholangitis, others are still migrating through the liver parenchyma causing lesions less severe than, but similar to, those of the acute disease; thus the liver is enlarged with numerous necrotic

or haemorrhagic tracts visible on the surface and in the substance. Subcapsular haemorrhages are usually evident, but rupture of these is rare.

This form of the disease, occurring 6–10 weeks after ingestion of approximately 500–1500 metacercariae, also appears in the late autumn and winter. It is presented as a rapid and severe haemorrhagic anaemia with hypoalbuminaemia and, if untreated, can result in a high mortality rate. However, it is not so rapidly fatal as the acute condition and affected sheep may show clinical signs for 1–2 weeks prior to death; these include a rapid loss of condition, reduced appetite, a marked pallor of the mucous membranes, and an enlarged and palpable liver. Submandibular oedema and ascites may be present.

Chronic fasciolosis, which is seen mainly in late winter/early spring, is the most common form of the disease. It occurs 4–5 months after the ingestion of moderate numbers (200–500) of metacercariae. The principal pathogenic effects are anaemia and hypoalbuminaemia and more than 0.5 mL blood per fluke can be lost into the bile ducts each day. Additional loss of plasma proteins occurs by leakage through the hyperplastic biliary mucosa and the pathogenic effect is exacerbated if the sheep is on a low plane of nutrition.

Clinical signs: Outbreaks of acute fasciolosis in sheep are generally presented as sudden deaths during autumn and early winter. On examination of the remainder of the flock, affected animals are weak, with pale mucous membranes and dyspnoea; in some instances they will have palpably enlarged livers associated with abdominal pain and ascites and often are reluctant to move.

Clinically, chronic fasciolosis is characterised by a progressive loss of condition, progressive weakness, lowered appetite and the development of anaemia and hypoalbuminaemia, which can result in emaciation, an open brittle fleece, pallor of the mucous membranes, submandibular oedema ('bottle-jaw') (Fig. 9.46) and ascites. The anaemia is hypochromic and macrocytic with an accompanying eosinophilia. *Fasciola* eggs can be demonstrated in the faeces. In light infections, the clinical effect may not be readily discernible, but the parasites can have a significant effect on production due to impairment of appetite and to their effect on the post-absorptive metabolism of protein, carbohydrates and minerals.

Diagnosis: This is based primarily on clinical signs, seasonal occurrence, prevailing weather patterns, and a previous history of

Fig. 9.46 Submandibular oedema ('bottle jaw') associated with chronic fluke infection.

fasciolosis on the farm or the identification of snail habitats. Diagnosis of ovine fasciolosis should present few problems, especially when a postmortem examination is possible. Routine haematological tests and examination of faeces for fluke eggs (note that eggs of *Fasciola* are brown–yellow and eggs of Paramphistomidae are colourless) are useful and may be supplemented by two other laboratory tests.

Routine haematology will often show the presence of anaemia (normochromic and normocytic) as a result of haemorrhage resultant from the direct feeding of the flukes. The packed cell volume (PCV) is also reduced. Fluke infection also leads to an eosinophilia (Table 9.5).

Fluke infections lead to a decrease in the albumin/globulin ratio. Hypoalbuminaemia due to protein loss occurs both during the parenchymal stage of infection by immature flukes and because of the presence of adult fluke in the bile ducts. Globulin levels increase as a result of increased immunoglobulin synthesis

Serum concentrations of liver-specific enzymes are generally higher in acute liver disease than in chronic liver disease and may be within normal limits in the later stages of subacute or chronic hepatic disease. Glutamate dehydrogenase (GLDH) is released when parenchymal cells are damaged and levels become elevated within the first few weeks of infection. Another enzyme, gamma-glutamyltranspeptidase (GGT), indicates damage to the epithelial cells lining the bile ducts; elevation of this enzyme takes place mainly after the flukes reach the bile ducts and raised levels are maintained for a longer period. Interpretation of raised liver enzyme activity can be difficult and careful interpretation of laboratory values in conjunction with clinical findings is essential.

Detection of antibodies against components of flukes in serum samples can also be undertaken, the enzyme-linked immunosorbent assay (ELISA) and the passive haemagglutination test being the most reliable. Antibodies to liver fluke can be detected in serum 2–4 weeks post infection but levels may rise or fall over time. A positive result does not necessarily indicate a current infection but a history of exposure. Serological testing is not widely available and may vary from country to country as to availability for either cattle or sheep.

Pathology: In **acute** fluke disease in sheep, at necropsy the liver is enlarged, friable, haemorrhagic and honeycombed with the tracts of migrating flukes (Fig. 9.47). The surface, particularly over the ventral lobe, is frequently covered with a fibrinous exudate. Subcapsular haemorrhages are common and these may rupture so that a quantity of blood-stained fluid is often present in the abdominal cavity (Fig. 9.48).

Table 9.5 Haematological/biochemical parameters in normal and fluke-infected sheep.

| Parameter | Normal | Fluke infected |
|---|------------|--|
| PCV (%) | 35 (27–45) | ≥6 |
| Eosinophils (%) | 0–10 | >10 |
| ($\times 10^3/\mu\text{L}$) | 0–1 | |
| Protein (g/L) | 60–79 | <55 |
| Albumin (g/L) | 28–34 | 10–20 |
| Globulin (g/L) | 32–43 | 65–80 |
| Glutamate dehydrogenase (GLDH) (iu/L) | 2–10 | 30× normal (150–300) Elevated ≥4 weeks post infection |
| Gamma glutamyltranspeptidase (GGT) (iu/L) | 0–32 | 25× normal levels in chronic fluke |

Fig. 9.47 Liver lesions associated with acute ovine fasciolosis.

In the **subacute** form, the liver is enlarged with numerous necrotic or haemorrhagic tracts visible on the surface and in the substance. Subcapsular haemorrhages are usually evident, but rupture of these is rare.

In the **chronic** form, the liver has an irregular outline and is pale and firm, the ventral lobe being most affected and reduced in size. The bile ducts are distended and frequently contain numerous adult flukes. The liver pathology is characterised by hepatic fibrosis and hyperplastic cholangitis (Fig. 9.49). Several different types of fibrosis are present. The first to occur is post-necrotic scarring found mainly in the ventral lobe and associated with the healing of fluke tracts. The second, often termed ischaemic fibrosis, is a sequela of infarction caused by damage and thrombosis of large vessels. Thirdly, a peribiliary fibrosis develops when the flukes reach the small bile ducts. Sometimes fluke eggs provoke a granuloma-like reaction, which can result in obliteration of the affected bile ducts.

Fig. 9.48 Massive subcapsular haemorrhage frequently seen in acute ovine fasciolosis.

Fig. 9.49 Liver showing lesions of chronic fasciolosis characterised by hepatic fibrosis and cholangitis.

The hyperplastic cholangitis in the larger bile ducts arises from the severe erosion and necrosis of the mucosa caused by the feeding mature flukes.

Epidemiology: There are three main factors influencing the production of the large numbers of metacercariae necessary for outbreaks of fasciolosis.

- 1 Availability of suitable snail habitats:** *G. truncatula* prefers wet mud to free water, and permanent habitats include the banks of ditches or streams, marshy areas and the edges of small ponds. Following heavy rainfall or flooding, temporary habitats may be provided by hoof marks, wheel ruts or rain ponds. Fields with clumps of rushes are often suspect sites. Though a slightly acid pH environment is optimal for *G. truncatula*, excessively acid pH levels are detrimental, such as occur in peat bogs and areas of sphagnum moss.
- 2 Temperature:** A mean day/night temperature of 10°C or above is necessary both for snails to breed and for the development of *F. hepatica* within the snail, and all activity ceases at 5°C. This is also the minimum range for the development and hatching of *F. hepatica* eggs. However, it is only when temperatures rise to 15°C and are maintained above that level that a significant multiplication of snails and fluke larval stages ensues.
- 3 Moisture:** The ideal moisture conditions for snail breeding and the development of *F. hepatica* within snails are provided when rainfall exceeds transpiration, and field saturation is attained. Such conditions are also essential for the development of fluke eggs, for miracidia searching for snails and for the dispersal of cercariae being shed from the snails.

In temperate countries such as Britain, these factors usually only exist from May to October. A marked increase in numbers of metacercariae on pasture is therefore possible during two periods. First, from what is known as the summer infection of snails, in which metacercariae appear on pasture from August to October (Fig. 9.50). These snail infections arise from miracidia that have hatched either from eggs excreted in the spring/early summer by infected animals, or from eggs which have survived the winter in an undeveloped state. Development in the snail occurs during the summer and the cercariae are shed from August until October. Alternatively, infections arise from the winter infection of snails, in which metacercariae appear on

Fig. 9.50 Summer infection of snails.

the pasture in May to June (Fig. 9.51). These are derived from snails which were infected the previous autumn, and in which larval development had temporarily ceased during the period of winter hibernation of the snail host and had recommenced in the spring. Both *F. hepatica* eggs and metacercariae can survive over the winter and play important roles in the epidemiology. The presence of metacercariae on pasture in early spring results in eggs being available by midsummer, when snail breeding is optimal. However, survival of metacercariae is poor under conditions of high temperatures and drought and they rapidly lose their infectivity during processes such as silage making, although they may survive for several months on hay.

In most European countries, the summer infection of snails is the more important and an increase in the numbers of metacercariae occurs annually from August to October. The extent of this increase is highest in years when summer rainfall is heavy. The winter infection of snails is much less important, but occasionally gives rise to large numbers of metacercariae in late spring and early summer, particularly when the preceding months have been unduly wet.

Fig. 9.51 Winter infection of snails.

Circulating antibodies to *F. hepatica* are readily detectable in sheep, but there is no evidence that, under field conditions, sheep ever become immune to reinfection with *F. hepatica*, and in the absence of treatment the flukes will live as long as the sheep. Severe outbreaks of ovine fasciolosis frequently involve adult sheep which have been previously exposed to infection. In contrast, although outbreaks do occur in young cattle, more usually an acquired immunity gradually develops; this limits the lifespan of the primary infection, slows the migration of secondary infection and eventually reduces the numbers of flukes established. Thus, in endemic areas, adult cattle often appear unaffected clinically whereas severe losses from fasciolosis may be occurring in adult sheep. Finally, it should be remembered that *F. hepatica* can infect a wide range of mammals, including horses, donkeys, deer, pigs and rabbits, and it is possible that on occasions these hosts may act as reservoirs of infection. Humans may also become infected, especially from the consumption of watercress from unfenced beds.

Most of the above comments on the ecology of *G. truncatula* also apply to the other amphibian species of *Lymnaea* which transmit the parasite. Differentiation of *Galba/Lymnaea* species is a specialist task and is usually based on morphological characteristics, although biochemical and immunological methods are now also employed. Note also that taxonomic revisions have also resulted in reclassification of many of these species.

In warmer areas, such as the southern USA or Australia, the sequence of events has a different seasonality, but the epidemiological principles are the same. For example, in both Texas and Louisiana snail activity is maximal during the cooler months of autumn, with peak numbers of metacercariae appearing in the winter.

The situation differs with *L. tomentosa* which, although classed as an amphibian snail, is well adapted to aquatic life in swampy areas or irrigation channels, and therefore temperature is the most important controlling biological factor. Thus, in most of eastern Australia, *L. tomentosa* continues to produce egg masses throughout the year, although the rate of reproduction is controlled by temperature and is at its lowest during the winter. The lower winter temperatures also delay hatching of fluke eggs and larval development in the snail so that large numbers of metacercariae first appear in late spring. During the summer and autumn there is a second wave of metacercarial production derived from new generations of snails. *Lymnaea tomentosa* can extend its range by floating/drifted on water currents.

There is some evidence that the prevalence of fasciolosis in hot countries is higher after several months of drought, possibly because the animals congregate around areas of water conservation and so the chances of snails becoming infected are increased.

Ecology of *Galba* species in temperate climates Since *Galba truncatula* is the most widespread and important species involved in the transmission of *F. hepatica*, it is discussed in detail. *Galba truncatula* is a small snail, the adults being about 1.0 cm in length. The shell is usually dark brown and has a turreted appearance, being coiled in a series of spiral whorls. When held with the turret upright and the aperture facing the observer, the latter is approximately half the length of the snail and is on the right-hand side, and there are 4.5 whorls. The snails are amphibious and although they spend hours in shallow water, they periodically emerge on to surrounding mud. They commonly inhabit drainage ditches and poorly drained land. They are capable of withstanding summer drought or winter freezing for several months by, respectively, aestivating or hibernating deep in the mud. Optimal conditions

include a slightly acid pH environment and a slowly moving water medium to carry away waste products. They feed mostly on algae and the optimum temperature range for development is 15–22°C; below 5°C development ceases. In Britain, for example, snails breed continuously from May to October, each snail being capable of producing up to 100,000 descendants over 3 months.

Treatment: The older drugs, such as carbon tetrachloride, hexachlorethane and hexachlorophene, may still be used in some countries, but these have been largely replaced by more efficient and less toxic compounds and only the latter will be discussed.

- **Acute ovine fasciolosis.** Until fairly recently, treatment was not highly successful due to the inefficiency of the older drugs against the early parenchymal stages. However, efficient drugs are now available and the one of choice is triclabendazole, which removes all developing stages over 2 days old in sheep. Other drugs are closantel and nitroxylnil, which will remove flukes over 4–6 weeks old. A single dose of triclabendazole accompanied with a move to fluke-free pasture or a well-drained recently cultivated field, should usually be adequate treatment. With closantel or nitroxylnil, a second treatment may be necessary 4–6 weeks after moving to fluke-free ground. Where sheep cannot be moved to clean ground, treatment should be repeated at 3-weekly intervals until 6 weeks after deaths have ceased.
- **Subacute ovine fasciolosis.** The drugs recommended for acute fasciolosis can be used against older flukes responsible for subacute fasciolosis. Movement to fluke-free pasture is again advisable following treatment, and where this is not possible treatment should be repeated at 4 and 8 weeks to eliminate maturing flukes. In addition to the above drugs, brotianide (available in some countries) is also effective.
- **Chronic ovine fasciolosis.** Outbreaks of chronic fasciolosis can be successfully treated with a single dose of any of a range of drugs (nitroxylnil, closantel, oxyclozanide and triclabendazole) and following treatment the anaemia usually regresses within 2–3 weeks. The roundworm anthelmintics albendazole, ricobendazole and netobimin are also effective against adult flukes, albeit at increased dosage rates.

Frequent treatment with flukicides which belong to the same chemical group or with the same anthelmintic season after season may enhance the possibility of development of drug-resistant flukes. Fluke resistant to triclabendazole have been reported in a number of countries. It is advisable to plan a control strategy which incorporates a change of flukicides from year to year, although the spectrum of activity of the drugs also needs to be considered.

Control: Control of fasciolosis may be approached in two ways: by reducing populations of the intermediate snail host or by using anthelmintics.

Reduction of snail populations Before any scheme of snail control is undertaken, a survey of the area for snail habitats should be made to determine whether these are localised or widespread. The best long-term method of reducing mud-snail populations such as *G. truncatula* is drainage, since it ensures permanent destruction of snail habitats. However, farmers are often hesitant to undertake expensive drainage schemes, although in some countries special drainage grants are available. When the snail habitat is limited a simple method of control is to fence off this area or treat annually with a molluscicide, copper sulphate being the most widely used. Although more efficient molluscicides such as *N*-tritylmorpholine have been developed, none are now generally available, or used,

because of environmental concerns. In Europe, experimental evidence indicated that a molluscicide could be applied either in the spring (May), to kill snail populations prior to the commencement of breeding, or in summer (July/August) to kill infected snails. The spring application should ensure better contact with the snails because pasture growth is limited, but in practice is often impractical because the saturated nature of the habitat makes vehicular access difficult. In the summer this is less of a problem, although molluscicide–snail contact may be reduced because of the increase in herbage growth. The application of a molluscicide should be combined with anthelmintic treatment to remove existing fluke populations and thus the contamination of habitats with eggs. When the intermediate snail host is aquatic, such as *L. tomentosa*, good control is possible by adding a molluscicide such as *N*-tritylmorpholine or niclosamide to the water habitat of the snail, but there are many environmental objections to the use of molluscicides in water or irrigation channels, and rapid recolonisation of snail habitats can occur.

Use of anthelmintics The prophylactic use of fluke anthelmintics is aimed at the following.

- 1 Reducing pasture contamination by fluke eggs at a time most suitable for their development, i.e. April to August.
- 2 Removing fluke populations at a time of heavy burdens or at a period of nutritional and pregnancy stress to the animal. To achieve these objectives, the following control programme for sheep in the British Isles is recommended for years with normal or below average rainfall. Since the timing of treatments is based on the fact that most metacercariae appear in autumn and early winter, it may require modification for use in other areas.
 - a In late April/early May treat all adult sheep with a drug effective against adult stages. At this time, products containing both a fasciolicide and a drug effective against nematodes that contribute to the PPR in faecal egg counts in ewes may be used.
 - b In October, treat the entire flock using a drug effective against parenchymal stages, such as triclabendazole or closantel.
 - c In January, treat the flock with any drug effective against immature and adult stages.
 - d In wet years further doses may be necessary. In June, 4–6 weeks after the April/May dose, all adult sheep should be treated with a drug effective against adult and late immature flukes. In October/November, 4 weeks after the early October dose, treat all sheep with a drug effective against parenchymal stages.
 - e The precise timing of the spring and autumn treatments will depend on lambing and service dates.

Meteorological forecasting of fasciolosis The life cycle of the liver fluke and the prevalence of fasciolosis are dependent on climate. This has led to the development of forecasting systems in Britain and Northern Ireland, for example, based on meteorological data, which estimate the likely timing and severity of the disease. In several western European countries, these forecasts are used as the basis for annual control programmes. Two different formulae have been developed.

- 1 Estimation of 'ground surface wetness', which is the critical factor affecting the summer infection of snails, using the formula $M = n(R - P + 5)$, where M is the month, R is the monthly rainfall in inches (1 inch = 2.54 cm), P is evapotranspiration

in inches and n is the number of wet days per month. A value of 100 or more per month is optimal for parasite development and therefore values of more than 100 are registered as 100. The formula is applied over the months when temperatures are suitable for snail breeding and parasite development, i.e. May–October in Europe, and the monthly values summated to give a seasonal index or Mt value. Since temperatures are generally lower in May and October in northern hemisphere countries, the values for these months are halved prior to summation. Where Mt exceeds 450, the prevalence of fasciolosis is likely to be high. The forecast is used to issue an early warning of disease by calculating data from May to August so that control measures can be introduced prior to shedding of cercariae. The disadvantage of the forecast is that it may overestimate the prevalence where there is an autumn drought or underestimate the likely prevalence where the presence of drainage ditches allows the parasite life cycle to be maintained in dry summers. Although this technique is mainly applied to the summer infection of snails, it is also used for forecasting the winter infection of snails by summing the values for August, September and October; if these exceed 250 and the following May or June has a high rainfall, then fasciolosis is forecast for the area.

- 2 'Wet day' forecast. This compares the prevalence of fasciolosis over a number of years with the number of rain-days during the summers of these years. In essence, widespread fasciolosis is associated with 12 wet days (over 1.0 mm of rainfall) per month from June to September where temperatures do not fall below the seasonal normal. Computer-based forecast systems have also been developed.

Fasciola gigantica

Common name: Tropical large liver fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description, gross: The adult fluke is larger than *F. hepatica*, the body is more transparent, and can reach 7.5 cm in length and 1.5 cm in breadth. The shape is more leaf-like, the conical anterior end is very short, and the shoulders, characteristic of *F. hepatica*, are barely perceptible (see Fig. 1.70b). The gut caeca are more highly branched than in *F. hepatica*.

Description, microscopic: The egg is larger (up to $197 \times 104 \mu\text{m}$) than that of *F. hepatica* but otherwise similar.

Final hosts: Cattle, buffalo, sheep, goat, pig, camel, deer, human

Intermediate hosts: Snails of the genus *Lymnaea*

Geographical distribution: Africa, Asia and tropical regions

Pathology: In acute infections in sheep, the liver is enlarged, friable, haemorrhagic and honeycombed with the tracts of migrating flukes. In the chronic form, the liver has an irregular outline and is pale and firm, the ventral lobe being most affected and reduced in size. The liver pathology is characterised by hepatic fibrosis and hyperplastic cholangitis. The hyperplastic cholangitis in the larger

bile ducts arises from the severe erosion and necrosis of the mucosa caused by the feeding mature flukes.

Treatment: For acute fluke infections in sheep, the drug of choice is triclabendazole. Other drugs include closantel and nitroxylin, which will remove flukes over 4 weeks old. Outbreaks of chronic fasciolosis can be successfully treated with a single dose of any of a range of drugs (nitroxylin, brotianide, closantel, oxyclozanide and triclabendazole).

For more details see Chapter 8.

Fascioloides magna

Common name: Large American liver fluke

Predilection site: Liver and occasionally bile ducts

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description gross: Flukes are large and thick and measure up to 10 cm long by 2.5 cm broad and around 3–4 mm in depth. The worms are oval, with a rounded posterior end (see Fig. 1.72).

Description microscopic: An anterior cone projection is absent.

Final hosts: Deer, cattle, sheep, goat, pig, horse

Intermediate hosts: A variety of freshwater snails: *Fossaria* species, *Lymnaea* species, *Stagnicola* species

Geographical distribution: Mainly occurs in North America, central, eastern and southwestern Europe, South Africa and Mexico

Pathogenesis: In contrast to the situation in deer and cattle, in sheep and goats the host response is negligible and the continual migration of the flukes through the liver parenchyma leads to haemorrhage, hepatitis and fibrosis. Occasionally flukes may be found in the lungs and in the peritoneal cavity. Infection can be fatal in sheep and goats.

Clinical signs: Infection in sheep and goats may cause sudden death.

Diagnosis: This is based primarily on clinical signs, and history of contact with grazing deer in known endemic areas. Large flukes, and the presence of cysts, are usually seen on postmortem. Faecal examination for the presence of fluke eggs is not a useful aid to diagnosis as *F. magna* infection is frequently non-patent in sheep and goats.

Pathology: In sheep and goats, the young immature flukes generally fail to mature and the presence of migratory flukes in the liver parenchyma leads to haemorrhage, hepatitis and fibrosis. Occasionally flukes may be found in the lungs and in the peritoneal cavity.

Epidemiology: The various snail intermediate hosts tend to occur in stagnant semi-permanent water that contains large amounts of dead or dying vegetation, swamp areas, or pools and streams. *Fascioloides magna* is indigenous to North America and is common in Canada and the Great Lake areas where the white-tailed deer and the elk are commonly infected. Domestic cattle and sheep become infected when they graze pasture where parasitised deer occur.

Treatment: For cattle and sheep the commonly used flukicides, such as triclabendazole, closantel, clorsulon and albendazole, are effective. Mature *F. magna* are susceptible to oxyclozanide.

Control: Avoid grazing sheep or cattle on areas which are frequented by deer. Elimination of the snail intermediate hosts is difficult due to their varied habitats. Similarly, removal of Cervidae may not be practical. Because of these factors, sheep rearing in particular is difficult in areas where the parasite is prevalent.

Notes: *Fascioloides magna* is primarily a parasite of deer (Cervidae) and is commonly found in white-tailed deer (*Odocoileus virginianus*), elk and moose.

For more details see Chapter 14.

Dicrocoelium dendriticum

Synonym: *Dicrocoelium lanceolatum*

Common name: Small lanceolate fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Dicrocoeliidae

Description, gross: There is no possibility of confusion with other flukes in the bile ducts of ruminants as *Dicrocoelium* is around 6 mm to 1.0 cm long and 1.5–2.5 mm wide, distinctly lanceolate and semi-transparent (see Fig. 1.74). The oral sucker is smaller than the ventral.

Description, microscopic: The gut is simple, consisting of two branches and resembles a tuning fork. Behind the ventral sucker the testes lie in tandem with the ovary immediately posterior. There are no spines on the cuticle (cf. *Fasciola*). The thick-shelled egg is small, 35–45 µm in length by 22–30 µm in width, dark brown with small round poles and slightly barrel-shaped walls and operculate, usually with a flattened side (see Fig. 4.3). The operculum is often difficult to see. It contains a miracidium, which completely fills the egg, when passed in the faeces.

Final hosts: Sheep, goat, cattle, deer and rabbit, occasionally horse and pig

Intermediate hosts: Two are required:

- 1 Land snails of many genera, principally *Cionella lubrica* in North America and *Zebrina detrita* in Europe. Some 29 other species have been reported to serve as first intermediate hosts, including the genera *Abida*, *Theba*, *Helicella* and *Xerophila*.
- 2 Brown ants of the genus *Formica*, frequently *F. fusca*.

Geographical distribution: Worldwide except for South Africa and Australia. In Europe the prevalence is high but in the British Isles prevalence is low, being confined to small foci throughout the country.

Pathogenesis: Although several thousand *D. dendriticum* are commonly found in the bile ducts, the livers are relatively normal; this is presumably due to the absence of a migratory phase. However, in heavier infections there is fibrosis of the smaller bile ducts and extensive cirrhosis can occur and sometimes the bile ducts become markedly distended. Condemnation of livers at slaughter may cause severe economic losses among cattle herds and sheep flocks.

Clinical signs: In many instances these are absent. Anaemia, oedema, emaciation and reduced wool growth have been reported in severe cases.

Diagnosis: This is entirely based on faecal examination for eggs and necropsy examination of the bile ducts for the presence of flukes.

Pathology: Infected livers are relatively normal; this is presumably due to the absence of a migratory phase. However, in heavier infections there is fibrosis of the smaller bile ducts and extensive cirrhosis can occur and sometimes the bile ducts become markedly distended (Fig. 9.52).

Epidemiology: There are two important features that differentiate the epidemiology of *Dicrocoelium* from that of *Fasciola*:

- 1 the intermediate hosts are independent of water and are evenly distributed on the terrain;
- 2 the egg can survive for months on dry pasture, presenting a reservoir additional to that in the intermediate and final hosts.

Treatment: Many flukicides show no activity against *D. dendriticum* when administered at the recommended fluke dose rates. Netobimin has been shown to be highly effective at a dose rate of 20 mg/kg. Albendazole, given orally at 20 mg/kg, is very effective, as is praziquantel at 50 mg/kg. Other drugs such as fenbendazole are also effective, but at very high dose rates (50 mg/kg).

Control: This is difficult because of the longevity of *D. dendriticum* eggs, the wide distribution of the intermediate hosts and the number of reservoir hosts. Control depends almost entirely on regular anthelmintic treatment.

Dicrocoelium hospes

Predilection site: Liver

Phylum: Platyhelminthes

Fig. 9.52 Liver lesions caused by severe *Dicrocoelium dendriticum*.

Class: Trematoda

Family: Dicrocoeliidae

Description: Details are essentially similar to *D. dendriticum* and the flukes are usually found in the liver and gallbladder of cattle, ox, and occasionally sheep and goats.

Hosts: Cattle, occasionally sheep, goat

Geographical distribution: Parts of Africa

Details are essentially similar to *D. dendriticum*.

Stilesia hepatica

Predilection site: Bile ducts

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, gross: The adult tapeworm measures around 0.5 m in length by 2 mm in width. The neck is broad and the scolex has prominent suckers. The genital organs are single and the opening pores alternate irregularly. The oval eggs lack a pyriform apparatus and measure about 26–30 by 16–19 µm.

Final hosts: Sheep and other ruminants

Intermediate hosts: The intermediate host is probably an oribatid mite.

Geographical distribution: Africa and Asia

Clinical signs: Infection is usually asymptomatic.

Diagnosis: Identification of eggs or proglottids in the faeces.

Pathogenesis: Generally considered to be of low pathogenicity.

Pathology: No significant lesions are induced despite large numbers of parasites almost occluding the bile ducts.

Epidemiology: *Stilesia hepatica* is very common in sheep and other ruminants.

Treatment and control: Treatment is rarely necessary, but praziquantel administered at 8–15 mg/kg has proved effective.

Notes: Large numbers of these tapeworms are often found in the bile ducts of sheep at slaughter and although they cause neither clinical signs nor significant hepatic pathology, the liver condemnations are a source of considerable economic loss, on aesthetic grounds.

Thysanosoma actinioides

For more details see section Small intestine.

Taenia hydatigena (metacestode)

Synonyms: *Taenia marginata*, *Cysticercus tenuicollis*

Predilection site: Abdominal cavity, liver (intermediate hosts); small intestine (definitive hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: The mature metacestode (*Cysticercus tenuicollis*) is about 5–7 cm in diameter and contains a single invaginated scolex (bladderworm) with a long neck.

Final hosts: Dog, fox, weasel, stoat, polecat, wolf, hyena

Intermediate hosts: Sheep, goat, cattle, deer, pig, horse

Geographical distribution: Worldwide

Pathogenesis: Heavy infections in young lambs can lead to hepatitis and death. Occasionally, also, the developing cysticerci are killed in the liver, presumably in sheep previously exposed to infection; in these cases the subcapsular surface of the liver is studded with greenish nodules of around 1 cm in diameter.

Severe infection of the liver or tissues may result in liver/carcass condemnation at slaughter. The mature cysticerci in the peritoneal cavity are usually benign. Concomitant immunity can occur in the intermediate host allowing metacestodes, acquired from a primary infection, to survive in the host, although the host is resistant to reinfection. Infrequently, large numbers of developing cysticerci migrate contemporaneously in the liver of the sheep or pig producing hepatitis cysticercosa, a condition whose gross pathology resembles acute fasciolosis and which is often fatal (Fig. 9.53).

Clinical signs: Loss of condition, emaciation and ascites may be present.

Diagnosis: Chronic infection in sheep is usually confirmed at meat inspection where the large larval cysts are observed on the mesentery, omentum and abdominal organs. The liver of animals that have died as a result of acute infestation may contain haemorrhagic tracts and developing metacestodes.

Pathology: The main lesions are seen in the liver, which exhibits a number of dark-red foci and streaking, and young cysticerci may be found in migratory tracts. Metacestode stages are frequently found attached to the omentum, intestinal mesentery and to the serosal surface of abdominal organs, especially the liver, in the intermediate ruminant hosts (Fig. 9.54).

Fig. 9.53 Hepatitis cysticercosa caused by massive infection with *Cysticercus tenuicollis*.

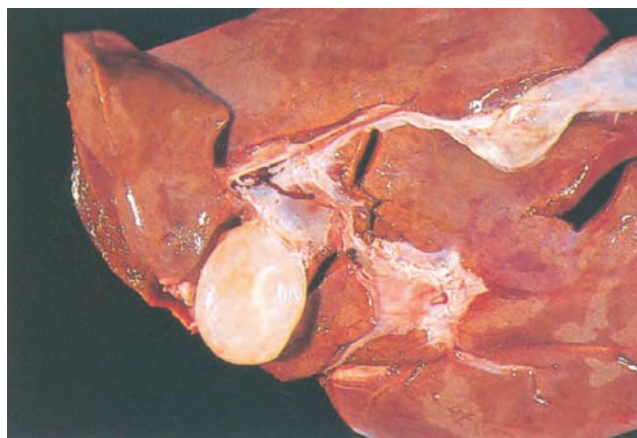

Fig. 9.54 Large fluid-filled *Cysticercus tenuicollis* attached to liver.

Epidemiology: Ruminants are infected by grazing pasture and forages contaminated with dog faeces harbouring eggs of *T. hydatigena*. A wolf and reindeer cycle exists in northern latitudes in which the metacestodes are found in the liver of the intermediate host and dogs can be infected as definitive hosts.

Treatment: No practical treatment is available for the intermediate host.

Control: This is similar to that of other taeniids and involves control of infection in the definitive host and the burial or disposal of ruminant carcasses and offal.

Notes: The correct nomenclature for the intermediate host stage is 'metacestode stage of *Taenia hydatigena*' rather than '*Cysticercus tenuicollis*'.

Echinococcus granulosus

For more details see Parasites of the respiratory system.

Ascaris suum

Common name: Large roundworm, white spot

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Hosts: Pig, wild boar, rarely sheep, cattle, human

Pathogenesis: In sheep, and occasionally cattle, migrating ascarids can cause eosinophilic granulomas and interstitial hepatitis and fibrosis with heavy eosinophilic infiltrates in the livers of sheep grazing contaminated areas. In heavy infections where death ensues, the lungs are moderately consolidated, with alveolar and interstitial emphysema and interlobular oedema.

Pathology: Microscopically, there is thickening of the alveolar septae, and effusion of fluid and macrophages into the alveoli. Larvae present within alveoli and bronchioles provoke an acute bronchiolitis.

Parasites of the pancreas

Eurytrema pancreaticum

Synonym: *Distoma pancreaticum*, *Eurytrema ovis*

Common name: Pancreatic fluke

Predilection site: Pancreatic ducts, rarely the bile ducts

Phylum: Platyhelminthes

Class: Trematoda

Family: Dicrocoeliidae

Description, gross: These are oval, leaf-shaped, reddish-brown flukes measuring around 8–16 mm by 5–8.5 mm.

Description, microscopic: The body is thick and the juvenile flukes are armed with spines that are often absent by the adult stage. The oral sucker is larger than the ventral sucker and the pharynx and oesophagus are short. The testes are positioned horizontally just behind the ventral sucker. A tubular cirrus sac is present. The uterus completely occupies the posterior body. Eggs measure around 40–50 µm by 25–35 µm and are similar to those of *Dicrocoelium*.

Final hosts: Cattle, buffalo, sheep, goat, pig, camel, human, primates

Intermediate hosts: Two are required:

- 1 Land snails, particularly of the genus *Bradybaena*.
- 2 Grasshoppers of the genus *Conocephalus* or tree crickets (*Oecanthus*).

Geographical distribution: South America, Asia and Europe

Treatment: There is no specific treatment for eurytrematosis, although praziquantel at 20 mg/kg for 2 days or albendazole at 7.5 mg/kg have been reported to be effective.

Control: This is not feasible where the intermediate hosts are endemic.

Eurytrema coelomaticum

Synonym: *Distoma coelomaticum*

Common name: Pancreatic fluke

Predilection site: Pancreatic ducts and occasionally the bile ducts and the duodenum

Phylum: Platyhelminthes

Class: Trematoda

Family: Dicrocoeliidae

Description, gross: A leaf-shaped reddish-brown fluke, with adults measuring around 8–12 by 6–7 mm.

Geographical distribution: Eastern Asia and South America

A third species, *Eurytrema ovis*, has been reported from sheep although this may be synonymous with *E. pancreaticum*.

For more details of these species see Chapter 8.

Parasites of the circulatory system

Elaeophora schneideri

Common name: Filarial dermatosis, 'sorehead'

Predilection site: Blood vessels

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Slender worms; males are around 5–8 cm and females up to 12 cm long.

Description, microscopic: Microfilariae are 270 µm, bluntly rounded anteriorly, and tapering posteriorly.

Final hosts: Sheep, goat, deer (elk, moose, mule deer)

Intermediate hosts: Tabanid flies

Geographical distribution: Western and southern USA

Pathogenesis: In *E. schneideri* infection in sheep, the circulating microfilariae are associated with a facial dermatitis, 'sorehead', in which a granulomatous inflammation of the skin occurs accompanied by intense pruritis. Occasionally the feet are also affected. This appears in the summer months. In severe cases there may be self-injury from rubbing, with abrasion, bleeding and scab formation. Lesions may alternate between periods of activity and inactivity. Lesions ultimately resolve with healing of the skin and regrowth of wool. It is thought that the natural hosts of *E. schneideri* are deer, in which the infection is asymptomatic, and that sheep may be abnormal hosts.

Clinical signs: Only the seasonal facial dermatitis in sheep is recognised as a clinical indication of elaeophorosis.

Diagnosis: Only in sheep is diagnosis required, and though the obvious method is by examination of a skin biopsy, microfilariae are often scarce in samples, and diagnosis is usually presumptive based on the locality, the facial lesions and the seasonal appearance of the dermatitis.

Pathology: The usual skin lesion seen in sheep is 5–10 cm in diameter, usually on the poll, although lesions may appear on the coronary band. Ischaemic chorioretinitis due to occlusive vasculitis has been reported in elk due to the circulating microfilariae.

Epidemiology: The natural hosts appear to be deer of *Odocoileus* spp. (white-tail and mule deer), and in these the infection is clinically inapparent. However, in American elk (*Cervus canadensis*) thrombosis due to the worms often results in necrosis of the muzzle, ears and optic nerves, resulting in severe facial damage, blindness and frequently death.

Treatment: No effective treatment reported

Control: Any reduction in vector numbers will reduce transmission.

Notes: These worms inhabit large blood vessels, but are only of local importance.

Onchocerca armillata

Common name: Aortic filariasis

Predilection site: Aorta

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Slender whitish worms; males are about 7 cm and females up to 70 cm long.

Description, microscopic: Microfilariae are unsheathed and measure 346–382 µm.

Final hosts: Cattle, sheep, goat, rarely camel

Intermediate hosts: Midges (*Culicoides*), blackflies (*Simulium*)

Geographical distribution: Africa, Middle East, India

Schistosomes

Schistosomes are flukes found in the circulatory system. The sexes are separate, the small adult female lying permanently in a longitudinal groove, the gynaecophoric canal, in the body of the male. The genus has been divided into four groups – *haematobium*, *indicum*, *mansoni* and *japonicum* – but the genus as currently defined is paraphyletic so revisions are likely.

Haematobium* group**Schistosoma bovis***

Common name: Blood fluke, bilharziosis

Predilection site: Portal and mesenteric veins, urogenital veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Final hosts: Cattle, sheep, goat

Intermediate hosts: Snails (*Bulinus contortus*, *B. truncates*, *Physopsis africana*, *P. nasuta*)

Geographical distribution: Africa, Middle East, southern Asia, southern Europe

Schistosoma mattheei

Predilection site: Portal, mesenteric and bladder veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Final hosts: Cattle, sheep, goat, human

Intermediate hosts: Snails (*Bulinus*)

Geographical distribution: South and Central Africa, Middle East

Notes: Thought to be synonymous with *S. bovis* but differs on morphological and pathological grounds and is restricted to the alimentary canal.

Indicum* group**Schistosoma indicum***

Predilection site: Portal, pancreatic, hepatic and mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Final hosts: Cattle, sheep, goat, horse, donkey, camel

Intermediate hosts: Snails (*Indoplanorbis*)

Geographical distribution: India

Schistosoma nasalis

Synonym: *Schistosoma nasalae*

Common name: ‘Snoring disease’

Predilection site: Veins of nasal mucosa

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Final hosts: Cattle, goat sheep, buffalo, horse

Intermediate hosts: Snails (*Lymnaea luteola*, *L. acuminata*, *Indoplanorbis exustus*)

Geographical distribution: India, Pakistan, Southeast Asia

Japonicum* group**Schistosoma japonicum***

Common name: Blood fluke, bilharziosis

Predilection site: Portal and mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Final hosts: Cattle, horse, sheep, goat, dog, cat, rabbit, pig, human

Intermediate hosts: Snails belonging to the genus *Oncomelania*

Geographical distribution: South and East Asia

Other schistosomes***Schistosoma turkestanicum***

Synonym: *Orientobilharzia turkstanicum*

Predilection site: Mesenteric veins and small veins of the pancreas and liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Geographical distribution: Asia

More details of all these species are given in Chapter 8.

Trypanosomes

Members of the genus *Trypanosoma* are haemoflagellates of overwhelming importance in cattle in sub-Saharan Africa but also occur in sheep and goats. See Chapter 2 for general and detailed descriptions of individual species of trypanosomes, and Chapter 8 for detailed descriptions on pathogenesis, epidemiology, treatment and trypanosome control.

Trypanosoma brucei brucei

Common name: Nagana

Predilection site: Blood. *Trypanosoma brucei brucei* is also found extravascularly in, for example, the myocardium, CNS and reproductive tract.

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Trypanozoon*

Description: *Trypanosoma brucei brucei* is pleomorphic in form and ranges from long and slender, up to 42 µm (average 29 µm), to short and stumpy, 12–26 µm (mean 18 µm), the two forms often being present in the same blood sample. The undulating membrane is conspicuous, the kinetoplast is small and subterminal and the posterior end is pointed. In the slender form the kinetoplast is up to 4 µm from the posterior end, which is usually drawn out, tapering almost to a point, and has a well-developed free flagellum; in the stumpy form the flagellum is either short or absent and the posterior end is broad and rounded with the kinetoplast almost terminal. Intermediate forms average 23 µm long and have a blunt posterior end and moderately long flagellum (see Figs 2.6 and 8.28). A fourth form with a posterior nucleus may be seen in laboratory animals. In fresh unfixated blood films, the organism moves rapidly within small areas of the microscope field.

Hosts: Cattle, horse, donkey, zebu, sheep, goat, camel, pig, dog, cat, wild game species

Distribution: Sub-Saharan Africa

Treatment: The two drugs in common use in cattle are isometamidium and diminazene aceturate and both should be suitable for use in sheep and goats. These are usually successful except where trypanosomes have developed resistance to the drug or in some very chronic cases. Treatment should be followed by surveillance, since reinfection followed by clinical signs and parasitaemia may occur within a week or two. Alternatively, the animal may relapse

after chemotherapy, due to a persisting focus of infection in its tissues or because the trypanosomes are drug-resistant.

Trypanosoma brucei evansi

Synonyms: *Trypanosoma evansi*, *Trypanosoma equinum*

Common names: Surra, el debab, mbori, murrina, mal de Caderas, doukane, dioufar, thaga

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Trypanozoon*

Hosts: Horse, donkey, camel, cattle, zebu, goat, pig, dog, water buffalo, elephant, capybara, tapir, mongoose, ocelot, deer and other wild animals. Many laboratory and wild animals can be infected experimentally.

Geographical distribution: North Africa, Central and South America, central and southern Russia, parts of Asia (India, Burma, Malaysia, southern China, Indonesia, Philippines)

Trypanosoma congolense

Common names: Nagana, paranagana, Gambia fever, ghindi, gobial

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Nannomonas*

Description: *Trypanosoma congolense* is small, monomorphic in form, 8–20 µm long. The undulating membrane is inconspicuous, the medium-sized kinetoplast is marginal and the posterior end is blunt. There is no free flagellum (see Figs 2.5 and 8.29). In fresh blood films the organism moves sluggishly, often apparently attached to red cells.

Hosts: Cattle, sheep, goat, horse, camel, dog, pig. Reservoir hosts include antelope, giraffe, zebra, elephant and warthog.

Distribution: Sub-Saharan Africa

Treatment: In infected cattle, the two drugs in common use are diminazene aceturate (Berenil) and homidium salts (Ethidium and Novidium) and are appropriate for use in sheep and goats infected with *T. congolense*. As with *T. brucei*, these drugs are usually successful except where trypanosomes have developed resistance to the drug or in some very chronic cases.

Trypanosoma vivax

Common names: Nagana, souma

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Duttonella*

Subspecies: *vivax*

Description: *Trypanosoma vivax* is monomorphic, ranging from 20 to 27 μm . The undulating membrane is inconspicuous, the large kinetoplast is terminal and the posterior end is broad and rounded. A short free flagellum is present (see Figs 2.4 and 8.30). In fresh blood films, *T. vivax* moves rapidly across the microscope field.

Hosts: Cattle, sheep, goat, camel, horse; antelope and giraffe are reservoirs

Geographical distribution: Central Africa, West Indies, Central and South America (Brazil, Venezuela, Bolivia, Colombia, Guyana, French Guiana), Mauritius

Treatment: As for *T. congolense*.

For more details of these species see Chapter 8.

Trypanosoma simiae

Synonyms: *Trypanosoma congolense simiae*, *Trypanosoma rod-haini*, *Trypanosoma porci*

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Nannomonas*

Hosts: Pig, camel, sheep, goat

Distribution: Central Africa

For more details see Chapter 11.

Stercorarian trypanosomes

These are relatively large trypanosomes found in the blood with faecal transmission by keds.

Trypanosoma melophagium

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Megatrypanum*

Description: Large trypanosome, 50–60 μm in length with the posterior end long and pointed. There is a prominent undulating membrane and a free flagellum. Tryptomastigote forms are rare in the blood.

Hosts: Sheep, goat, cattle

Geographical distribution: Worldwide

Pathogenesis: Non-pathogenic

Diagnosis: Infections in the blood are so sparse they can only be detected by culture in selective medium.

Epidemiology: Tryptomastigotes are transmitted by the sheep ked, *Melophagus ovinus*, and epimastigote and amastigote forms in the midgut multiply by binary fission. Epimastigote forms change into small metacyclic tryptomastigote forms in the hindgut. Sheep are infected when they bite into the keds and the tryptomastigotes are released and pass through the intact mucosa. It has been suggested that replication does not occur in the sheep. Infection is linked to the presence and abundance of ked infections.

Treatment and control: Not required, although general ectoparasite control strategies effective against keds will also control infection levels of the trypanosome.

Babesiosis

For details on the general life cycle and epidemiology of babesiosis see Chapter 8. Control measures are essentially similar and require control of tick vectors. Topical application of acaricides may provide some level of protection but may be difficult in sheep, expensive, and may have a negative cost–benefit. Under certain conditions, it may be more beneficial to attain endemic stability, allowing early infection and development of immunity.

Babesia motasi

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: *Babesia motasi* is a large species, 2.5–4 by 2 μm , and the parasites are usually pyriform. The merozoites occur singly, or in pairs, and the angle between members of a pair is usually acute.

Hosts: Sheep, goat

Geographical distribution: Southern Europe, Middle East, former Soviet Union, Southeast Asia and Africa

Pathogenesis: Strains of *B. motasi* from Europe produce a mild clinical response characterised by fever and anaemia but alone are rarely responsible for significant death losses. Strains from the Mediterranean basin may be more pathogenic and some strains are transmissible to goats, but this is not a consistent observation.

Clinical signs: Disease may be acute or chronic. Animals show pyrexia, prostration, marked anaemia and haemoglobinuria in the acute form, and may die. There are no characteristic signs in the chronic disease.

Diagnosis: Examination of blood films, stained with Giemsa, will reveal the parasites in the red cells.

Pathology: In pathogenic infections, the principal lesions include splenomegaly with soft dark-red splenic pulp and prominent

splenic corpuscles. The liver is enlarged and yellowish-brown and the gallbladder is distended with thick dark bile. The mucosa of the abomasum and intestine, and the subcutaneous, subserous and intramuscular connective tissues are oedematous and icteric with patches of haemorrhage. The blood is thin and watery, and the plasma tinged with red.

Epidemiology: Transmitted by ticks of the genus *Haemaphysalis* (*H. punctata*, *H. otophila*), *Dermacentor* (*D. silvarum*) and *Rhipicephalus* (*R. bursa*).

Treatment: Diminazene aceturate is effective against *B. motasi*.

Babesia ovis

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: *Babesia ovis* is a small species, 1–2.5 µm long, mostly rounded and in the margin of the host erythrocytes, with paired pyriform trophozoites usually lying at an obtuse angle.

Hosts: Sheep, goat

Geographical distribution: Southern Europe, former Soviet States, Middle East, Asia

Pathogenesis: Infections occur as a pathogenic entity in southern Europe and the Middle East but are generally mild in indigenous sheep, with severe clinical signs occurring in animals introduced from a non-endemic area. Death, if it occurs, is due to organ failure which, in turn, is due not only to destruction of the erythrocytes with resultant anaemia, oedema and icterus, but also to the clogging of the capillaries of various organs by parasitised cells and free parasites. The stasis from this sludging causes degeneration of the endothelial cells of the small blood vessels, anoxia, accumulation of toxic metabolic products, capillary fragility and eventual perivascular escape of erythrocytes and macroscopic haemorrhage.

Clinical signs: The clinical signs of infection include anaemia, jaundice, oedema and haemoglobinuria. Infections are often mild and often are inapparent.

Diagnosis: Examination of blood films, stained with Giemsa, will reveal the parasites in the red cells. Usually less than 0.6% of the erythrocytes are infected.

Pathology: In pathogenic infections, the principal lesions include splenomegaly with soft dark-red splenic pulp and prominent

splenic corpuscles. The liver is enlarged and yellowish-brown and the gallbladder is distended with thick dark bile. The mucosa of the abomasum and intestine, and the subcutaneous, subserous and intramuscular connective tissues are oedematous and icteric with patches of haemorrhage. The blood is thin and watery, and the plasma tinged with red.

Epidemiology: *Rhipicephalus bursa* has been shown to be a vector for this parasite, and *Ixodes ricinus*, *I. persulcatus* and *Dermacentor reticulatus* are suspected vectors.

Treatment: Diminazene aceturate is effective against *B. ovis*. Quinuronium sulphate is still used in some countries.

Theileriosis

Theileria spp. are widely distributed in cattle and sheep in Africa, Asia, Europe and Australia, have a variety of tick vectors, and are associated with infections that range from clinically inapparent to rapidly fatal. Although the speciation of many *Theileria* is still controversial, largely because of their morphological similarity, there are two species of major veterinary importance in sheep (Table 9.6).

Theileria hirci

Synonym: *Theileria lestoquardi*

Common names: Malignant theileriosis of small ruminants

Predilection site: Blood, lymph nodes, spleen

Phylum: Apicomplexa

Class: Aconoidasida

Family: Theileriidae

Description: Trophozoites are found in lymphocytes and erythrocytes as round (0.6–2.0 µm in diameter), oval or rod-shaped (1.6 µm long) forms (Fig. 9.55). Binary or quadruple fission takes place in the erythrocytes. Meronts (Koch bodies), averaging 8 µm in diameter (range 10–20 µm) in size, and containing 1–80 granules, are common in the lymphocytes of the spleen and lymph nodes.

Hosts: Sheep, goat

Geographical distribution: Southern Europe, Middle East, Asia, North and East Africa

Pathogenesis: Highly pathogenic, causing an acute and highly fatal disease in adult sheep and goats with mortalities of 46–100%. The infection is mild in young lambs and kids due to maternal

Table 9.6 *Theileria* species reported in sheep and goats.

| Species | Disease | Tick vectors | Hosts | Distribution |
|--|------------------------|---|-------------------|---|
| <i>Theileria hirci</i> (syn. <i>Theileria lestoquardi</i>) | Malignant theileriosis | <i>Rhipicephalus bursa</i> , <i>Hyalomma anatolicum</i> | Sheep, goat | Southern Europe, Middle East, Asia, North and East Africa |
| <i>Theileria ovis</i> | Benign theileriosis | <i>Rhipicephalus bursa</i> in Mediterranean basin; <i>Rhipicephalus evertsi</i> in Africa | Sheep, goat | Europe, Africa, Asia, India |
| <i>Theileria recondita</i> | Non-pathogenic | <i>Haemaphysalis punctata</i> | Sheep, goat, deer | Western Europe (Germany, UK) |
| <i>Theileria separata</i> | Non-pathogenic | <i>Rhipicephalus evertsi</i> | Sheep, goat | Sub-Saharan Africa |
| <i>Theileira</i> spp. | Pathogenic | <i>Haemaphysalis</i> spp. | Sheep | China |

Fig. 9.55 Meront of *Theileria hirci*.

immunity. An acute form is more common, but subacute and chronic forms have been observed.

Clinical signs: In the acute form there is fever (40–41.7°C, 104–107°F), inappetence, cessation of rumination, rapid heartbeat, weakness, swelling of superficial lymph nodes and eyelids, diarrhoea (containing blood and mucus) and jaundice and haemorrhage in submucous, subserous and subcutaneous tissues may occur. Affected animals become emaciated and death occurs. In chronic infections there is intermittent fever, inappetence, emaciation, anaemia and jaundice.

Diagnosis: Diagnosis depends on the detection of meronts in blood smears, lymph node biopsies or lymph node or spleen smears on postmortem.

Pathology: The lymph nodes are always swollen, the liver usually swollen, the spleen markedly enlarged and the lungs oedematous. Infarcts are often present in the kidneys, and there are petechiae on the mucosa of the abomasum and irregularly disseminated red patches on the intestinal mucosa.

Epidemiology: The tick vectors are thought to be *Rhipicephalus bursa* and *Hyalomma anatolicum*.

Treatment: A single injection of parvaquone at a dose rate of 20 mg/kg i.m., or buparvaquone at 2.5 mg/kg given on two occasions, are effective. A single dose of halofuginone at 1.2 mg/kg orally is also reported to be effective.

Control: Tick control measures can be considered for controlling disease. Topical application of acaricides may provide some level of protection but may be difficult in sheep, expensive, and may have a negative cost–benefit.

Notes: Causes significant losses in small ruminant populations in the Mediterranean and North African regions.

Theileria ovis

Common name: Benign theileriosis of small ruminants

Predilection site: Blood, lymph nodes

Phylum: Apicomplexa

Class: Aconoidasida

Family: Theileriidae

Description: Erythrocytic stages are similar in appearance to *T. hirci* and are found in lymphocytes and erythrocytes as round (0.6–2.0 µm in diameter), oval or rod-shaped (1.6 µm long) forms but are much more sparse, with less than 2% of erythrocytes infected.

Hosts: Sheep, goat

Geographical distribution: Europe, Africa, Asia, India

Pathogenesis: The pathogenicity and mortality are low although prevalence may be very high in endemic areas.

Clinical signs: The infection is usually mild and clinically inapparent.

Diagnosis: Demonstration of the parasites in stained blood or lymph node smears. The organism is indistinguishable from *T. hirci* but the small number of parasites present and the lack of pathogenicity help to differentiate them.

Pathology: No associated pathology

Epidemiology: The tick vectors are *Rhipicephalus bursa* in the Mediterranean basin and *Rhipicephalus evertsi* in Africa.

Treatment and control: Not usually required

Rickettsia

Although *Rickettsia* are now considered to be in the kingdom Bacteria, for historical reasons they are included within parasitological texts and for this reason mention is made to some genera and species of importance in sheep and goats.

Anaplasma phagocytophilum

Synonyms: *Anaplasma phagocytophila*, *Ehrlichia phagocytophila*, *Cytoecetes phagocytophila*, *Ehrlichia equi*, *Anaplasma platys*

Common names: Tick-borne fever, pasture fever, canine granulocytic ehrlichiosis, human granulocytic ehrlichiosis, equine granulocytic ehrlichiosis

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: Blood smears stained with Giemsa or Wright's stains reveal one or more loose aggregates (morulae or inclusion bodies, 1.5–5 µm in diameter) of blue–grey to dark-blue, coccoid, coccobacillary or pleomorphic organisms within the cytoplasm of neutrophils (Fig. 9.56).

Hosts: Sheep, cattle, dog, horse, deer, rodents

Geographical distribution: Probably worldwide, Europe (UK, Norway, Finland, the Netherlands and Austria)

Fig. 9.56 Inclusions of *Anaplasma phagocytophilum*.

Pathogenesis: Organisms enter the dermis via a tick bite and are then spread via the blood and/or the lymph and localise in mature granulocytes, mainly in neutrophils but also in eosinophils, of the peripheral blood. However, it is not clear whether they invade mature cells or precursor cells within the myelopoietic system. After endocytosis, multiplication occurs within cytoplasmic phagosomes and the organisms can be found in many organs (e.g. spleen, lungs and liver). The veterinary significance of tick-borne fever in sheep is threefold. First, although the disease in itself is transient, its occurrence in very young lambs on rough upland pastures may lead to death through inability to maintain contact with the dam. Secondly, the disease, possibly because of the associated leucopaenia, predisposes lambs to louping-ill, tick pyaemia (enzootic staphylococcosis) and pasteurellosis. Finally, the occurrence of the disease in adult sheep or cattle newly introduced into an endemic area may cause abortion or temporary sterility in males, possibly as consequences of the pyrexia.

Both animals and humans can be co-infected with various *Anaplasma*, *Ehrlichia*, *Borrelia*, *Bartonella*, *Rickettsia*, *Babesia* and arboviral species. Infection with any of these organisms causes a wide range of clinical and pathological abnormalities, ranging in severity from asymptomatic infection to death. The risk of acquiring one or more tick-borne infections may be dependent on the prevalence of multi-infected vectors. For example, *A. phagocytophilum* and *Borrelia burgdorferi* share both reservoir hosts and vectors, and in geographical areas where tick-borne fever is endemic, borreliosis is also prevalent.

Clinical signs: In sheep, following an incubation period of 7 days there is fever, dullness and inappetence, which persist for around 10 days. During this time, although leucopaenia is marked, the characteristic 'morula' inclusions may be seen in a variable proportion of the polymorphonuclear leucocytes present. Recovery is usually uneventful, although such animals remain carriers for many months.

Diagnosis: Tick-borne fever should be considered when an animal presents with an acute febrile illness in an endemic geographic area. Stained blood smears should be examined and, with Wright's stain, morulae typically appear as dark-blue, irregularly stained densities in the cytoplasm of neutrophils. The colour of the morulae is usually darker than that of the cell nucleus. Morulae are often sparse and difficult to detect and a negative blood smear cannot rule out *A. phagocytophilum* infection. Specific diagnostic tests include the

indirect fluorescent antibody test (IFAT), immunoblot analyses, ELISA and polymerase chain reaction (PCR) analyses. The most widely accepted diagnostic criterion is a fourfold change in titre by IFAT. However, cross-reactivity may occur with other members of the genera *Anaplasma* and *Ehrlichia*.

Pathology: The disease is characterised by haematological changes typified by thrombocytopenia and leucopaenia. The leucopaenia is a result of early lymphopaenia later accompanied by neutropaenia. Thrombocytopenia is one of the most consistent haematological abnormalities in infected dogs. It may be moderate to severe and persists for a few days before returning to normal. Biochemical abnormalities may include mildly elevated serum alkaline phosphatase and alanine aminotransferase activities.

Epidemiology: Rodents, as well as domestic and wild ruminants (sheep and deer), have been reported as reservoir hosts of *A. phagocytophilum* in Europe. The predominant reservoir host varies depending on the local natural and agricultural landscape. The vector of *A. phagocytophilum* in Europe is the common sheep tick, *Ixodes ricinus*. In endemic areas the prevalence of infection in young hill lambs is virtually 100%.

Treatment: Treatment of tick-borne fever in sheep is rarely indicated. When tick pyaemia in lambs is a problem, one or two prophylactic injections of long-acting oxytetracycline protect against infection for 2–3 weeks. Doxycycline 5–10 mg/kg for 3 weeks appears to be the most effective regimen for treating infections in dogs and cats. Severe disease may require treatment for longer periods. The most common side effects of doxycycline treatment are nausea and vomiting, which are avoided by administering the drug with food.

Control: In sheep, prophylaxis depends on tick control by dipping.

Notes: The newly reclassified *Anaplasma phagocytophilum* combo nov. (formerly known as three separate ehrlichiae *E. phagocytophila*, *E. equi* and *Anaplasma platys* [formerly known as *E. platys*]) causes canine, equine and human granulocytic ehrlichiosis.

Anaplasma marginale

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: In Giemsa-stained blood films the organisms of *A. marginale* are seen as small, round, dark-red 'inclusion bodies' approximately 0.3–1.0 µm within the red cell (see Fig. 8.39). Often there is only one organism in a red cell and characteristically this lies at the outer margin; however, these two features are not constant.

Hosts: Cattle, wild ruminants

Geographical distribution: Africa, southern Europe, Australia, South America, Asia, former Soviet states and USA

Anaplasma centrale

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: The mildly pathogenic *A. centrale* is similar to *A. marginale*, except that the organisms are commonly found in the centre of the erythrocyte.

Hosts: Cattle, wild ruminants (sheep may act as reservoirs of infection)

Anaplasma ovis

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: Small, round, dark-red ‘inclusion bodies’ approximately 0.3–1.0 µm within the erythrocyte.

Hosts: Sheep, goat

Eperythrozoon ovis

Synonym: *Mycoplasma ovis*

Predilection site: Blood

Kingdom: Bacteria

Phylum: Firmicutes

Order: Mycoplasmatales

Family: Mycoplasmataceae

Description: Pleomorphic coccobacilli occurring either as eperythrocytic organisms in depressions on the cell surface, or free in the plasma (Fig. 9.57). Single comma-shaped or ring-form cocci predominate in light to moderate infections but form irregular complex bodies in severe parasitaemias. Cocci appear light blue with Giemsa or Romanowsky’s stains.

Hosts: Sheep, goat

Geographical distribution: Worldwide

Pathogenesis: Most infections are normally benign, but *E. ovis* is occasionally responsible for fever, anaemia and loss of weight. The onset of clinical signs is insidious. Lambs infected at about 2–3 months of age show growth retardation and are slow to reach sexual maturity.

Fig. 9.57 Intraerythrocytic forms of *Eperythrozoon ovis*.

Clinical signs: Disease in lambs is mild and limited to vague ill-thrift.

Diagnosis: Identification from staining artefacts requires good blood films and filtered Giemsa stain. The organisms appear as cocci or short rods on the surface of the erythrocytes, often completely surrounding the margin of the red cell. However, the organisms of *Eperythrozoon* are relatively loosely attached to the red cell surface and are often found free in the plasma.

Pathology: Initial haematological changes are a fall in PCV, total erythrocytes and haemoglobin and as the parasitaemia drops there is gradual development of an autoimmune haemolytic anaemia. Platelet counts are reduced and prothrombin times are prolonged.

Epidemiology: *Eperythrozoon ovis* is transmitted by stable flies (*Stomoxys calcitrans*) and keds (*Melophagus ovinus*) and in the tropics and subtropics by mosquitoes (*Aedes camptorhynchus*, *Anopheles annulipes*, *Culex annulirostris*) and ticks (*Haemaphysalis plumbeum* and *Rhipicephalus bursa*). Transplacental infection is also thought to occur.

Treatment and control: Tetracyclines should be effective but control is not usually practical or necessary.

Notes: The taxonomy of this species is subject to much debate and this genus has now been reclassified into the bacterial genus *Mycoplasma* (class Mollicutes) based on 16S rRNA gene sequences and phylogenetic analysis.

Rickettsia conorii

Common names: Boutonneuse fever, Mediterranean spotted fever, Indian tick typhus, East African tick typhus

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Rickettsiaceae

Description: Small, pleomorphic, Gram-negative, coccoid, obligatory intracellular organisms infecting endothelial cells of smaller blood vessels.

Hosts: Rodents, dog, cattle, sheep, goat, human

Geographical distribution: Southern Europe, Africa, India and the Oriental region

Pathogenesis: Infections appear to be non-pathogenic.

Diagnosis: The rickettsiae can be demonstrated by staining blood or organ smears with Giemsa or may be detected serologically.

Epidemiology: The vector of Mediterranean boutonneuse fever is *Rhipicephalus sanguineus*. Apart from dogs, sheep and cattle, other small free-living mammals such as rats, mice and shrews are believed to play an important role in the cycle of infection within tick vectors.

Treatment and control: Not usually required although, if necessary, tetracyclines are usually effective.

The following species occurs in sheep and goats but is generally of more importance in cattle (see Chapter 8 for more detailed information).

Ehrlichia ruminantium

Synonym: *Cowdria ruminantium*

Common names: Heartwater, cowdriosis, malkopsiekte (Afrikaans)

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: Organisms are seen as close-packed colonies consisting of less than ten to many hundred cocci. The organism varies in size from 0.2 µm to greater than 1.5 µm. The diameter of individual organisms in a given cluster is rather uniform but groups are very pleomorphic. The small granules tend to be coccoid, with larger ones looking like rings, horseshoes, rods and irregular masses.

Hosts: Cattle, sheep, goat and wild ruminants

Parasites of the nervous system

Taenia multiceps

Synonyms: *Multiceps multiceps*, *Coenurus cerebralis*

Common names: Gid, sturdy, staggers, coenurosis

Predilection site: Brain and spinal cord (intermediate hosts); small intestine (final hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: When mature the *Coenurus cerebralis* cyst is readily recognised as a large fluid-filled transparent bladder up to 5 cm or more in diameter.

Description, microscopic: The coenurus bears clusters of several hundred protoscolices on its internal wall.

Final hosts: Dog, fox, coyote, jackal

Intermediate hosts: Sheep, cattle, deer, pig, horse, camel, human, primates

Geographical distribution: Worldwide

Pathogenesis: The coenurus takes about 8 months to mature in the CNS and, as it develops, it causes damage to the brain tissue resulting in neurological disturbances. These cysts can cause pressure atrophy, which may lead to perforation of the skull. When cysts locate in the spinal cord, the resulting pressure can lead to paresis of the hindlimbs. Although an acute form of coenurosis can occur, chronic disease is more frequently identified. Acute disease is likely to occur when sheep are grazed on pasture heavily contaminated with faeces from untreated dogs. The migration of large numbers of larval stages through the brain can rapidly lead to neurological dysfunction and death. Chronic disease presents as a progressive focal lesion of the brain with signs of neurological dysfunction appearing about 3–6 months from initial infection and is usually seen in sheep of 6–24 months of age. Coenurosis is much less common in cattle.

Clinical signs: Clinical signs can be acute or chronic and depend on the location and size of the cyst or cysts and include circling behaviour, visual defects and peculiarities in gait, stumbling, uncoordinated movements, hyperaesthesia or paraplegia. As the infection progresses animals may become anorexic and lose weight and death may result. The clinical syndrome is often known as 'gid' or 'staggers', in which the animal holds its head to one side and turns in a circle to the affected side.

Diagnosis: It is difficult to diagnose infection in sheep or goats unless obvious neurological signs are apparent. Even then other organisms, such as *Listeria monocytogenes*, *Oestrus ovis* and louping-ill, should be considered in any evaluation of acute coenurosis. Most diagnoses are made at postmortem. Where cysts are located on the surface of the brain it is sometimes possible to palpate the local softening of the frontal bones of the skull.

Pathology: The cyst or cysts are mainly located in one cerebral hemisphere and occur less frequently in the cerebellum and spinal cord (Fig. 9.58). The growth of the cysts within the brain or skull causes pressure atrophy of adjacent cerebral tissue. The migration of large numbers of immature stages in the brain of lambs can lead to acute meningoencephalitis. In acute cases of coenurosis, pale yellow tracts are frequently present on the surface of the brain. They are composed of necrotic tissue with marked cellular infiltration. In chronic coenurosis there may be compression of brain tissue by the developing cyst and the increased intracranial pressure can result in local softening of the bones of the skull, either above the cyst or in other areas.

Epidemiology: Where livestock, particularly sheep, have access to grazing land that is contaminated with infective dog faeces, then there is a risk of larval migration of the metacystode stage into the CNS.

Fig. 9.58 *Coenurus cerebralis* cyst on the surface of the cerebellum from an infected sheep.

Treatment: Surgical removal is possible if the cyst is situated on the brain surface. This may be detected by local softening of the skull or by detailed neurological examination. However, for many cases there is no treatment.

Control: This can be achieved by ensuring that dogs, in particular sheepdogs, do not have access to the heads of slaughtered or dead sheep or goats. It is essential that all sheep carcasses are buried as soon as possible. In areas where coenurosis is endemic, the regular deworming of dogs with an effective anthelmintic every 6–8 weeks will reduce the contamination into the environment and, by breaking the sheep–dog cycle, may lead to eradication of the disease. Foxes are not thought to be an important final host for *T. multiceps*.

Raillietia caprae

Predilection site: Ear canal

Class: Arachnida

Subclass: Acari

Order: Mesostigmata

Family: Halarachnidae

Description, gross: The mites are oval and pale yellow, adults measuring approximately 1 mm in length. They have a smooth cuticle with relatively few setae.

Description, microscopic: The holodorsal shield is heavily patterned but with a well-developed tritosternum, longer peritremes and the presence of both a genital and sternal shield in the female. This species has a short dorsal shield (500–600 µm) with 17 pairs of setae.

Final hosts: Goat, sheep

Clinical signs: Infestations are usually inapparent but the presence of mites in the ear canal may lead to otitis media and otitis interna with head shaking, head rotation, circling and incoordination.

***Gedoelestia* spp.**

For more details see Parasites of the respiratory system.

Toxoplasma gondii

For more details see Parasites of the reproductive/urogenital system.

Parasites of the reproductive/urogenital system

Toxoplasma gondii

Predilection site: Muscle, lung, liver, reproductive system, CNS, placenta

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: Tachyzoites are found developing in vacuoles in many cell types, for example fibroblasts, hepatocytes, reticular cells and myocardial cells. In any one cell there may be 8–16 organisms, each measuring 6.0–8.0 µm. Tissue cysts, measuring up to 100 µm in diameter, are found mainly in the muscle, liver, lung, brain and placenta, and may contain several thousand lancet-shaped bradyzoites (Fig. 9.59).

Intermediate hosts: Any mammal, including human, or birds. Note that the final host, the cat, may also be an intermediate host and harbour extra-intestinal stages.

Final hosts: Cat, other felids

Geographical distribution: Worldwide

Pathogenesis: Infections are usually acquired via the digestive tract, and so organisms are disseminated by the lymphatics and portal system with subsequent invasion of various organs and tissues.

Fig. 9.59 Tissue cyst of *Toxoplasma gondii*.

Pathogenic effects are always related to the extra-intestinal phase of development. In heavy infections, the multiplying tachyzoites may produce areas of necrosis in vital organs such as the myocardium, lungs, liver and brain; during this phase the host can become pyrexical and lymphadenopathy occurs. As the disease progresses bradyzoites are formed, this chronic phase being usually asymptomatic. In pregnant animals, exposed for the first time to *T. gondii* infection, congenital disease may occur. The predominant lesions are found in the CNS, although other tissues may be affected. Thus, retinochoroiditis is a frequent lesion in congenital toxoplasmosis.

Clinical signs: Undoubtedly the most important role of toxoplasmosis, particularly in sheep, is its association with abortion in ewes and perinatal mortality in lambs (Fig. 9.60). If infection of the ewe occurs early in gestation (<55 days), there is death and expulsion of the small fetus, which is seldom observed. If infection occurs in mid-gestation, abortion is more readily detected, the organisms being found in the typical white lesions, 2.0 mm in diameter, in the cotyledons of the placenta and in fetal tissues; alternatively, the dead fetus may be retained, mummified and expelled later. If the fetus survives *in utero*, the lamb may be stillborn or, if alive, weak. Ewes that abort due to *T. gondii* in one year usually lamb normally in subsequent years.

Diagnosis: Tachyzoites of *T. gondii* are often difficult to find in tissue sections, but are more likely to be present in sections of brain and placenta. Identification can be confirmed by immunohistochemistry, while PCR may be used to identify parasite DNA in tissues. Several serological tests have been developed of which the dye test is the longest established serological method, and in many ways represents the gold standard, at least in humans. The dye test uses live virulent *Toxoplasma* tachyzoites, a complement-like 'accessory-factor' and test serum. When specific antibody acts on the tachyzoites, the latter do not stain uniformly with alkaline methylene blue. The test has proven unreliable in some species. The IFAT gives titres comparable with the dye test, but is safer as it uses killed tachyzoites and can be used to differentiate IgM and IgG antibodies. Other tests for the detection of *Toxoplasma* antibodies include a direct agglutination test, a latex agglutination test and an ELISA.

Abortion in sheep and goats due to *T. gondii* must be differentiated from other infectious causes of abortion, including infections with *Chlamydophila abortus* (enzootic abortion), *Coxiella burnetii* (Q fever), *Brucella melitensis*, *Campylobacter fetus fetus*, *Salmonella*

spp., border disease, and the viruses that cause bluetongue, Wesselsbron's disease and Akabane disease.

Pathology: In heavy infections, the multiplying tachyzoites may produce areas of necrosis in vital organs such as the myocardium, lungs, liver and brain. In sheep abortions, characteristically the placental intercotyledonary membranes are normal, but white foci of necrosis, approximately 2–3 mm in diameter, may be visible in the cotyledons (Fig. 9.61). Microscopically, these foci appear as areas of coagulative necrosis that are relatively free of inflammation. Inflammation, when present, is non-suppurative. *Toxoplasma* tachyzoites are seen only rarely in association with these foci, usually at the periphery of the lesion. Examination of the brain may reveal focal microgliosis. The lesions often have a small central focus of necrosis that might be mineralised. Focal leucomalacia in cerebral white matter, due to anoxia arising from placental pathology, is often present. Focal microgliosis is more specific, as leucomalacia reflects placental damage, but may occur in other conditions such as border disease or rarely ovine chlamydiosis.

Epidemiology: The cat plays a central role in the epidemiology of toxoplasmosis and the disease is virtually absent from areas where cats do not occur. It is difficult to explain the widespread prevalence of toxoplasmosis in ruminants, particularly sheep, in view of the relatively low number of oocysts shed into the environment. It has been suggested that pregnant ewes are most commonly infected during periods of concentrate feeding prior to 'tupping' or lambing, the stored food having been contaminated with cat faeces in which millions of oocysts may be present. Further spread of oocysts may occur via coprophagous insects, which can contaminate vegetables, meat and animal fodder. It has been suggested that venereal transmission can occur in sheep.

Treatment: Not indicated

Control: On farms, control is difficult, but where possible animal feedstuffs should be covered to exclude access by cats and insects. Monensin and decoquinate have also been administered to ewes in mid-pregnancy in attempts to control abortion due to toxoplasmosis. Sheep that abort following toxoplasmosis usually lamb normally in subsequent years. It has often been advised that such sheep should be mixed with replacement stock some weeks before mating in the hope that these will become naturally infected and develop immunity before becoming pregnant. Presumably, the value of this technique depends on the replacements being exposed to

Fig. 9.60 *Toxoplasma gondii*: aborted foetus and necrotic placenta.

Fig. 9.61 Cotyledons of aborted placenta showing white focal lesions.

circumstances similar to those of the initial outbreak. It is sometimes also advised to mix replacement stock with ewes at the time of the outbreak of abortion in order to facilitate transmission of infection. This is extremely unwise, since other causes of abortion, notably the agent of enzootic abortion of ewes, if also present, may affect the replacement stock and be responsible for abortion in subsequent years. Fortunately, a vaccine is now available for sheep, which is less of a ‘hit or miss’ than the above techniques. This is a live vaccine consisting of tachyzoites attenuated by repeated passage in mice. The strain used has lost the capacity to form tissue cysts and therefore the potential to form oocysts in cats. It is usually recommended to vaccinate the whole flock initially and thereafter only annual vaccination of replacements. The vaccine consists of 104–106 tachyzoites and is given as a single dose intramuscularly at least 3 weeks prior to tupping.

Parasites of the locomotory system

Taenia ovis

Synonym: *Cysticercus ovis*

Common names: Ovine cysticercosis, ‘sheep measles’, sheep bladder worm

Predilection site: Small intestine (final host); muscle (intermediate host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description: Mature cysticerci are ovoid, white and around 3.5–10 mm and contain a single protoscolex, which is invaginated and is armed with hooks and a rostellum.

Final hosts: Dog, fox, wild carnivores

Intermediate hosts: Sheep, goat

Geographical distribution: Worldwide

Pathogenesis: Ovine cysticercosis is primarily important because of aesthetic objections to the appearance of the cysts in sheep meat and, in consequence, it can be a significant cause of economic loss through condemnation at meat inspection.

Clinical signs: Adult tapeworms normally induce only mild symptoms in the host and are considered of little pathogenic importance. Infected intermediate hosts do not usually show clinical signs of disease. Sheep can develop a strong acquired immunity to reinfection but this immunity does not have a major impact on existing cysts.

Diagnosis: Diagnosis in sheep and goats is by identification of cysts at meat inspection. Cysts may be present in the heart, tongue, cheek muscles, diaphragm and skeletal muscles (Fig. 9.62).

Pathology: The mature, ovoid, white cysticerci are grossly visible in the cardiac and skeletal musculature of sheep and goats. Commonly, the cysticerci are degenerate with a green or cream caseous or calcified centre.

Epidemiology: Ruminants are infected by grazing pasture and forges contaminated with dog or fox faeces harbouring eggs of *T. ovis*.

Fig. 9.62 *Cysticercus ovis* in sheep heart.

The thick-walled eggs can survive on pasture for up to 6 months under ideal weather conditions.

Treatment: No practical treatment is available for the intermediate host.

Control: Regular treatment of dogs with an effective anthelmintic will reduce contamination of the environment. Dogs should be denied access to raw sheep and goat meat and carcasses. A highly protective recombinant vaccine is available in some countries.

Notes: The correct nomenclature for the intermediate host stage is ‘metacestode stage of *Taenia ovis*’ rather than ‘*Cysticercus ovis*’.

Toxoplasma gondii

For more details see Parasites of the reproductive/urogenital system.

Sarcocystosis

Sarcocystis is one of the most prevalent parasites of livestock. The parasites derive their name from the intramuscular cyst stage (sarcocyst) present in the intermediate (prey) host. The nomenclature used in this book incorporates the names of the **intermediate** and **final hosts** in that order. *Sarcocystis* species affecting sheep and goats are host-specific for their intermediate hosts and family-specific for their final hosts. Further general details on nomenclature, diagnosis and epidemiology are given in Chapters 2 and 8.

There is no effective treatment for infection, either in the final or in the intermediate host. Where an outbreak occurs in sheep or goats, it has been suggested that the introduction of amprolium into the diet of the animals has a prophylactic effect. Amprolium and halofuginone (0.66 mg/kg orally on two consecutive days) may be used in sheep to avoid clinical disease after infection.

The only control measures possible are those of simple hygiene. Farm dogs should not be housed in, or allowed access to, fodder stores nor should they be allowed to defecate in pens where livestock are housed. It is also important that they are not fed uncooked meat.

Sarcocystis ovicanis

Synonyms: *Sarcocystis tenella*, *Isospora bigemina*

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: In the intermediate host the first-generation meronts found in the endothelial cells are 19–29 by 7.5–24 μm and contain 120–280 merozoites. Tissue cysts are microscopic in size (500 \times 60–100 μm) and are found in skeletal and cardiac muscle (Fig. 9.63). The wall of the cyst appears thick (up to 2.5 μm) and radially striated with long palisade-like protrusions without fibrils visible on electron microscopy.

Intermediate host: Sheep

Final host: Dog

Geographical distribution: Worldwide

Pathogenesis: In the sheep intermediate host, the principal pathogenic effect is attributable to the second stage of merogony in the vascular endothelium. *Sarcocystis ovicanis* is highly pathogenic for lambs, reportedly causing severe myositis and encephalomyelitis in lambs in several countries and has been incriminated as the cause of abortion in ewes. Generally, however, clinical signs are rarely observed in *Sarcocystis* infection and the most significant effect is the presence of cysts in the muscles resulting in downgrading or condemnation of carcasses. While the dog-borne species were thought to be of primary importance in this context, there is increasing evidence that cat-borne species are also responsible for lesions in meat.

Clinical signs: In heavy infections in sheep, there is anorexia, fever, anaemia, loss of weight, a disinclination to move and sometimes recumbency; in lambs a dog-sitting posture has been recorded. Abortions may occur in breeding stock.

Pathology: In sheep, meronts present in endothelial cells of capillaries in various organs lead to endothelial cell destruction. As the organisms enter muscle, a wide range of change may be encountered. Microscopic inspection of *Sarcocystis*-infected muscle often reveals occasional degenerate parasitic cysts surrounded by variable numbers of inflammatory cells (very few of which are eosinophils) or, at a later

Fig. 9.63 Sarcocyst (*Sarcocystis ovicanis*) in sheep muscle.

stage, macrophages and granulation tissue. Usually there is no muscle fibre degeneration, but there may be thin linear collections of lymphocytes between fibres in the region. The extent of muscle change bears little relationship to the numbers of developing cysts, but generally very low numbers of *Sarcocystis* produce no reaction. As cysts mature, the cyst capsule within the enlarged muscle fibre becomes thicker and more clearly differentiated from the muscle sarcoplasm.

Sarcocystis ovifelis

Synonyms: *Sarcocystis gigantea*, *Sarcocystis medusififormis*, *Isospora bigemina*

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: In sheep, the meronts found in the endothelial cells are quite small, measuring 2–8 μm in diameter. In contrast, the bradyzoite cysts can be very large and visible to the naked eye as whitish streaks running in the direction of the muscle fibres. They have been reported as reaching several centimetres in length, but more commonly range up to 1.5 cm by 0.2–5 mm. The cyst wall has numerous cauliflower-like protrusions 1–4.5 μm long, each containing numerous fibrils. The parasitised host cell is enclosed in connective tissue forming a secondary cyst wall.

Intermediate hosts: Sheep

Final host: Cat

Geographical distribution: Worldwide

Pathogenesis: Infection in the final host is normally non-pathogenic, although mild diarrhoea has occasionally been reported. Generally, however, clinical signs are rarely observed in *Sarcocystis* infection and the most significant effect is the presence of cysts in the muscles resulting in downgrading or condemnation of carcasses.

Clinical signs: Infection is usually asymptomatic but may occasionally cause a febrile illness.

Pathology: In sheep, the tissue cysts may just be visible to the naked eye, especially in the oesophagus and tongue, but are more likely to be detected on histopathology.

Sarcocystis capracanis

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: In goats, the tissue cysts are microscopic in size (130–800 \times 50–70 μm) and are found in skeletal and cardiac muscle. The wall of the cyst appears thick (up to 2.6 μm) and radially striated with long finger-like protrusions.

Intermediate host: Goat

Final hosts: Dog, fox, wolf

Geographical distribution: Worldwide

Pathogenesis: In goats, the merogony stages in the vascular endothelium are pathogenic for the goat and can cause abortion and death. Generally, however, clinical signs are rarely observed in *Sarcocystis* infection and the most significant effect is the presence of cysts in the muscles resulting in downgrading or condemnation of carcasses.

Clinical signs: In heavy infections in goats there is anorexia, fever, anaemia, loss of weight, a disinclination to move and sometimes recumbency. Abortions may occur in breeding stock.

Pathology: Similar to that described for *S. oivicanis* in sheep.

Sarcocystis hircicanis

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: In the goat, the tissue cysts are up to 2.5 mm in size and are found in skeletal and cardiac muscle. The wall of the cyst is thin, smooth and striated, with long hair-like protrusions.

Intermediate host: Goat

Final hosts: Dog, fox, wolf

Geographical distribution: Europe, Asia

Pathogenesis, clinical signs, pathology: Similar to *S. capracanis*

Sarcocystis hircifelis

Synonym: *Sarcocystis moulei*

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: The sarcocysts are elongate, compartmented and up to 12 mm in length and have a thick striated wall.

Intermediate host: Goat

Final host: Cat

Geographical distribution: Worldwide

Pathogenesis: Non-pathogenic

Clinical signs: Infection is usually asymptomatic.

Parasites of the integument

Besnoitia besnoiti

Predilection site: Skin, conjunctiva

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: The pseudocysts are non-septate and about 100–600 µm in diameter, with a thick wall containing thousands of merozoites but no merozoites (see Fig. 2.26).

Intermediate hosts: Cattle, goat, wild ruminants (wildebeest, impala, kudu)

Final hosts: Cat, wild cats (lion, cheetah, leopard)

Geographical distribution: Worldwide, although important in tropical and subtropical countries, especially in Africa.

For further details on pathogenesis, diagnosis, treatment and control see Chapter 8.

Przhevalskiana silenus

Synonyms: *Hypoderma ageratum*, *Hypoderma crossi*, *Przhevalskiana ageratum*

Common name: Goat warble

Predilection site: Subcutaneous connective tissue

Class: Insecta

Order: Diptera

Family: Oestridae

Description, adults: The adult flies are 8–14 mm in length, have large eyes, a grey thorax and grey tessellated abdomen.

Description, larvae: The L₃ larvae are large (up to 25 mm in length), club-shaped, tapering towards the posterior end, with a pair of posterior spiracles. The body is composed of 11 segments with small spines at the conjunction of segments.

Hosts: Domestic goats, less commonly sheep, with gazelles as wild reservoirs over much of its range.

Geographical distribution: Asia, Middle East, North Africa and southern Europe

Pathogenesis: Heavy infestations can result in loss of weight and reduction in milk production; however, the chief importance of *Przhevalskiana* is in hide damage.

Clinical signs: Symptoms depend on the intensity of infestation and on the number of larvae in the subcutaneous tissue. Generally, hosts are restless, reduce feeding, and significantly infested animals lose condition. Except for poor growth and decreased milk yield in cases of heavy infestation, the host animals show no appreciable signs until the larvae and characteristic ‘warbles’ appear at the skin surface.

Diagnosis: The presence of the larvae in swellings under the skin, detected by palpation, allows diagnosis. Respiratory holes at the centre of each swelling, with associated reddish dried exudate, may be observed. The eggs may also be found on the hairs of the animals in the summer. Serological diagnosis has been demonstrated to be effective.

Pathology: The pathology is variable and depends on the intensity of infestation. Histologically, a fibrous thick-walled cavity is formed

around the third-stage larva by granulation tissue, surrounded by a hyalinised and eosinophilic cuff. After granulocyte infiltration there may be a second infiltration by lymphocytes, plasma cells, macrophages and giant cells.

Epidemiology: Younger animals appear to be more prone to infestation than older animals. Flock prevalences of between 30 and 90% have been reported in goat herds in southern Italy and Greece, with mean intensities of about five larvae per animal.

Treatment: Organophosphate insecticides such as trichlorophon appear to be less effective when used to treat goat warble fly infestation than for bovine hypodermosis. However, the macrocyclic lactones abamectin, ivermectin, doramectin, eprinomectin and moxidectin have been shown to be highly effective against *P. silenus* infestation.

Control: A programme incorporating a single annual treatment of macrocyclic lactone should form the basis of effective goat warble fly infestation control in areas where the disease is prevalent.

Notes: Limited geographical distribution, but locally of veterinary importance.

Hypoderma diana

Common name: Deer warble

Predilection site: Subcutaneous connective tissue

Class: Insecta

Order: Diptera

Family: Oestridae

Description, larvae: The mature larvae are thick and somewhat barrel-shaped, tapering anteriorly. When mature they are 25–30 mm in length and most segments bear short spines. Larvae are dirty white in colour when newly emerged from the host, but rapidly turn dark brown. The pupa is almost black. The larvae are relatively host-specific and live as subcutaneous parasites of deer.

Hosts: Deer, occasionally horse, sheep

Notes: *Hypoderma diana* is capable of infecting many species of deer, but does not infect cattle; however, it has been reported in sheep.

ECTOPARASITES

LICE

Heavy louse infestation is known as pediculosis. Blood-sucking lice have been implicated in the transmission of disease; however, lice are predominantly of importance because of the direct damage they cause. This effect is usually a function of their density. A small number of lice is very common and presents no problem. However, louse populations can increase dramatically, reaching high densities. Transfer of lice from animal to animal, from flock to flock or herd to herd is usually by direct physical contact. Because lice do not survive for long off their host, the potential for animals to pick up infestations from dirty housing is limited, although it cannot be ignored. Occasionally, lice may also be transferred between animals by attachment to flies (phoresy).

Description: Lice have a segmented body divided into a head, thorax and abdomen. They have three pairs of jointed legs and a pair of short antennae. All lice are dorsoventrally flattened and wingless. The sensory organs are poorly developed; the eyes are vestigial or absent.

Diagnosis: The lice and their eggs may be seen within the hair and on the skin when the coat is parted. The lice may be removed and identified under a light microscope.

Pathology: The pathology of louse infestation is extremely variable. Infestations may induce alopecia, irritation, papulocrustous dermatitis and self-excoriation. Sucking lice may cause anaemia.

Epidemiology: Generally, for the transfer of louse infestation, close bodily contact is necessary. Transmission occurs when sheep or goats are brought together as in sale yards, and especially when animals are housed for the winter since the heavy fleece or coat provides habitats that are readily colonised by lice. Adult lice positioned near the tip of the wool fibre or hair are passed on to the new host as it brushes past an infested animal. In sheep, it can take a single infested animal just 4 months to infest the entire flock. Lice populations peak in spring and lambs may be particularly susceptible to infestation.

Treatment: In sheep, several topical insecticides, such as amidine, amitraz or organophosphates (e.g. chlorfenvinphos, coumaphos, chlorpyrifos, crotoxyphos, trichlorophon, phosmet and propet-amphos), applied in dips or sprays are effective but are becoming more limited in their availability in some countries due to safety and environmental concerns. Two treatments, 14 days apart, may be required. Topical application of the pour-on pyrethroid cypermethrin, the spot-on deltamethrin and the insect growth regulator triflumuron have also been shown to be effective. The pyrethroids, which act by diffusion over the body surface in the sebum and give protection for 8–14 weeks, are probably the treatment of choice. Macrocyclic lactones (ivermectin, doramectin and moxidectin) may also be used, although they have only limited activity against chewing lice. Essential oils have been shown to be very effective against chewing lice when groomed into the fleece.

The situation for goats is different in that few treatments have been specifically evaluated for use in goats and pour-on treatments may be less effective because of the variability in hair fibres found on different goat breeds.

Control: Insecticide resistance is widespread in lice, and its rapid spread may be linked to the facultative parthenogenesis seen in many louse species. Hence, in an attempt to reduce the risk of selection for resistance, rotation of chemical classes is strongly advised. A good degree of louse control can be achieved by shearing because solar radiation and dehydration reduce the hatch rate of louse eggs. Subsequently, another good management procedure is to treat sheep immediately after shearing, which ensures a greater proportion of lice come into contact with insecticide and reduces the volume of chemical necessary to achieve this. If ewes are dipped during early pregnancy, the risk that they will still be louse infested at lambing is reduced, as is the chance of the lambs becoming infested. Dipping the lambs then results in the flock becoming as nearly louse-free as possible. The ewe lambs, when old enough to be mated, should not then be in a position to so readily infest their progeny. This could lead to a situation where treatment is necessary less frequently, assuming that there is a residual louse population as is commonly the case.

Bovicola ovis**Synonym:** *Damalinea ovis***Predilection site:** Upper epidermal layers mainly on the back and upper parts of the body**Class:** Insecta**Order:** Phthiraptera**Suborder:** Ischnocera**Family:** Trichodectidae**Description:** These chewing lice are up to 3 mm long, reddish-brown in colour, with a relatively large head that is as wide as the body and rounded anteriorly. The mouthparts are ventral. *Bovicola* has a three-segmented antenna and a single claw on each tarsus (Fig. 9.64; see also Fig. 3.69).**Host:** Sheep**Geographical distribution:** Worldwide**Pathogenesis:** *Bovicola* may cause intense irritation, resulting in rubbing and scratching, with matting and loss of hair, involving almost the whole body in extreme cases. The scratching animal may tear or pull out the fleece and exuded serum from bite wounds may cause wool matting and discoloration. Wounds may attract blow-flies. Lice reduce the quality of wool and can reduce wool production if left uncontrolled.**Epidemiology:** *Bovicola ovis* is very active, roaming in the wool over the entire body. It is susceptible to high temperatures, but it is also intolerant of moisture. In a damp fleece, with a relative humidity of more than 90%, it will die in 6 hours, and when covered by water it will drown in an hour.**Clinical signs:** Restlessness, rubbing and damage to the coat would suggest that lice are present, and when the hair is parted the parasites will be found. Lice appear as small yellowish specks in the hair**Fig. 9.64** Chewing louse, *Bovicola ovis*.

and the small pale eggs are readily found scattered throughout the coat.

Bovicola caprae**Synonym:** *Damalinea caprae***Common name:** Red louse**Predilection site:** Skin**Class:** Insecta**Order:** Phthiraptera**Suborder:** Ischnocera**Family:** Trichodectidae**Description:** These chewing lice are up to 3 mm long and reddish-brown in colour. The head is relatively large, at least as wide as the body, and rounded anteriorly. The mouthparts are ventral. *Bovicola* has a three-segmented antenna and a single claw on each tarsus.**Host:** Goat**Geographical distribution:** Worldwide**Pathogenesis:** See *B. ovis*.***Bovicola limbata*****Synonym:** *Damalinea limbata***Common name:** Red louse**Predilection site:** Skin**Class:** Insecta**Order:** Phthiraptera**Suborder:** Ischnocera**Family:** Trichodectidae**Description:** These chewing lice are up to 3 mm long and reddish-brown in colour. The head is relatively large, at least as wide as the body, and rounded anteriorly. The mouthparts are ventral. *Bovicola* has a three-segmented antenna and a single claw on each tarsus.**Host:** Goat (Angora)**Geographical distribution:** Worldwide**Pathogenesis:** See *B. ovis*.***Linognathus ovillus*****Common names:** Long-nosed louse, sheep face louse**Predilection site:** Skin, found mainly on the face**Class:** Insecta**Order:** Phthiraptera**Suborder:** Anoplura**Family:** Linognathidae

Fig. 9.65 Sucking louse, *Linognathus ovillus*.

Description: This sucking louse is blue-black with a long narrow head and slender body (Fig. 9.65; see also Fig. 3.55). It measures approximately 2.5 mm in length. Members of this family do not have eyes or ocular points. The second and third pairs of legs are larger than the first pair and end in stout claws. In species of the genus *Linognathus* the thoracic sternal plate is absent or if present is weakly developed. Paratergal plates are absent from the abdomen. The eggs are exceptional in being dark blue, and are less easy to see on hair.

Host: Sheep

Geographical distribution: Worldwide, but particularly common in Australia and New Zealand

Pathogenesis: Lice cause sheep to rub and scratch, sometimes to the point of denuding areas of skin. Infestation by *Linognathus* spp. results in a chronic dermatitis characterised by constant irritation and rubbing and biting of the fleece. Because they are blood-feeders, anaemia is common where high populations of lice exist. Anaemia may predispose animals to respiratory or other diseases. *Linognathus ovillus* is a known vector of *Eperythrozoon ovis* in sheep.

Clinical signs: *Linognathus ovillus* is mainly found on the face of sheep but at high densities may spread over the entire body (Fig. 9.66). Infested animals will stamp their feet or bite the infested areas. Sheep infested with lice have a ragged appearance, often with tags of wool hanging from the fleece. Newly infested sheep are very sensitive to lice. Others which have had lice for long periods can develop quite severe infestations but show few signs. Often lousy wool has a yellow colour due to a heavy suint and skin secretions.

Linognathus pedalis

Common name: Sheep foot louse

Predilection site: Skin, legs, belly and feet

Class: Insecta

Fig. 9.66 Infestation of sucking lice, *Linognathus ovillus*.

Order: Phthiraptera

Suborder: Anoplura

Description: The foot louse *Linognathus pedalis* is bluish-grey, with a long pointed head and can reach up to 2 mm in length when fully engorged. This species does not have eyes or ocular points. The second and third pairs of legs are larger than the first pair and end in stout claws. The thoracic sternal plate is absent or if present is weakly developed. Paratergal plates are absent from the abdomen.

Host: Sheep

Geographical distribution: *Linognathus pedalis* is common in the USA, South America, South Africa and Australasia.

Pathogenesis: On the host *L. pedalis* is more sedentary than *L. ovillus* and tends to occur in aggregations in its preferred sites, which are the more lightly woolled areas of the body such as the legs, belly and feet. However, at high densities both species may spread over the entire body. Infestation by *Linognathus* results in a chronic dermatitis characterised by constant irritation and rubbing and biting of the fleece. Because they are blood-feeders, anaemia may occur where very high populations of lice exist. Anaemia may predispose animals to respiratory or other diseases.

Clinical signs: See *L. ovillus*. In Merinos and other heavily woolled breeds, it is usually first detected at crutching.

Epidemiology: In its normal habitat on the legs, it is exposed to great fluctuations in temperature and, having adapted to survive in these conditions, it is one of the few lice which can live away from the host's body and is viable on pasture for about a week. As a consequence of this, infestations may be picked up off contaminated pasture.

Linognathus stenopsis

Common name: Goat sucking louse

Predilection site: Skin

Class: Insecta

Order: Phthiraptera

Suborder: Anoplura

Family: Linognathidae

Description: *Linognathus stenopsis* is up to 2 mm long when fully fed, with a long pointed head. This species does not have eyes or ocular points. The second and third pairs of legs are larger than the first pair and end in stout claws. The thoracic sternal plate is absent or if present is weakly developed. Paratergal plates are absent from the abdomen.

Host: Goat

Geographical distribution: Worldwide

Pathogenesis: see *L. ovillus*.

Linognathus africanus

Common names: African sheep louse, African blue louse

Predilection site: Skin, face

Class: Insecta

Order: Phthiraptera

Suborder: Anoplura

Description: Female lice are 2.2 mm long and males 1.7 mm.

Hosts: Goat, occasionally sheep

Geographical distribution: Africa, although probably now worldwide

MITES

The ectoparasitic mites of sheep and goats feed on blood, lymph, skin debris or sebaceous secretions, which they ingest by puncturing the skin, scavenging from the skin surface or imbibing from epidermal lesions. Most ectoparasitic mites spend their entire lives associated with their host, so that transmission from host to host is primarily by physical contact. Infestation by mites is called acariosis and can result in severe dermatitis, known as mange, which may cause significant welfare problems and economic losses.

Demodex ovis

Synonym: *Demodex ariae*

Predilection site: Hair follicles and sebaceous glands, most commonly on the face

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Demodicidae

Description: Species of *Demodex* have an elongate tapering body, up to 0.1–0.4 mm in length, with four pairs of stumpy legs ending in small blunt claws in the adult (see Fig. 3.100). Setae are absent from the legs and body. The legs are located at the front of the body, and as such the striated opisthosoma forms at least half the body length.

Host: Sheep

Geographical distribution: Worldwide

Pathogenesis: This form of mange is rare in sheep and is of little economic importance, as it is confined to the face region and mild in character. Large numbers of mites may cause hide damage.

Clinical signs: Ovine demodectic mange is uncommon. Clinical signs include alopecia and scaling, especially on the face, neck and shoulders.

Diagnosis: For confirmatory diagnosis, deep scrapings are necessary to reach the mites deep in the follicles and glands. This is best achieved by taking a fold of skin, applying a drop of liquid paraffin, and scraping until capillary blood appears.

Pathology: Lesions may be papular, nodular and, rarely, pustular. The mites in sebaceous glands occasionally induce folliculitis or furunculosis.

Epidemiology: Probably because of its location deep in the dermis, it is very difficult to transmit *Demodex* between animals unless there is prolonged contact. In nature such contact only occurs during suckling, and it is thought that most infections are acquired in the early weeks of life. Transmission appears to occur during the earlier days of suckling.

Treatment: In many cases, demodicosis spontaneously resolves and treatment is unnecessary. Systemic macrocyclic lactones may be effective.

Control: Control is rarely applied.

Notes: Species of the genus *Demodex* are highly specialised mites that live in the hair follicles and sebaceous glands of a wide range of wild and domestic animals, including humans. They are believed to form a group of closely related sibling species that are highly specific to particular hosts: *Demodex phylloides* (pig), *Demodex canis* (dog), *Demodex bovis* (cattle), *Demodex equi* (horse), *Demodex musculi* (mouse), *Demodex ratti* (rat), *Demodex caviae* (guinea pig), *Demodex cati* (cat) and *Demodex folliculorum* and *Demodex brevis* (human). Various morphological variations may be seen on a host; these are sometimes, probably incorrectly, ascribed separate species status.

Demodex caprae

Predilection site: Hair follicles and sebaceous glands

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Demodicidae

Description: See *D. ovis*

Host: Goat

Geographical distribution: Worldwide

Pathogenesis: The disease is similar to that in cattle. The initial lesions on the face and neck extend to the chest and flanks and may eventually involve the whole body, with the formation of cutaneous nodules of up to 20 mm in diameter containing yellowish caseous

material with large numbers of mites. This form of mange is rarely debilitating, and is of greatest importance as a cause of downgrading or condemnation of goat skins.

Clinical signs: Pea-sized nodules containing caseous material and mites, particularly on the withers, lateral neck, back and flanks. Concurrent pyoderma may occur, leading to furunculosis with ulceration and crust formation.

Diagnosis: For confirmatory diagnosis, deep scrapings are necessary to reach the mites deep in the follicles and glands. This is best achieved by taking a fold of skin, applying a drop of liquid paraffin, and scraping until capillary blood appears.

Pathology: Cutaneous nodules consist of follicular cysts lined with squamous epithelium and filled with waxy keratin squames and mites. Eruption of the cysts onto the skin may form a thick crust; rupture within the dermis may form an abscess or granulomatous reaction.

Epidemiology: Probably because of its location deep in the dermis, it is very difficult to transmit *Demodex* between animals unless there is prolonged contact. Such contact usually only occurs during suckling, and as such it is thought that most infections are acquired in the early weeks of life. The muzzles, neck, withers and back are common sites of infestation.

Treatment: In many cases, demodicosis spontaneously resolves and treatment is unnecessary. The organophosphate trichlorphon, used on three occasions 2 days apart, and systemic macrocyclic lactones may be effective.

Control: Control is rarely applied.

Psoroptes ovis

Synonyms: *Psoroptes communis* var. *ovis*, *Psoroptes cuniculi*, *Psoroptes cervinus*, *Psoroptes bovis*, *Psoroptes equi*, *Psoroptes aucheniae*

Common name: Scab mite

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Psoroptidae

Description: Mites of the genus *Psoroptes* are non-burrowing mites, up to 0.75 mm in length and oval in shape (see Fig. 3.92). All the legs project beyond the body margin. Its most important recognition features are the pointed mouthparts and the three-jointed pretarsi (pedicels) bearing funnel-shaped suckers (pulvilli) (see Fig. 3.87). Adult females have jointed pretarsi and pulvilli on the first, second and fourth pairs of legs and long whip-like setae on the third pair. In contrast, the smaller adult males, which are recognisable by their copulatory suckers and paired posterior lobes, have pulvilli on the first three pairs of legs and setae on the fourth pair. The legs of adult females are approximately the same length, whereas in males the fourth pair is extremely short.

Hosts: Sheep, cattle, goat, horse, rabbit, camelids

Geographical distribution: Worldwide, particularly Europe and South America, but not Australia or New Zealand

Pathogenesis: The mites are non-burrowing and feed superficially on a lipid emulsion of skin cells, bacteria and lymph on the host skin, produced as a result of a hypersensitivity reaction to the presence of antigenic mite faecal material. This hypersensitivity causes inflammation, surface exudation, scale and crust formation, with excoriation (scratching) due to self-trauma. Infestation is described as psoroptic mange or sheep scab (Fig. 9.67). The serous exudate produced in response to the mites dries on the skin to form a dry yellow crust, surrounded by a border of inflamed skin covered in moist crust. Mites are found on the moist skin at the edge of the lesion, which extends rapidly and may take as little as 6–8 weeks to cover three-quarters of the host's skin. Eventually the crust lifts off as the new fleece grows.

Infestation in sheep leads to severe pruritus, wool loss, restlessness, biting and scratching of infested areas, weight loss, reduced weight gain and, in some cases, death. When handled, infested sheep may demonstrate a 'nibble reflex', characterised by lip smacking and protrusion of the tongue; others may show epileptiform fits lasting 5–10 minutes. In sheep, lesions may occur on any part of the body, but are particularly obvious on the neck, shoulders, back and flanks. In severe cases the skin may be excoriated, lichenified and secondarily infected, with numerous thick-walled abscesses of between 5 and 20 mm in diameter. Sheep scab can affect sheep of all ages but may be particularly severe in young lambs and sheep in poor condition.

The incidence of the disease varies according to season. In warm weather, mite populations may decline, leaving residual populations in sites such as the axilla, groin, infraorbital fossa and inner surface of the pinna and auditory canal during spring, summer and early autumn. Populations of *Psoroptes* may also be found localised in the ears of sheep, causing chronic irritation, often associated with haematomas, head shaking and scratching.

Clinical signs: The earliest phase following infection is seen as a zone of inflammation with the appearance of small vesicles and serous exudate. As the lesion spreads, the centre becomes dry and covered by a yellow crust while the borders, in which the mites are multiplying, are moist. Scab lesions occur most frequently around the shoulders and the back. The first visible sign is usually a patch of lighter wool, but as the area of damage enlarges, the sheep responds to the intense itching associated with mite activity by rubbing and

Fig. 9.67 Sheep with psoroptic mange. (Courtesy of Prof Eduardo Berriatua.)

scratching against fence posts and other objects, so that the wool becomes ragged and stained, and is shed from large areas. In addition to wool loss, the sheep may become restless and preoccupied in scratching. As a result, weight gains may be impaired in growing animals, while in adults there may be weight loss.

Diagnosis: Another non-burrowing mite, *Chorioptes*, can be common in sheep, and it is essential that this less pathogenic mite should be differentiated from the more pathogenic *Psoroptes*. The important differential features are shown in Fig. 3.87. Although relatively easy to identify the active disease within a flock, the latent lesions make it more difficult to declare a flock free of infection. Particular attention should be paid to the areas in which these lesions are found. A sample may be obtained from skin scrapings taken around the lesion; this can then be examined microscopically.

Pathology: The mite faeces and its flora, shed cuticle and enzymes in the peritrophic membrane that surrounds the faecal pellets induce a profound inflammatory response by the host. Histopathology includes subcorneal eosinophilic pustules, and a dermal infiltrate composed of eosinophils, neutrophils, macrophages and lymphocytes, accompanied by mast cell hyperplasia. There is pronounced dermal oedema.

Epidemiology: Transmission is primarily through physical contact and the majority of sheep become infected while the mites are active and multiplying. However, transmission may also occur via the environment. The length of time a mite can survive off its host is strongly affected by ambient temperature and humidity, but at low temperatures (<15°C) and high humidity (>75%), survival may be in excess of 18 days, allowing transmission from housing, bedding or contaminated machinery such as shearing equipment. Time of year may have an important impact on off-host survival. This has important implications for the potential for transmission from the environment to new hosts, transmission being considerably greater in the winter.

The period when the mite infestation has declined, either as a response to environmental conditions or the host's immune response, is also very significant in the epidemiology of the disease. Sheep that appear to be uninfested but which carry small populations of mites may be introduced to healthy flocks during summer and autumn and subsequently initiate outbreaks.

Treatment: Plunge dipping is generally recommended for sheep scab control. Sheep should remain in the bath for at least 1 minute, and the head should be immersed at least twice. They should be held in clean pens before dipping and it is customary to hold them in draining pens for a time afterwards to conserve dip and assist in its proper disposal. Modern acaricides have been developed which have an affinity for wool grease, so that as a succession of sheep go through the bath the acaricide is gradually 'stripped out', and manufacturers give directions for replenishment after a specified number of sheep have been dipped. Other methods of applying acaricide, such as showering, have not been shown to be effective against scab mites.

In most countries in which control is practised, only specified acaricides are permitted for use in dips. For many years only gamma-hexachlorocyclohexane (HCH) was used, but this has been largely replaced by the organophosphates diazinon and propetamphos, which in addition to giving the required persistence in the fleece are rapidly detoxified and excreted from tissues. The synthetic pyrethroids flumethrin and α -cypermethrin were licensed for the control of sheep scab but due to concerns over health and safety their use has declined in many countries.

Two treatments with injectable ivermectin 200 µg/kg at an interval of 7 days have given complete clearance of *P. ovis*. Additionally, doramectin 300 µg/kg or moxidectin 200 µg/kg give control following a single injection; all are now licensed in several countries for this purpose.

Control: Because of its short population turnover period of 10 days there is very rapid spread, and it is this character which has led to legislative control in many countries since the economic consequences of uncontrolled sheep scab are serious. For example, the disease was presumed to have been eradicated from the UK in 1952, there having been no notifications of outbreaks for a number of years; it reappeared in 1973, most probably having been introduced as the quiescent phase in imported sheep and very rapidly spread to flocks throughout the UK. It was eradicated from Australia and New Zealand many years ago, but remains notifiable in these countries. Legislation in support of control is based on inspection of flocks, limitation of movement of sheep in, and from, areas in which the infection has been diagnosed, and compulsory treatment of all sheep at prescribed times.

A common source of infection of a flock is through the introduction of new animals. These must be checked over thoroughly and subjected to a quarantine period if possible. Common grazing, where flocks mix together, is another important transmission route and where this is practised, control is particularly difficult unless all owners coordinate their treatment activities.

Notes: The taxonomy of the mites in this genus is confused, with mites located in different parts of the body or on different hosts traditionally given different species names; however, little good evidence exists to support this nomenclature.

Psorobia ovis

Synonym: *Psorergates ovis*

Common name: Sheep itch mite

Predilection site: Skin, all over the body

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Psorergatidae

Description: *Psorobia ovis* is a small mite, roughly circular in form and less than 0.2 mm in diameter (see Fig. 3.103). The legs are arranged more or less equidistantly around the body circumference, giving the mite a crude star shape. Larvae of *P. ovis* have short stubby legs. The legs become progressively longer during the nymphal stages until, in the adult, the legs are well developed and the mites become mobile. Adults are about 190 µm long and 160 µm wide. The tarsal claws are simple and the empodium is pad-like. The femur of each leg bears a large, inwardly directed curved spine. In the adult female, two pairs of long whip-like setae are present posteriorly; in the male there is only a single pair.

Hosts: Sheep, particularly fine-wooled breeds such as the Merino

Geographical distribution: Australia, New Zealand, southern Africa, North and South America. It has not been reported in Europe.

Pathogenesis: Infection is most common in fine-wool breeds such as the Merino and Corriedale and is acquired by contact when the

wool is short; as the fleece lengthens, it presents a barrier to the transfer of mites. The spread of the mite population is very slow, and infestation is rarely found in animals less than 6 months old. The animal may be 3 years or more before the whole fleece area is affected.

Though a non-burrowing mite, *Psorobia* attacks the skin itself, living in the superficial layers and causing chronic irritation and skin thickening. The earliest signs are small pale areas of wool on the shoulders, body and flanks, which gradually extend over the rest of the fleece, with irritation increasing as the mite population grows. Sheep rub, bite and chew their wool, which becomes ragged, with loose strands trailing from the sides of the body. In long-standing cases, large patches of wool may be lost. The fleece itself contains much scurf and has a slightly yellowish hue, while the staple is very dry and easily broken. Microscopically, there is a hyperkeratosis and marked desquamation, with the deeper superficial layers showing round-cell infiltration and eosinophilia in the immediate vicinity of the parasite. In severe cases the whole fleece, which is difficult to shear because of its matted consistency, must be discarded. In less severely affected sheep and especially in older animals (which have become tolerant of the itch because of their thickened damaged skin), fleeces are downgraded.

Clinical signs: These parasites are severely irritating, causing host animals to rub and bite at their fleece. The fleece may be weakened and the wool may break easily.

Diagnosis: To obtain mites it is necessary, having clipped away a patch of wool, to apply a drop of mineral oil and scrape the skin down to the blood capillary level. The mites themselves are easily identified using a microscope. The absence of mites in a single scraping is not sufficient evidence for a negative diagnosis.

Pathology: Infection induces pruritis; light dry scabs may be present.

Epidemiology: The adult mites are spread by direct contact between hosts and are most often transferred between shorn sheep. Mites are generally found at higher densities in winter and spring. *Psorobia ovis* is very sensitive to desiccation, can only survive for 24–48 hours off the host and only the adults are mobile. As a consequence of these factors, the spread of infestation through a flock is generally slow and is most evident during the winter months.

Treatment: *Psorobia* is relatively unsusceptible to most acaricides, although the formamidine amitraz and lime–sulphur dips have been shown to be of considerable value. Otherwise, the older arsenic–sulphur preparations may be used. Macrocytic lactones are highly effective against this species, with a single treatment usually killing all the mites.

Control: Sheep should be dipped soon after shearing. Annual dipping after shearing will suppress the mite population, keeping the infestation rate low, but rarely eradicating it completely.

Sarcoptes scabiei

Common name: Scabies

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Sarcoptidae

Description: The adult of this species has a round, ventrally flattened, dorsally convex body (see Fig. 3.89). Adult females are 0.3–0.6 mm long and 0.25–0.4 mm wide, while males are smaller, typically up to 0.3 mm long and 0.1–0.2 mm wide. The posterior two pairs of limbs do not extend beyond the body margin. In both sexes, the pretarsi of the first two pairs of legs bear empodial claws and a sucker-like pulvillus, borne on a long stalk-like pretarsus. The sucker-like pulvilli help the mite grip the substrate as it moves. The third and fourth pairs of legs in the female and the third pair of legs in the male end in long setae and lack stalked pulvilli. The mouthparts have a rounded appearance. These mites have no eyes or stigmata. The dorsal surface of the body of *S. scabiei* is covered with transverse ridges, but also bears a central patch of triangular scales. The dorsal setae are strong and spine-like. The anus is terminal and only slightly dorsal. There are a number of host-adapted varieties of *S. scabiei* that differ subtly in their morphology.

Pathogenesis, sheep: The mites, unlike the non-burrowing mites of the genus *Psoroptes*, are generally found in regions without wool, such as the face, ears, axillae and groin, and spread slowly. Affected areas are at first erythematous and scurfy. The intense pruritus characteristic of sarcoptic mange is present, and sheep scratch and rub the head, body and legs against trees, posts and walls. Because of the itch, sheep are almost continuously restless and are unable to graze, so that there is progressive emaciation. In haired sheep the whole body may be affected. Sarcoptic mange has a wide geographic distribution in many sheep-raising areas of the world, such as the Middle East. In Africa it occurs in the local breeds of haired sheep and, because of hide damage, is of considerable economic importance, more than a million sheepskins being exported from the region annually. Sarcoptic mange of sheep in Britain has not been encountered for more than 30 years.

Pathogenesis, goats: This form of mange in goats is worldwide in distribution, but is of greatest economic importance in areas where the goat is the basic domestic ruminant such as India and West Africa. In goats the condition is often chronic, and may have been present simply as 'skin disease' for many months before definitive diagnosis has been made. As in other sarcoptic infections the main signs are irritation with encrustations, loss of hair and excoriation from rubbing and scratching. In long-standing cases the skin becomes thickened and nodules may develop on the less well haired parts of the skin, including the muzzle, around the eyes and inside the ears.

Treatment: In sheep, treatment and control are similar to those described for the more common psoroptic mange. In goats, repeated treatment is often necessary, sometimes over several months in long-standing cases. The acaricide which has been most widely used is gamma-HCH, and where this is no longer available there may be problems obtaining a suitable drug licensed for use in goats. Although not licensed for the treatment of milking goats, a single injection of systemic macrocyclic lactone may be effective. Corticosteroid therapy has been reported to aid recovery as it suppresses the pruritus.

For further details see Chapter 11.

Chorioptes bovis

Synonyms: *Chorioptes ovis*, *Chorioptes equi*, *Chorioptes caprae*, *Chorioptes cuniculi*, *Chorioptes japonensis*

Predilection site: Skin, particularly the legs, feet, base of tail and upper rear surface of the udder

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Psoroptidae

Description: In the adult female, tarsi I, II and IV have short-stalked pretarsi and tarsi III have a pair of long, terminal, whip-like setae. The first and second pairs of legs are stronger than the others and the fourth pair has long slender tarsi. In the male, all legs possess short-stalked pretarsi and pulvilli. However, the fourth pair is extremely short, not extending beyond the body margin. Male *C. bovis* are characterised by a very long opisthosomal seta 1 (ae) and short spatulate setae 2 (l4 and d5), on well-developed posterior lobes (see Fig. 3.93). The mouthparts are distinctly rounder, and the abdominal tubercles of the male are noticeably more truncate, than those of *Psoroptes*.

Hosts: Cattle, sheep, horse, goat, rabbit

Pathogenesis: In sheep, the mites are found mainly on the legs and feet and, though very common, little harm is caused. When clinical cases do occur, they are typically in the form of foot mange, affecting the forefeet. The mites cluster about the accessory digits and along the coronary border of the outer claws, causing crusting below the accessory digits and in the interdigital spaces. Lambs are thought to become infected by contact with the legs of the ewe. In some cases there may be spread from the limbs to the face and other regions and, in occasional severe cases, pustular dermatitis (with wrinkling and thickening of the skin) may occur.

It has been noted in New Zealand that when the mange spreads to the scrotum the thickened and inflamed skin allows the scrotal temperature to remain high, resulting in testicular atrophy and cessation of spermatogenesis. Infected rams have impaired reproductive ability or sterility, though their general health is not affected. The condition is not irreversible; semen production and fertility return to normal after successful mange treatment. Prevalence of leg and scrotal mange is usually highest in the autumn and winter months, and declines in spring.

In goats, the mites occur mostly on the forefeet around the accessory digits and claws. However, they may also occur higher on the foot and on the pastern. The lesions produced are relatively mild. Infestation rates of *C. bovis* tend to be higher in goats than sheep, with up to 80–90% of goats in individual herds being parasitised.

Treatment: Chorioptic mange in sheep is easily treated by dipping or by local treatment with a suitable acaricide. Macrocytic lactones are an effective treatment against chorioptic mange. Crotoxyphos (0.25%) applied as a spray can also be used to treat infestations.

In goats, a suitable acaricidal wash, scrubbed on to the lesions on two occasions 14 days apart, is effective.

Notes: The names *Chorioptes ovis*, *Chorioptes equi*, *Chorioptes caprae* and *Chorioptes cuniculi* used to describe the chorioptic mites found on sheep, horses, goats and rabbits, respectively, are now all thought to be synonyms of *Chorioptes bovis*.

For further details see Chapter 8.

Melophagus ovinus

Common name: Sheep ked

Predilection site: Skin on the neck, shoulders and belly

Class: Insecta

Order: Diptera

Family: Hippoboscidae

Description, adult: Hairy, brown, wingless, ‘degenerate’ fly, approximately 5.0–8.0 mm long with a short head and broad, dorsoventrally flattened, brownish thorax and abdomen (Fig. 9.68; see also Fig. 3.32). The abdomen is indistinctly segmented and is generally soft and leathery. Both sexes are completely wingless and even the halteres are absent. They have piercing blood-sucking mouthparts and strong legs provided with claws that enable them to cling onto wool and hair.

Host: Sheep

Geographical distribution: Worldwide, but most common in temperate areas

Pathogenesis: Since keds suck blood, heavy infections may lead to loss of condition and anaemia. Inflammation leads to pruritus, biting, rubbing, wool loss and a vertical ridging of the skin known as ‘cockle’. *Melophagus ovinus* is also responsible for an allergic dermatitis in sheep characterised by small nodules on the grain layer of the skin, reduced weight gain and darkened patches at the affected site. They are spread by contact and long-wooled breeds appear to be particularly susceptible.

Melophagus ovinus is the vector of the non-pathogenic *Trypanosoma melophagium*. If the sheep eats a ked, the metacyclic stages may penetrate the buccal mucosa.

Clinical signs: Intense irritation from infestation causes sheep to rub, bite and scratch themselves, tearing the fleece. Heavy infestation may cause anaemia. The piercing mouthparts of keds create open wounds susceptible to further bacterial and parasitic infections. The faeces of the keds produce stains in the coat that do not wash out readily.

Diagnosis: Adults and pupae may be seen on the host animal, most frequently around the ribs.

Fig. 9.68 Sheep ked, *Melophagus ovinus*.

Epidemiology: Keds are permanent ectoparasites. The spread of sheep keds is largely through contact, and the movement of keds from ewes to lambs is an important route of infestation. Within a flock, transfer occurs when sheep keds move to the tips of the fleece in response to increasing air temperature. Air temperature must usually be 21°C or above before many keds are observed on the surface of the fleece. Consequently, transfer between animals is more likely, and occurs more rapidly, in summer than in winter. Sheep with dense, long or clotted fleeces are more likely to spread the infection because the keds come to the surface of such fleeces. Heavy infestations of keds are most commonly seen in autumn and winter. Poorly fed animals or those that are not sufficiently protected against cold weather are most liable to suffer from keds, and the parasites are particularly common towards the end of winter.

Treatment: Organophosphates and pyrethroids applied as dips, sprays or pour-on formulations are highly effective at treating *M. ovinus* infestations. Pupae are resistant to treatment but shearing removes pupae and adults.

Control: Specific measures are rarely undertaken, since the routine use of insecticides for the control of blowflies and ticks usually also results in the efficient control of keds.

Notes: The sheep ked is of considerable economic importance and is generally regarded as one of the most damaging ectoparasites of sheep in North and South America. The overall losses in the USA due to keds have been estimated to be about US\$40 million per year.

FLY STRIKE (MYIASIS)

Myiasis is the infestation of the organs or tissues of host animals by the larval stages of dipterous flies, usually known as maggots or grubs. The fly larvae feed directly on the host's necrotic or living tissue. A small number of species are obligate ectoparasites and must have a living host to complete their development. However, the majority are facultative parasites and these can develop in both living and dead organic matter. The facultative species can be subdivided into primary and secondary facultative species. The primary species usually adopt an ectoparasitic habit and are capable of initiating myiasis, but may occasionally live as saprophages in decaying organic matter and animal carcasses. The secondary facultative ectoparasites normally live as saprophages and usually cannot initiate a myiasis; they may secondarily invade pre-existing infestations. The three obligate species of myiasis fly are dealt with in Chapter 17.

Clinical signs: Infestations resulting from small numbers of larvae may be tolerated well by sheep; nothing can be seen until the fleece is parted, revealing the damaged skin and the larvae. Heavily affected sheep are anorexic, appear dull and usually stand away from the main flock. The fleece in the affected area is darker, has a damp appearance and a foul odour.

Diagnosis: This is based on the clinical signs and recognition of maggots in the lesion.

Treatment: Once the problem is diagnosed, all affected sheep should be separated and the area surrounding the lesion clipped. Where possible larvae should be removed and killed; larvae that are more than 24 hours old that are allowed to drop from the lesion will survive and subsequently emerge as adults. The lesion should be dressed with a suitable preparation of dilute insecticide, such as diazinon, cypermethrin or deltamethrin.

Control: This should be based largely on the prophylactic treatment of sheep with insecticides. The problems associated with this are the relatively short period spent by the larvae on the sheep, the repeated infestations (which occur throughout the season) and the rapidity with which severe damage occurs. Any insecticide used must therefore not only kill the larvae but also persist in the fleece. Organophosphate and pyrethroid insecticides may give effective protection for up to 10 weeks. Application of these insecticides is made by hand spraying, plunge dipping, in a spray race or by jetting. In the northern hemisphere, two annual treatments, usually in May and August, should give protection for the whole of the fly season. The insect growth inhibitors cyromazine and dicyclanil give excellent protection for 8 or 12 weeks, respectively, after a single application. These chemicals are applied as a pour-on, ideally before the anticipated seasonal challenge.

Other measures that should be taken to aid control are the prevention of diarrhoea by effective worm control and the removal of excess wool from the groin and perineal area to prevent soiling, a technique known as crutching. Shearing reduces strike risk in ewes and the docking of lamb tails will also significantly reduce the risk of breech strike. Appropriate disposal of carcasses, which otherwise offer an excellent alternative breeding place for blowflies, is also recommended.

Lucilia

Description, adults: *Lucilia* blowflies measure up to 10 mm in length and are characterised by a metallic greenish to bronze sheen (Fig. 9.69; see also Fig. 17.6b). The adults are characterised by the

Fig. 9.69 Greenbottle, *Lucilia sericata*.

presence of a bare stem-vein, bare squamae and the presence of three pairs of post-sutural dorsocentral bristles on the thorax (see Fig. 3.39). The sexes are very similar in appearance, but may be distinguished by the distance between the eyes, which are almost touching anteriorly in males and separated in females.

Adult *Lucilia sericata* and *L. cuprina* may be distinguished from most other species of *Lucilia* by the presence of a pale creamy-white basicostal scale at the base of the wing, three post-sutural acrostichal bristles on the thorax and one anterodorsal bristle on the tibia of the middle leg. However, definitive identification to species can only be confirmed using a small number of subtle morphological features, such as the colour of the fore femur, the number of paravertical setae present on the back of the head and, most reliably, the shape of the male genitalia.

Description, larvae: Larvae are smooth, segmented and measure 10–14 mm in length. They possess a pair of oral hooks at the anterior extremity and, at the posterior, peritremes bearing spiracles (see Fig. 3.40a).

Hosts: Mainly sheep, but a range of other domestic and wild animals may be affected including humans.

Pathogenesis: Two species, *L. sericata* and *L. cuprina*, are important primary facultative agents of myiasis. Other species of *Lucilia* may be occasional or secondary invaders of established myiasis. After the eggs are deposited on the wool, the larvae emerge and crawl down the wool on to the skin. They secrete proteolytic enzymes which digest and liquefy the tissues. Second- and third-stage larvae may also abrade the skin with their mouth hooks.

Infestations resulting from a single batch of eggs may be tolerated well by sheep, produce few clinical signs and be difficult to detect without detailed examination. When the larvae cease feeding and leave the host, the lesions created by such small infestations heal well and usually without complications.

However, the odour of an existing infestation may attract more blowflies and induce further oviposition; the high humidity at an active strike lesion may also enhance egg and larval survival. Hence, once infested, sheep become far more likely to receive multiple strikes. At the initial lesion site there may be alopecia and underlying scar tissue formation, while the lesion spreads from its margins as further ovipositions occur and waves of larvae feed under the surrounding wool (Fig. 9.70). The irritation and distress caused by the expanding lesion is extremely debilitating and sheep can rapidly lose condition.

Pathology: Sheep struck by *Lucilia* show a rapid increase in body temperature and respiratory rate. The animals become anaemic and suffer severe toxæmia, with both kidney and heart tissues affected. The feeding activity of the larvae may cause extensive tissue damage which, in combination with the larval proteases produced, results in the development of inflamed, abraded or undermined areas of skin (Fig. 9.71). Infested animals become lethargic, appear depressed and cease feeding, resulting in loss of weight and anorexia. If untreated, multiple infestations rapidly lead to death from toxæmia, usually within about 2 weeks of the initial infestation, although the precise time required will depend on the intensity of infestation.

Epidemiology: The epidemiology of cutaneous myiasis in sheep depends on factors that affect the prevalence of blowflies and those which affect host susceptibility. The three principal factors are as follows.

Fig. 9.70 Blowfly strike of sheep by larvae of *Lucilia sericata*.

- 1 Temperature.** High ambient temperatures allow elevated levels of fly activity and, provided the relative humidity is also high, favour the creation of suitable areas of microclimate in the fleece that attract the adult flies to lay their eggs. In temperate areas, the rising temperatures of late spring allow overwintering larvae to complete their development and the first wave of adult blowflies to emerge. Ambient temperature then determines the number of generations and hence the maximum abundance of flies over the summer.
- 2 Rainfall.** Persistent rain can make the fleece more attractive to the adult female flies, stimulate oviposition and increase the survival of eggs and first-stage larvae, which require areas of high humidity in the wool to persist.
- 3 Host susceptibility.** This is increased where putrefactive odours, often resulting from the bacterial decomposition of organic matter, develop in the fleece. The commonest causes of this are soiling of the hindquarters due to diarrhoea, bacterial fleece rot and injuries due to fighting, especially on the head in rams. Long fleece, long tails and wrinkled skin folds in some

Fig. 9.71 Inflamed and damaged skin caused by feeding blowfly larvae.

breeds may also increase host susceptibility. Footrot, caused by two anaerobic Gram-negative bacteria, *Bacteroides nodosus* and *Fusobacterium necrophorum*, is also an important predisposing factor leading to foot strike.

Lucilia sericata

Synonym: *Phaenicia sericata*

Common names: Greenbottle, sheep blowfly

Predilection site: Skin, skin wounds

Class: Insecta

Order: Diptera

Family: Calliphoridae

Geographical distribution: Worldwide. Originally *Lucilia sericata* was probably endemic to the Palaearctic. However, as a result of natural patterns of movement and artificial dispersal by humans and livestock in the past few hundred years, the species is now found worldwide. *Lucilia sericata* is more common in cool-temperate habitats, such as Europe, and is often replaced by the closely related *Lucilia cuprina* in warm-temperate and subtropical habitats.

Pathogenesis: Blowfly strike by *L. sericata* occurs most commonly in the perineal and tail-head region and is strongly associated with the accumulation of faeces in wool around the anus and tail (see Fig. 17.8). There is little recorded involvement of dermatitis in predisposing sheep to strike by *L. sericata* in northern Europe. Following initial strike by *L. sericata* secondary blowfly species may also invade the site of infestation. These secondary invaders include other species of *Lucilia*, *Calliphora* spp. and, in some regions, *Chrysomya* spp.

Lucilia sericata adults may act as passive vectors of *Mycobacterium avium avium*, *M. a. paratuberculosis* and *M. a. hominissuis*.

Epidemiology: The risk of myiasis by *L. sericata* has been shown to increase with increasing flock size and stocking density, and to decrease with increasing farm altitude. Initially in spring, unshorn adults may be most at risk. Immediately following shearing the risk of strike in adult sheep is considerably reduced. However, the susceptibility of strike in lambs increases, peaking in late summer as their fleeces grow and as populations of pasture nematodes increase, against which they have no acquired immunity, leading to diarrhoea and faecal soiling. In temperate areas under summer conditions, up to four generations may develop per year. In these areas, the final generation overwinters in the soil as larvae, to emerge as adults in the following spring. The precise timing of spring emergence and the growth of the population is highly temperature dependent. In warmer climates the number of generations per annum is greater and up to nine or ten have been recorded in southern Africa and Australia. The period of risk is more prolonged in warm, moist weather.

Notes: *Lucilia sericata* is the most important agent of sheep myiasis throughout northern Europe and was first recorded as an ectoparasite in England in the fifteenth century. *Lucilia sericata* arrived in New Zealand over 100 years ago and soon established itself as the primary myiasis fly in the country, occurring in 75% of all cases of sheep strike. However, now *L. cuprina* appears to be displacing *L. sericata* to become the most important primary cause of fly strike in sheep in New Zealand.

Lucilia cuprina

Synonyms: *Phaenicia cuprina*, *Phaenicia pallescens*

Common name: Greenbottle, Australian sheep blowfly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Family: Calliphoridae

Geographical distribution: It is thought that the original distribution of *Lucilia cuprina* may have been either Afro-tropical or Oriental. However, as a result of natural patterns of movement and artificial dispersal by humans and livestock in the past few hundred years, the species is now found worldwide, although in general *L. cuprina* occurs in warm-temperate and subtropical habitats. There are believed to be two subspecies: *L. c. cuprina* is distributed throughout the Neotropical, Oriental and southern Nearctic regions, while *L. c. dorsalis* is found throughout the sub-Saharan, Afro-tropical and Australasian regions. However, the two subspecies interbreed readily in the laboratory and intermediate forms are believed to be common. The simple division into two subspecies is therefore certainly an oversimplification of the complex pattern of genetic variation that occurs between populations of *L. cuprina*.

Pathogenesis: In Australia and New Zealand, body strike caused by *L. cuprina* is frequently the main form of myiasis. Body strike occurs most commonly around the shoulders and back region and is frequently associated with the incidence of bacterial dermatophilosis caused by the bacterium *Dermatophilus congolensis*. Body strike in Australasia is also often associated with bacterial fleece rot, a superficial dermatitis induced by moisture and proliferation of the bacterium *Pseudomonas aeruginosa* on the skin, resulting in a matted band of discoloured fleece. It is possible that dermatophilosis and fleece rot act synergistically in attracting blowflies and their subsequent oviposition. However, where the Merino breed is prevalent, breech and tail strike may also be common due to the conformation of this breed and the wrinkled skin in the breech area that favours the accumulation of urine and faeces.

Following initial strike by *Lucilia cuprina*, a variety of secondary species may also invade the site of infestation. They frequently extend the injury, rendering the strike one of great severity. These secondary invaders include *Calliphora* spp. and *Chrysomya* spp.

Lucilia cuprina is suspected of spreading diseases such as gastroenteritis and anthrax among host animals.

Epidemiology: In warmer parts of its range nine or ten generations per year have been recorded and *L. cuprina* may be active all year round in some parts of its range.

Notes: *Lucilia cuprina* is absent from most of Europe, although it has been recorded from southern Spain and North Africa. *Lucilia cuprina* was probably introduced into Australia towards the middle or end of the nineteenth century and it is now the dominant sheep myiasis species for mainland Australia and Tasmania, being present in 90–99% of fly-strike cases. In the early 1980s *L. cuprina* was discovered in New Zealand and was most probably introduced from Australia. Now, despite its low abundance, in northern areas of New Zealand it appears to be displacing *L. sericata* to become the most important primary cause of fly strike in sheep.

Lucilia cuprina is also the primary myiasis fly of sheep in southern Africa. Although this species had been known in South Africa since 1830, little sheep strike was recorded until the early

decades of the twentieth century, possibly as a result of the introduction of more susceptible Merino breeds or changes in husbandry practices.

In North America, *L. cuprina* is known to be present, although it does not appear to be economically important in sheep myiasis.

Calliphora

Description: The larvae are smooth, segmented and measure 10–14 mm in length. They possess a pair of oral hooks at the anterior extremity, spiracles on the anterior segment and, posteriorly, spiracular plates. The arrangement of the posterior spiracles on these plates serves to differentiate the species.

Hosts: Mainly sheep, but any other animal may be affected.

Pathogenesis: When involved in myiasis, secondary blowflies are attracted by the odour of the infestation, and their larvae extend and deepen the lesion. The irritation and distress caused by the lesion is extremely debilitating and the host animal can rapidly lose condition. The latter is often the first obvious sign of strike as the lesion occurs at the skin surface and is sometimes observed only on close examination.

Epidemiology: Secondary flies usually follow an initial strike by a primary fly such as *Lucilia cuprina* and invade the site of infestation. They frequently extend the injury, rendering the strike one of great severity.

Clinical signs, diagnosis, pathology, epidemiology, treatment and control are as for *Lucilia*.

Calliphora augur

Common names: Lesser brown blowfly, bluebodied blowfly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Family: Calliphoridae

Description: The adult *Calliphora augur* is predominantly brown or brown–yellow in colour with a patch of metallic blue on the medial abdomen. The adult body is approximately 11 mm in length.

Geographical distribution: Australasia, mainly eastern Australia

Pathogenesis: It breeds mostly in carcasses but will lay into wounds. As a result *Calliphora augur* is an important native Australasian species found as a secondary or tertiary invader of sheep strike in the Australasian region.

Calliphora albifrontalis

Synonym: *Calliphora australis*

Common name: Western Australian brown blowfly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Family: Calliphoridae

Description: In the adult *Calliphora albifrontalis* the thorax is non-metallic blue–black in colour but the abdomen is predominantly brown or brown–yellow.

Geographical distribution: Australasia

Pathogenesis: *Calliphora albifrontalis* is an important native Australasian species found as a secondary or tertiary invader of sheep strike in the Australasian region. In Western Australia, *C. albifrontalis* may be responsible for up to 10% of single-species strikes.

Calliphora nociva

Synonym: *Calliphora dubia*

Common name: Lesser brown blowfly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Family: Calliphoridae

Description: The adult *Calliphora nociva* is predominantly brown or brown–yellow in colour and closely resembles *C. augur* except for the colour patch on the abdomen, which is a much brighter blue on *C. nociva* than on *C. augur*. *Calliphora nociva* displaces *C. augur* in Western Australia.

Geographical distribution: Australasia, mainly Western Australia

Pathogenesis: *Calliphora nociva* is an important native Australasian species found as a secondary or tertiary invader of sheep strike in the Australasian region.

Calliphora stygia

Synonyms: *Pollenia stygia*, *Calliphora laemica*

Common name: Eastern golden haired blowfly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Family: Calliphoridae

Description: The adult *Calliphora stygia* is a large native Australasian blowfly with a grey thorax and yellow–brown mottled abdomen. It is one of the earliest flies to visit a corpse and will also feed on living sheep, causing fly strike.

Geographical distribution: Australasia

Pathogenesis: *Calliphora stygia* is a common secondary invader of ovine myiasis, present in strikes from October to May.

Epidemiology: *Calliphora stygia* is adapted to cooler conditions than other flies and occurs in largest numbers in spring and autumn, but may be found on sunny days in winter as well. This adaptation to the cold gives it an advantage on carrion during the cooler months, and in spring in particular many thousands of these flies can develop from carcasses. In summer, high temperatures and competition from species such as *Chrysomya rufifacies* reduce its abundance and *C. stygia* becomes scarce. In Western Australia, *C. stygia* is displaced by the very similar *C. albifrontalis*.

Calliphora vicina

Synonym: *Calliphora erythrocephala*

Common name: Bluebottle

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Family: Calliphoridae

Description: Bluebottles are stout and characterised by a metallic blue sheen on the body. The thoracic squamae have long dark hair on the upper surface. *Calliphora vicina* and *C. vomitoria* may be distinguished from each other by the presence of yellow–orange jowls with black hairs in the former and black jowls with predominantly reddish hairs in the latter.

Geographical distribution: Worldwide

Pathogenesis: In addition to acting as a secondary invader of myiasis, *C. vicina* has also been recorded laying eggs on living small mammals. Attempts to induce primary sheep strike by *C. vicina* have proved unsuccessful and it has been suggested that this species may be physiologically unable to infest sound sheep, either because the sheep body temperature is fatally high or because larvae are unable to feed on the animal tissues without the prior activity of *Lucilia* larvae.

Calliphora vomitoria

Common name: Bluebottle

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Family: Calliphoridae

Description: Bluebottles are stout and characterised by a metallic blue sheen on the body (see Fig. 17.9). The thoracic squamae have long dark hair on the upper surface. *Calliphora vicina* and *C. vomitoria* may be distinguished from each other by the presence of yellow–orange jowls with black hairs in the former and black jowls with predominantly reddish hairs in the latter.

Geographical distribution: Worldwide

Protophormia terraenovae

Synonym: *Phormia terraenovae*

Common name: Blackbottle

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Family: Calliphoridae

Description, adults: *Protophormia terraenovae* is a black-coloured blowfly with an overlying metallic blue–green sheen. This species is very similar to *Phormia regina* in appearance.

Description, larvae: The third-stage larvae of both *P. terraenovae* and *P. regina* are characterised by strongly developed, fairly pointed tubercles on the posterior face of the last segment. In third-stage larvae of *P. terraenovae* the tubercles on the upper margin of the last segment are longer than those of *P. regina*, being longer than half the width of a posterior spiracle, whereas in *P. regina* they are less than half the width of a posterior spiracle in length. The larvae of *P. terraenovae* also possess dorsal spines on the posterior margins of segment 10, which are absent in larvae of *P. regina*. In *P. terraenovae* the anterior thoracic spiracle is black or black–brown and is difficult to distinguish from the general body colour (see Fig. 3.42a).

Hosts: Mainly sheep, but may also be a serious pest of cattle and reindeer.

Geographical distribution: Northern Canada, USA, Europe, Scandinavia, Russia

Phormia regina

Common names: Blackbottle, black blowfly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Family: Calliphoridae

Description, adults: *Phormia regina* is a black-coloured blowfly with an overlying metallic blue–green sheen. This species is very similar to *Protophormia terraenovae* in appearance.

Description, larvae: See *P. terraenovae*. In *Phormia regina* the anterior spiracle is yellow or orange and stands out clearly against the dark background colour of the thorax (see Fig. 3.42b).

Hosts: Mainly sheep, but any other mammal and bird may be affected.

Geographical distribution: Northern Canada, USA, Europe, Scandinavia, Russia

A range of other, more opportunistic ectoparasites can also be found on sheep and goats and these are listed in the host–parasite checklists at the end of this chapter. More detailed descriptions of these parasites may be found in Chapter 17.

HOST–PARASITE CHECKLISTS

In the following checklists, the codes listed below apply.

Helminths

N, nematode; T, trematode; C, cestode; A, acanthocephalan.

Arthropods

F, fly; L, louse; S, flea; M, mite; Mx, maxillopod; Ti, tick.

Protozoa

Co, coccidia; Bs, blood sporozoa; Am, amoeba; Fl, flagellate; Ci, ciliate.

Miscellaneous ‘protozoal organisms’

B, blastocyst; Mi, microsporidian; My, *Mycoplasma*; P, Pneumocystidomycete; R, *Rickettsia*.

Parasites of horses

ENDOPARASITES

Parasites of the digestive system

MOUTH

Entamoeba equibuccalis

Predilection site: Mouth

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Hosts: Horse

Description: Trophozoites are 7–14 µm in diameter and have no cysts. The nucleus has a small central endosome and a ring of small peripheral granules.

Geographical distribution: Worldwide

Pathogenesis: Non-pathogenic

OESOPHAGUS

No parasites reported.

STOMACH

Members of the genus *Habronema*, and the closely related genus *Draschia*, are parasitic in the stomach of the horse. *Habronema* inhabits the mucus layer of the gastric mucosa and may cause a catarrhal gastritis but is not considered an important pathogen, while *Draschia* parasitises the fundic region of the stomach wall and provokes the formation of large fibrous nodules that are occasionally significant. The chief importance of these parasites is as a cause of cutaneous habronematidosis or 'summer sores' in warm countries.

Final hosts: All are parasites of the horse and other equines.

Intermediate hosts: Dipteran flies of the genera *Musca*, *Stomoxys* and *Haematobia* (*Lyperosia*)

Epidemiology: The seasonality of cutaneous lesions is related to the activity of the fly vectors.

Treatment: A number of modern broad-spectrum anthelmintics including oxfendazole, oxbendazole, albendazole and the macrocyclic lactones have been shown to have activity against the adult parasites in the stomach. Cutaneous lesions are best treated with ivermectin. The use of insect repellents has some benefit and radiation therapy and cryosurgery have been used in more chronic cases.

Control: Obviously any measures taken to prevent injuries and to control fly populations will be beneficial. Stacking manure and using insecticides during the day, for example, limit fly populations and attack. Skin wounds should be treated with either fly repellents or a combination of antiseptic and insecticide.

Draschia megastoma

Synonym: *Habronema megastoma*

Predilection site: Stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Slender white translucent worms 0.7–1.3 cm long; adult males are 7–10 mm and females 10–13 mm. The worms are recognised by their heads, which are slightly constricted from the main body (see Fig. 1.59).

Description, microscopic: The pharynx is funnel-shaped. The hind end of the male is usually spirally coiled with four pairs of pre-cloacal papillae. Spicules are uneven in length, with the left being about twice as long as the right. The eggs are thin-shelled and elongate and measure around 35 by 8 µm and hatch in the stomach.

Geographical distribution: Worldwide

Pathogenesis: In the stomach the worms live in colonies in the mucosa around which develop large nodular fibrous tumour-like lesions (Fig. 10.1). These occur in the fundus region and seem to be well tolerated unless they protrude into the lumen sufficiently to interfere mechanically with stomach function or, more rarely, cause abscessation or perforation when the lesions become secondarily infected with pyogenic bacteria. *Draschia megastoma* can cause a skin reaction, cutaneous habronematidosis or 'summer sores', when larvae are deposited on broken skin or open wounds by infected flies.

Clinical signs: The presence of adult worms in the stomach causes very little clinical disturbance. Cutaneous habronematidosis presents

Fig. 10.1 Large nodular tumour-like lesion in the stomach induced by *Draschia megastoma* infection.

as intense itching of the affected skin. Non-healing granulomatous lesions, raised above the surface of the skin, may be a feature (see *Habronema*).

Diagnosis: Usually only low numbers of eggs or larvae are present in the faeces. Eggs may be demonstrated in gastric lavage taken via a stomach tube. Sometimes larvae can be identified in the small granulomatous skin lesions.

Pathology: Adult worms burrow into the submucosa of the stomach producing large tumour-like nodules, filled with a creamy pus-like substance, causing the mucosa to protrude into the gastric lumen. The worms provoke a surrounding granulomatous reaction, which contains a central core of necrotic and cellular debris and large numbers of eosinophils. Burrowing larvae in the conjunctivae cause an ulcerative weeping lesion at the medial canthus, which becomes progressively more nodular as the lesion becomes more granulomatous. Mineralised granules, caseous debris and larvae may be found in the lesion. Larvae in the skin cause lesions that are rapidly progressive and proliferative in nature, comprising ulcerated masses of granulation tissue that haemorrhages readily. Lesions may be single or multiple and range in size from 5 to 15 cm. On section, the lesions are caseous and histologically there are aggregates of eosinophils scattered throughout the connective tissue, which contains a few macrophages and multinucleate giant cells surrounding degenerating larvae. The surface of the lesion is usually covered with a fibronecrotic exudate overlying a highly vascular granulation tissue infiltrated with neutrophils.

Habronema microstoma

Synonym: *Habronema majus*

Predilection site: Stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Slender white translucent worms 1.5–2.5 cm long; adult males are 16–22 mm and females 15–25 mm. The male has wide caudal alae and the tail has a spiral twist. The spicules are unequal in length, the left being about twice as long as the right.

Description, microscopic: The buccal cavity is cylindrical in shape and the pharynx contains a dorsal and ventral tooth in its anterior part. The male has four pairs of pre-cloacal papillae. Spicules are uneven in length, with the slender left one longer than the right. The very elongated, ellipsoidal, small eggs are thin-shelled, about 45–59 by 10–16 μm and larvated when shed in faeces. Both eggs and larvae can be found in faeces. Eggs resemble those of *Draschia* but are slightly larger.

Geographical distribution: Worldwide

Pathogenesis: The adult *Habronema* in the stomach may cause a mild catarrhal gastritis with excess mucus production. Nodules are not usually present. More important are the granulomatous lesions of cutaneous habronematidosis, commonly known as ‘summer sores’, and the persistent conjunctivitis with nodular thickening and ulceration of the eyelids associated with invasion of the eyes. Larvae have also been found associated with small lung abscesses.

Clinical signs: These are usually absent in gastric habronematidosis. Lesions of cutaneous habronematidosis are most common in areas of the body liable to injury and occur during the fly season in warm humid countries, although it also occurs in temperate regions. During the early stages, there is intense itching of the infected wound or abrasion, which may cause further self-inflicted damage. Subsequently a reddish-brown, non-healing, cauliflower-like granuloma develops that protrudes above the level of the surrounding skin and may be up to 8.0 cm in diameter (Fig. 10.2). These lesions are known as ‘summer sores’ in acute cases. Later the lesion may become more chronic, fibrous and inactive, but will not heal until the advent of cooler weather when fly activity ceases. Invasion of the eye produces a persistent conjunctivitis with nodular ulcers, especially at the medial canthus. Sometimes larvae invade the skin of the prepuce and glans penis of stallions.

Diagnosis: This is based on the finding of non-healing reddish cutaneous granulomas. The larvae, recognised by spiny knobs on their tails, may be found in material from these lesions. Gastric infection is not easily diagnosed since *Habronema* eggs and larvae are not readily demonstrable in the faeces by routine techniques.

Pathology: Adult worms in the mucosa of the stomach have been associated with a mild ulceration. Burrowing larvae in the conjunctivae cause an ulcerative weeping lesion at the medial canthus, which becomes progressively more nodular as the lesion becomes more granulomatous.

Fig. 10.2 Ulcerated granuloma (‘summer sore’) on commissure of lips of horse due to cutaneous habronematidosis.

Habronema muscae**Predilection site:** Stomach**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Spiruroidea

Description, gross: Slender white translucent worms, 1.0–2.5 cm long; adult males are 8–14 mm and females 13–22 mm. The male has wide caudal alae and the tail has a spiral twist. It is unlikely to be confused with other nematodes in the stomach since *Draschia* is associated with characteristic lesions and *Trichostrongylus axei* is less than 1.0 cm in length.

Description, microscopic: There are two lateral trilobed lips; the pharynx is cylindrical and has a thick cuticular lining. There are four pairs of pre-cloacal papillae and one or two papillae behind the cloaca. The cloacal region is covered with small cuticular ridges. Spicules are uneven in length, with the slender left one about five times longer than the right. The vulva is situated near the middle of the body and opens dorsolaterally. The elongated, oval, small eggs are thin-shelled, 40–50 by 10–12 μm , and larvated when shed in faeces. Eggs or larvae may be observed in the faeces.

Final host: Horse and other equines**Intermediate hosts:** Dipteran flies of the genera *Musca*, *Stomoxys* and *Haematobia* (*Lyperosia*)**Geographical distribution:** Worldwide***Trichostrongylus axei*****Synonym:** *Trichostrongylus extenuatus***Common name:** Stomach hairworm**Predilection site:** Stomach**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Trichostrongyloidea

Description, gross: The adults are small, hair-like, light brownish-red and difficult to see with the naked eye. Males measure around 3–6 mm and females 4–8 mm in length.

Description, microscopic: The male spicules are dissimilar and unequal in length, the right being shorter than the left (see Table 1.3a). The medium-sized egg is an irregular ellipse with one side wall slightly flattened and dissimilar poles of medium width. It is thin-shelled, smooth and measures around 70–108 by 30–48 μm and usually contains 16 or more blastomeres.

Hosts: Cattle, sheep, goat, deer, horse, donkey, pig and occasionally human**Geographical distribution:** Worldwide**Clinical signs:** *Trichostrongylus axei* is responsible for gastritis in horses.**Pathology:** In the horse, initial lesions are circumscribed areas of hyperaemia in the gastric mucosa, which progresses to catarrhal

or lymphocytic inflammation and erosion of the epithelium. This may be associated with necrosis. Over time, infection can lead to a chronic proliferative inflammation and shallow depressed ulcers may be present.

Treatment and control: This is as described under treatment and control of strongylosis in the horse.***Gasterophilus***

Species of *Gasterophilus*, known as bots, are obligate parasites of horses, donkeys, mules, zebras, elephants and rhinoceroses. Nine species are recognised in total, six of which are of interest as veterinary parasites of equids.

Description, adults: Bot flies are robust dark flies, 10–15 mm in length (Fig. 10.3). The body is densely covered with yellowish hairs. In the female the ovipositor is strong and protruberant. The wings of adult *Gasterophilus* characteristically have no cross-vein dm-cu (see Fig. 3.46).

Description, larvae: When mature and present in the stomach or passed in faeces, the larvae are cylindrical, 16–20 mm long, and reddish-orange with posterior spiracles (see Fig. 3.47). Differentiation of mature larvae of the various species can be made on the numbers and distribution of the spines present on various segments (see Fig. 3.48).

Geographical distribution: All species of *Gasterophilus* were originally restricted to the Palaearctic and Afro-tropical regions, but three species, *Gasterophilus nasalis*, *G. haemorrhoidalis* and *G. intestinalis*, have been inadvertently introduced into the New World.

Pathogenesis: The presence of larvae in the buccal cavity may lead to stomatitis with ulceration of the tongue. On attachment by their oral hooks to the stomach lining, larvae provoke an inflammatory

**Fig. 10.3** *Gasterophilus* spp.

Fig. 10.4 *Gasterophilus* larvae in the stomach of a horse.

reaction with the formation of funnel-shaped ulcers surrounded by a rim of hyperplastic epithelium (Fig. 10.4). These are commonly seen at postmortem examination of horses in areas of high fly prevalence and although dramatic in appearance their true pathogenic significance remains obscure.

Clinical signs: Burrowing of the first-stage larvae in the mouth lining, tongue and gums can produce pus pockets, loosen teeth and cause loss of appetite in the host. Larvae attached to the gastrointestinal mucosa cause inflammation and ulceration. The adult fly can cause irritation and intense avoidance reactions when hovering around the host and laying eggs on the skin. Ovipositing females may be tenacious, laying eggs on mobile as well as stationary animals. Females will pursue galloping horses and immediately resume oviposition when the horse stops.

Diagnosis: The adult flies may be visible and recognisable on and around the host. The eggs are also easily recognisable on the host and may be identified by colour and location. Damage to the mouth and tongue may be detected. The presence of larval parasites in the stomach is difficult to identify except by observation of the larvae in faeces.

Pathology: The burrowing of first- and second-stage *Gasterophilus* larvae in the tissues of the tongue and mouth may result in lesions, the appearance of which is dependent on the degree of burrowing activity. Active tunnelling removes virtually all tissue in the path of the larvae including nerves and capillaries leading to haemorrhage and exocytosis into the tunnels, which fill with erythrocytes mixed with macrophages, lymphocytes and some eosinophils. The tunnels may become infected with bacteria, which result in microabscesses, composed of clotted erythrocytes, bacteria, disintegrating epithelial cells and large numbers of neutrophils. Cells surrounding the tunnel exhibit pyknosis and epithelial hydropic degeneration and became separated from each other.

Interdental gingiva invaded by larvae appear hyperaemic and denuded of epithelia. Recession and ulceration of the gingiva produces periodontal pockets. Extensive invasion by larvae leads to compound periodontal pockets.

The attachment of third-stage larvae results in ulceration at the site of attachment with intense fibrosis below the ulcer. The cephalic portions of embedded larvae become surrounded by a cellular exudate containing erythrocytes and mononuclear cells.

Epidemiology: Adult flies are most active during late summer.

Treatment: The most widely used specific drugs included trichlorphon and dichlorvos, but these have generally been replaced by broad-spectrum macrocyclic lactone compounds such as ivermectin and moxidectin.

Control: The most effective means of control of this parasite is to remove the eggs from the host's coat. This requires, where possible, daily examination of the animal, paying particular attention to the area around the lips. If eggs are found during the summer and autumn, subsequent infection can be prevented by vigorously sponging with warm water containing an insecticide. The warmth stimulates hatching and the insecticide kills the newly hatched larvae.

From the life cycle it is clear that in temperate areas during the winter almost the entire *Gasterophilus* population will be present as larvae in the stomach, since adult fly activity ceases with the advent of the first frosts in autumn. A single treatment during the winter should therefore effectively break the cycle. In certain areas, where adult fly activity is prolonged by mild conditions, additional treatments may be required. Despite the lack of understanding of the pathogenic effect of bots, treatment is usually recommended as owners are concerned when larvae appear in the faeces. Treatment, however, does reduce fly populations and thus the fly worry associated with egg-laying.

Gasterophilus haemorrhoidalis

Common name: Bot flies

Predilection site: Stomach

Class: Insecta

Family: Oestridae

Description: In *G. haemorrhoidalis*, the spines on the ventral surface of the larval segments are arranged in two rows. The head segment has only lateral groups of denticles and the dorsal row of spines on the eighth segment is not broadly interrupted medially. The mouth hooks are uniformly curved dorsally and directed laterally, and the body spines are sharply pointed (see Fig. 3.48d).

Hosts: Horse, donkey

Geographical distribution: Worldwide

Gasterophilus inermis

Common name: Bot flies

Predilection site: Stomach

Class: Insecta

Family: Oestridae

Description: In *G. inermis* the spines on the ventral surface of the larval segments are arranged in two rows. The head segment has only lateral groups of denticles and the dorsal row of spines on the eighth segment are not broadly interrupted medially. The mouth hooks are strongly curved, with their tips directed backwards and approaching the base; body spines are sharply pointed (see Fig. 3.48b). Body segment 3 has three complete rows of spines,

and body segment 11 has one row of spines interrupted by a broad median gap.

Hosts: Horse, donkey, zebra

Geographical distribution: Northern Europe, northern Asia, Africa

Gasterophilus intestinalis

Common name: Bot flies

Predilection site: Stomach

Class: Insecta

Family: Oestridae

Description: In *G. intestinalis*, the mouth hooks are not uniformly curved dorsally and the body spines have blunt tips (see Fig. 3.48a).

Hosts: Horse, donkey.

Geographical distribution: Worldwide

Gasterophilus nasalis

Common name: Throat bot flies

Predilection site: Stomach

Class: Insecta

Family: Oestridae

Description: *Gasterophilus nasalis* has spines on the ventral surface of the larval segments arranged in a single row. The first three body segments are more or less conical and the third segment has a dorsal row of spines and sometimes ventral spines (see Fig. 3.48c).

Hosts: Horse, donkey and zebra

Geographical distribution: Worldwide, particularly the Holarctic

Gasterophilus nigricornis

Common names: Bot flies, broad-bellied horse bot

Predilection site: Duodenum

Class: Insecta

Family: Oestridae

Description: In *G. nigricornis*, spines on the ventral surface of the larval segments are arranged in a single row. The first three body segments are more or less cylindrical, showing sharp constrictions posteriorly, and the third segment is without spines dorsally or ventrally.

Hosts: Horse, donkey

Geographical distribution: Middle East, southern Russia and China

Gasterophilus pecorum

Common names: Bot flies, dark-winged horse bot

Predilection site: Mouth, tongue, oesophagus, stomach

Class: Insecta

Family: Oestridae

Description: *Gasterophilus pecorum* has spines on the ventral surface of the larval segments that are arranged in two rows. The head segment has two lateral groups of denticles and one central group, the latter situated between the antennal lobes and mouth hooks. The dorsal rows of spines are broadly interrupted medially on segments 7 and 8. Segments 10 and 11 have no spines.

Hosts: Horse, donkey

Geographical distribution: Europe, Africa, Asia

Pathogenesis: *Gasterophilus pecorum* is the most pathogenic species in the genus. Large numbers of attached larvae can cause inflammation, hinder swallowing and may eventually lead to death resulting from constriction of the oesophagus.

Clinical signs: Burrowing of the first-stage larvae in the mouth lining, tongue and gums can produce pus pockets, loosen teeth and cause loss of appetite in the host. Large numbers of attached larvae can cause inflammation and choking and hinder swallowing.

Diagnosis: Larvae present in the pharynx can usually be seen on direct inspection. Larvae further down the digestive tract can only be detected by observation of the mature detached larvae in faeces.

SMALL INTESTINE

Strongyloides westeri

Common name: Threadworm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Rhabditoidea

Description, gross: Slender hair-like worms, 6–9 mm long. Only females are parasitic.

Description, microscopic: The long oesophagus may occupy up to one-third of the body length and the uterus is intertwined with the intestine giving the appearance of twisted thread. Unlike other intestinal parasites of similar size, the tail has a blunt point. *Strongyloides* eggs are oval, thin-shelled, smooth and small (40–52 × 32–40 μm), being half the size of typical strongyle eggs (see Fig. 4.4). The side walls are symmetrical and the poles are wide and the egg contains a short thick larva. The hatched L₁ is passed out in the faeces.

Hosts: Horse, donkey, zebra, rarely pig

Geographical distribution: Worldwide

Pathogenesis: Mature parasites are found in the duodenum and proximal jejunum and if present in large numbers may cause inflammation with oedema and erosion of the epithelium. This results in catarrhal enteritis with impairment of digestion and absorption. Migration of larvae through the lungs can cause severe haemorrhage and respiratory distress. Skin penetration may result in irritation and dermatitis.

Clinical signs: Foals with heavy burdens show acute diarrhoea, weakness and emaciation. Older animals may harbour large burdens without showing clinical signs.

Diagnosis: The clinical signs in very young animals, usually within the first few weeks of life, together with the finding of large numbers of the characteristic eggs or larvae in the faeces are suggestive of strongyloidosis. It should be emphasised, however, that high faecal egg counts may be found in apparently healthy animals. The mare of an infected foal will often not pass any eggs in faeces even though she is the source of infection through her milk.

Pathology: Adult worms establish in tunnels in the epithelium at the base of the villi in the small intestine. In large numbers they may cause villous atrophy, with a mixed mononuclear inflammatory cell infiltration of the lamina propria. Crypt epithelium is hyperplastic and there is villous clubbing.

Epidemiology: Infections are very common especially in warm and humid environments. *Strongyloides* infective larvae are not ensheathed and are susceptible to extreme climatic conditions. However, warmth and moisture favour development and allow the accumulation of large numbers of infective stages. A second major source of infection for the very young animal is the reservoir of larvae in the tissues of their dams and this may lead to clinical strongyloidosis in foals in the first few weeks of life. Successive progeny from the same dam often show heavy infections.

Treatment: Specific control measures for infection are rarely necessary. Not all anthelmintics show high efficacy, but most of the modern benzimidazoles are effective. Macrocytic lactones are effective against adult worms.

Control: Reduction in numbers of free-living larvae by removal of faeces and provision of dry bedding and areas may limit numbers and transmission. On stud farms, foals are often given an anthelmintic treatment against *S. westeri* at 1–2 weeks of age.

Parascaris equorum

Synonyms: *Ascaris equorum*, *Ascaris megacephala*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: This very large, rigid, stout, whitish nematode cannot be confused with any other intestinal parasite of equines. Males measure 15–25 cm and females up to 40–50 cm in length.

Description, microscopic: The adult parasites have a simple mouth opening surrounded by three large lips, and in the male the tail has small caudal alae. The dorsal lip has two double papillae and each ventrolateral lip has one double subventral and a small lateral papilla. Spicules are long and stout. The medium-sized egg of *P. equorum* is almost spherical (85–100 × 80–90 µm), brownish and thick-shelled with an outer pitted albuminous coat.

Hosts: Horse, donkey, zebra

Geographical distribution: Worldwide

Pathogenesis: During the migratory phase of experimental infections, up to 4 weeks following infection, the major signs are frequent coughing accompanied in some cases by a greyish nasal discharge, although the foals remain bright and alert. Light intestinal infections are well tolerated, but moderate to heavy infections will cause unthriftiness in young animals with poor growth rates, dull coats and lassitude. A wide variety of other clinical signs, including fever, nervous disturbances and colic, has been attributed to field cases of parascariasis, but these have not been observed in experimental studies.

Clinical signs: Adult worms in heavy infections can cause severe enteritis resulting in alternating constipation and foul-smelling diarrhoea. Large numbers of larvae may cause coughing, with fever and anorexia. The hair coat may be dull and the animal appears malnourished.

Diagnosis: This depends on clinical signs and the presence of spherical, thick, brownish, rough-shelled eggs on faecal examination. Occasionally, atypical thick-walled eggs are seen that lack the dark outer shell. If disease due to prepatent infection is suspected, faecal examination having proved negative, diagnosis may be confirmed by administration of an anthelmintic when large numbers of immature worms may be observed in the faeces.

Pathology: Gross changes are provoked in the liver and lungs by migrating *P. equorum* larvae. In the liver, larvae cause focal haemorrhages and eosinophilic tracts that resolve, leaving whitish areas of fibrosis. Larval migration in the lungs also leads to haemorrhage and infiltration by eosinophils, which are later replaced by accumulations of lymphocytes, while subpleural greyish-green lymphocytic nodules develop around dead or dying larvae; these nodules are more numerous following reinfection. These liver and lung lesions are usually of little pathological significance.

Although the presence of worms in the small intestine (Fig. 10.5) is not associated with any specific lesions, heavy infections have occasionally been reported as a cause of impaction and perforation

Fig. 10.5 *Parascaris equorum* from the intestine of an infected horse.

leading to peritonitis. Adult worms may cause catarrhal enteritis and intermittent diarrhoea. However, under experimental conditions, unthriftiness is a major sign and despite maintaining a good appetite infected foals lose weight and may become emaciated. Competition between a large mass of parasites and the host for nutrients may be the underlying cause of this weight loss.

Epidemiology: Infection with *P. equorum* is common throughout the world and is a major cause of unthriftiness in young foals. There are two important factors in the epidemiology of infection. First is the high fecundity of the adult female parasite, some infected foals passing millions of eggs in the faeces each day. Secondly, the extreme resistance of the egg in the environment ensures its persistence for several years. The sticky nature of the outer shell may also facilitate passive spread of eggs, adhering to the udder and teats of the pregnant mare.

In the northern hemisphere, summer temperatures are such that many eggs become infective at a time when a population of susceptible foals is present. The infections acquired by these result in further contamination of pasture with eggs, which may survive during several subsequent grazing seasons. Although mature horses may harbour a few adult worms and act as carriers, heavy burdens are usually confined to yearlings and to foals, which become infected from the first month or so of life; infection is maintained largely by seasonal transmission between these groups of young animals. Exposed foals often develop immunity, resulting in partial or total loss of the worm population.

Treatment: Benzimidazoles (e.g. fenbendazole, oxfendazole, oxi-bendazole), pyrantel, ivermectin and moxidectin have all been shown to be effective against adult and larval stages when given orally. However, there are recent reports of suspected resistance of *P. equorum* to moxidectin and ivermectin, some worms remaining after treatment.

Control: Since transmission is largely on a foal-to-foal basis, it is good policy to avoid using the same paddocks for nursing mares and their foals in successive years. Treatment should start when foals are about 8 weeks old and be repeated at appropriate intervals depending on the anthelmintic used. As the eggs are highly resistant to desiccation and most chemical disinfectants, regular removal of manure and bedding from stables and steam cleaning is recommended.

Notes: Infection with *P. equorum* is common throughout the world and is a major cause of unthriftiness in young foals.

Tapeworms

Several tapeworm species are found in horses, donkeys and other equines. Intermediate hosts for all species are forage mites of the family Oribatidae, in which the intermediate cysticeroid stages are found.

Diagnosis: Where clinical signs occur they may be difficult to differentiate from more common causes of unthriftiness and digestive upsets. However, it may be possible to confirm the presence of *Anoplocephala* by demonstration of the typical eggs on faecal examination or on postmortem. An enzyme-linked immunosorbent assay (ELISA) can be used to detect IgG to these parasites. A saliva antibody test has recently also become available.

Epidemiology: Horses of all ages may be affected, but clinical cases have been reported mainly in animals up to 3–4 years of age.

Treatment: Specific treatment for *Anoplocephala* infection is rarely called for but a number of compounds have been reported as effective, including pyrantel at increased dosage rates (38 mg/kg). Praziquantel at 1 mg/kg is also effective.

Control: Control is difficult, since forage mites are widespread on pasture. Treatment with an effective anthelmintic before the animals enter new grazing may help to control *Anoplocephala* infections in areas where problems have arisen.

Anoplocephala perfoliata

Predilection site: Terminal ileum, caecum

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, gross: *Anoplocephala perfoliata* can measure up to 4–8 cm in length by 1.2 cm wide.

Description, microscopic: There is a small rounded scolex, 2–3 mm in diameter, with a lappet behind each of the four suckers, but there is neither a rostellum nor hooks. It has a very short neck and the strobila widens rapidly, individual proglottids being much wider than they are long. Eggs are irregularly spherical or triangular, 65–80 µm in diameter, and contain a hexacanth embryo. They have a thin smooth multilayered shell. The oncosphere is supported by a pair of chitinous projections, the pyriform apparatus. Gravid proglottids release the eggs as they disintegrate. Oncospheres can survive for 6–9 months in the environment unless they are frozen.

Geographical distribution: Worldwide

Pathogenesis: *Anoplocephala perfoliata* has been considered to be relatively non-pathogenic but there is increasing evidence that heavy infections may cause severe clinical signs and may even prove fatal. *Anoplocephala perfoliata* is usually found around the ileocaecal junction (Fig. 10.6) and causes ulceration of the mucosa at its

Fig. 10.6 *Anoplocephala perfoliata* tapeworms around the ileocaecal junction.

site of attachment and inflammation and thickening of the intestinal wall; these lesions have been incriminated as a cause of intussusception of the ileum into the caecum. Cases of intestinal obstruction and perforation of the intestinal wall have been recorded associated with massive infections.

Clinical signs: In most infections there are no clinical signs. However, when there are significant pathological changes in the intestine there may be unthriftiness, enteritis and colic. Perforation of the intestine will prove rapidly fatal.

Pathology: The mucosa at the site of attachment may be inflamed, thickened and ulcerated, particularly in the area of the ileocaecal junction where it may lead to partial or fatal occlusion of the ileocaecal orifice.

Anoplocephala magna

Common name: Dwarf equine tapeworm

Predilection site: Small intestine, rarely stomach

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, gross: *Anoplocephala magna* is similar morphologically to *A. perfoliata* but much longer, measuring up to 80.0 cm.

Description, microscopic: The scolex is large, 4–6 mm wide, with suckers opening anteriorly, and there are no lappets on the scolex. The neck is short, as are the segments, being much wider than they are long. The genital organs are single and the pores are unilateral. Eggs are similar to those of *A. perfoliata* but slightly smaller and rounder, measuring 50–60 µm.

Geographical distribution: Worldwide

Pathogenesis: Heavy infections of *A. magna* may cause catarrhal, haemorrhagic or ulcerative enteritis. Cases of intestinal obstruction, colic and perforation of the intestinal wall have been recorded associated with massive infections.

Clinical signs: Rare, but infection causes diarrhoea and colic.

Pathology: The mucosa at the site of attachment may be inflamed, thickened and ulcerated.

Paranoplocephala mamillana

Synonym: *Anoplocephaloides mamillana*

Predilection site: Small intestine, rarely stomach

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, gross: *Paranoplocephala mamillana* is only around 10–50 by 4–6 mm in size.

Description, microscopic: There are no lappets on the narrow scolex and the suckers are slit-like. The scolex is large and without rostellum and hooks. The gravid segments are wider than they are

long. Eggs are irregularly spherical or triangular and measure 51 by 37 µm in diameter.

Geographical distribution: Worldwide

Pathogenesis: *Paranoplocephala* is usually considered to be relatively non-pathogenic.

Clinical signs: In most infections there are no clinical signs.

Diagnosis: It may be possible to confirm the presence of *Paranoplocephala* by the demonstration of the typical eggs on faecal examination or on postmortem.

Pathology: Infection is rarely associated with lesions but occasionally the site of attachment is inflamed and slightly ulcerated.

Epidemiology: Horses of all ages may be affected.

Coccidiosis

Several species of coccidia have been reported from horses. Few details are available on the life cycles, pathogenesis and epidemiology. Similarly, little is also known about treatment and control of equine coccidiosis but, by analogy with other hosts, sulphonamides can be tried. Prevention is based on good management and hygiene. Young animals should be kept off heavily contaminated pastures when they are most susceptible. Good feeding of dams prior to parturition and rearing of animals of similar ages limits the build-up and spread of oocysts.

Eimeria leuckarti

Synonym: *Globidium leuckarti*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Hosts: Horse, donkey

Description: Oocysts are ovoid or pyriform, flattened at the small end and very large, measuring 70–90 by 49–69 µm (mean 80 × 60 µm), with a thick dark shell and distinct micropyle. Sporocysts are elongate, 30–43 by 12–15 µm, with a Stieda body and residuum. The sporozoites are up to 35 µm long, lie lengthwise head to tail in the sporocysts and have a clear globule at the broad end.

Life cycle: Complete details of the life cycle are not known and merogony stages have not been described. Early gamonts are found in the cells of the lamina propria of the small intestine. The prepatent period is 15–33 days and sporulation time is 15–41 days.

Geographical distribution: Worldwide

Pathogenesis: Occurs in the small intestine of horses and donkeys and has been incriminated as the cause of intermittent diarrhoea.

Diagnosis: Diagnosis is difficult. Because of the heavy nature of the oocysts, sedimentation techniques should be employed or, if flotation is used, a concentrated sugar solution is necessary.

Fig. 10.7 'Giant' meront of *Eimeria leuckarti*.

Pathology: The pathology includes marked inflammatory changes in the mucosa and disruption of villous architecture due to the presence of large meront stages (Fig. 10.7).

Eimeria solipedum

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Hosts: Horse, donkey

Description: Oocysts are spherical, orange to yellowish-brown, 15–28 μm in diameter, without an oocyst residuum or micropyle. Sporocysts are ellipsoid to oval, 5 by 3 μm .

Geographical distribution: Russia, Commonwealth of Independent States (CIS)

Pathogenesis: Has been reported to cause intermittent diarrhoea.

Diagnosis: Identification of oocysts from faecal samples.

Epidemiology: Almost 10% of horses in the former Soviet Union (now Russia and CIS) have been found to be infected.

Eimeria uniungulata

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Hosts: Horse, donkey

Description: Oocysts are oval or ellipsoid, light orange, 15–24 by 12–17 μm , without an oocyst residuum or micropyle. Sporocysts are oval, 6–10.5 by 4–6 μm , with a central sporocyst residuum.

Geographical distribution: Russia, CIS

Pathogenesis: Not reported

Epidemiology: Infection has been reported in 1–10% of horses in the former Soviet Union (now Russia and CIS).

Other protozoa

Cryptosporidium parvum

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Hosts: Cattle, sheep, goat, horse, deer, human

Description: Mature oocysts are ovoidal or spheroidal, 5.0 by 4.5 μm (range 4.6–5.4 \times 3.8–4.7 μm), with a length/width ratio of 1.19.

Geographical distribution: Worldwide

Pathogenesis: Cryptosporidiosis has been reported in immunodeficient foals as a cause of diarrhoea.

Clinical signs: Clinically the disease is characterised by anorexia and diarrhoea.

Epidemiology: Several mammals act as hosts to *C. parvum* but little is known of the importance of their involvement in transmitting infection to, or maintaining infection in, domestic livestock. In the UK, surveys in horses have shown the presence of *C. parvum* in 28% of thoroughbred foals, although there was no association between infection and diarrhoea. Subsequent studies have demonstrated the genotype in horses to be genotype 2.

Treatment: There is no known effective drug therapy. Where cryptosporidiosis is diagnosed, supportive treatment, in the form of anti-diarrhoeals and fluids, is usually sufficient.

For more details see Chapter 8.

Giardia intestinalis

Synonyms: *Giardia duodenalis*, *Giardia lamblia*, *Lamblia lamblia*

Predilection site: Small intestine

Phylum: Fornicata

Class: Trepomonadea

Family: Giardiidae

Description: The trophozoite has a pyriform to ellipsoidal, bilaterally symmetrical body, 12–15 μm long by 5–9 μm wide. The dorsal side is convex and there is a large sucking disc on the ventral side. There are two anterior nuclei, two slender axostyles, eight flagellae in four pairs and a pair of darkly staining median bodies. The median bodies are curved bars resembling the claws of a hammer. Cysts are ovoid, 8–12 by 7–10 μm , and contain four nuclei.

Hosts: Human, cattle, sheep, goat, pig, horse, alpaca, dog, cat, guinea pig, chinchilla

Geographical distribution: Worldwide

Pathogenesis: Infection in horses is considered non-pathogenic.

Clinical signs: No associated clinical signs

Treatment and control: Not required

Notes: There is still controversy over the classification of *Giardia* spp. The current molecular classification places isolates into eight distinct assemblages. Some authors give separate specific names to organisms isolated from different hosts, although species specificity of many isolates is unknown. Phylogenetic data suggest that *G. intestinalis* is a species complex composed of several species that are host-specific.

For more details see Chapter 8.

LARGE INTESTINE

Large strongyles

Members of the genus *Strongylus* live in the large intestine of horses and donkeys and, with *Triodontophorus*, are commonly known as the large strongyles. Since members of these genera form only one component of the total parasitic burden of the large intestine of the horse, general aspects on their epidemiology, treatment and control are described under the general introduction to small strongyles.

Diagnosis of these migratory species is difficult during the migratory prepatent phase and is based on grazing history and clinical signs. Because of the long prepatent period, clinically apparent strongylosis may be associated with no, or low, faecal egg counts. Species or generic diagnosis is not usually required but may be undertaken by specialist laboratories based on morphology of larvae or adult worms.

Strongylus edentatus

Synonym: *Alfortia edentatus*

Common name: Large strongyles

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Strongylinae

Description, gross: Robust dark-red worms that are easily seen against the intestinal mucosa (Fig. 10.8). The well-developed buccal capsule of the adult parasite is prominent, as is the bursa of the male. Male are 2.3–2.8 cm and females 3.3–4.4 cm. The head end is wider than the rest of the body.

Description, microscopic: Species differentiation is based on size and the presence and shape of the teeth in the base of the buccal capsule. The buccal capsule is wider anteriorly than at the middle and contains no teeth (see Fig. 1.38a). The medium-sized eggs have almost similar poles and barrel-shaped side walls. They have a smooth thin shell, measure 78–88 by 48–52 µm and contain a morula with several large blastomeres.

Fig. 10.8 *Strongylus edentatus* feeding on the mucosa of the large intestine.

Hosts: Horse, donkey

Geographical distribution: Worldwide

Pathogenesis: In *S. edentatus* infection, there are gross changes in the liver associated with early larval migration, but these rarely result in clinical signs. Similarly, the haemorrhages and fluid-filled nodules which accompany later larval development in subperitoneal tissues rarely result in clinical signs.

For details of the pathogenesis of infection with adult worms see *S. vulgaris*.

Clinical signs: Diarrhoea, fever, oedema, anorexia, depression and weight loss

Pathology: Haemorrhagic tracts may be produced in the hepatic parenchyma from migrating larvae and parenchymal scars of fibrous tissue on the hepatic capsule are often found on postmortem. Migrating larvae may also elicit subperitoneal haematomas, haemorrhage, peritonitis and omental adhesions. In the gut wall they may form nodules and haemorrhagic foci.

Strongylus equinus

Common name: Large strongyles

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Strongylinae

Description, gross: Robust dark-red worms that are easily seen against the intestinal mucosa. The well-developed buccal capsule of the adult parasite is prominent as is the bursa of the male. Male are 2.6–3.5 cm and females 3.8–4.7 cm. The head end is not marked off from the rest of the body.

Description, microscopic: Species differentiation is based on size and the presence and shape of the teeth in the base of the buccal capsule. The buccal capsule is oval in outline and there are external

and internal leaf crowns. At the base of the buccal capsule is a large dorsal tooth with a bifid tip and two smaller subventral teeth (see Fig. 1.38b). The dorsal oesophageal gland opens into the buccal capsule through a number of pores situated in a thickened ridge, the dorsal gutter, formed by the wall of the buccal capsule. The male has two simple slender spicules. In the female, the vulva lies 12–14 mm from the posterior extremity. The eggs are similar to those of *S. edentatus* and measure 75–92 by 41–54 μm .

Hosts: Horse, donkey

Geographical distribution: Worldwide

Pathogenesis: Despite the invasive behaviour of the parasitic larval stages, little specific pathogenic effect can be attributed to them. There has been little work on the pathogenesis of migrating larvae of *S. equinus*. For details of the pathogenesis of infection with adult worms see *S. vulgaris*.

Clinical signs: Diarrhoea, fever, oedema, anorexia, depression and weight loss

Pathology: Haemorrhagic tracts may be produced in the hepatic parenchyma from migrating larvae and parenchymal scars of fibrous tissue on the hepatic capsule are often found on postmortem. Omental adhesions may also be a sequela to larval migration. In the gut wall they may form nodules and haemorrhagic foci.

Epidemiology: *Strongylus equinus* is relatively less prevalent and abundant than other members of the genus.

Strongylus vulgaris

Synonym: *Delafondia vulgaris*

Common name: Large strongyles

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Strongylinae

Description, gross: Robust dark-red worms that are easily seen against the intestinal mucosa. The well-developed buccal capsule of the adult parasite is prominent as is the bursa of the male. Male are 14–16 mm and females 20–24 mm. The head end is not marked off from the rest of the body.

Description, microscopic: Species differentiation is based on size and the presence and shape of the teeth in the base of the buccal capsule. The buccal capsule is oval in outline and contains two ear-shaped teeth at its base (see Fig. 1.38c). The elements of the leaf crowns are fringed at their distal extremities. The dorsal oesophageal gland opens into the buccal capsule through a number of pores situated in a thickened ridge, the dorsal gutter, formed by the wall of the buccal capsule. The thin-shelled eggs are similar to those of *S. edentatus* and measure 83–93 by 48–52 μm .

Hosts: Horse, donkey

Geographical distribution: Worldwide

Pathogenesis: *Strongylus vulgaris* is now much less common than it was 20–30 years ago in many countries, but is still the most significant and pathogenic nematode parasitic in horses. Larval forms cause endoarteritis in the mesenteric circulation, resulting in colic and thromboembolic infarction of the large bowel, while the adults cause anaemia and ill-thrift. Much of the information concerning *S. vulgaris* has been derived from experimental infection of foals. A few weeks after infection with several hundred L₃, a clinical syndrome of fever, inappetence and dullness occurs, sometimes accompanied by colic. At necropsy, these signs are associated with arteritis and thrombosis of intestinal blood vessels, with subsequent infarction and necrosis of areas of bowel. However, a syndrome of this severity is not commonly reported in foals under natural conditions, probably because larval intake is continuous during grazing; it has been shown experimentally that foals may tolerate large numbers of larvae administered in small doses over a long period. Maximum adult burdens are usually 100–200 worms.

The pathogenesis of infection with adult worms is associated with damage to the large intestinal mucosa due to the feeding habits of the worms and, to some extent, to the disruption caused by emergence of young adults into the intestine following completion of their parasitic larval development. These worms have large buccal capsules and feed by ingestion of plugs of mucosa as they move over the surface of the intestine. Although the worms appear to feed entirely on mucosal material, the incidental damage to blood vessels can cause considerable haemorrhage. Ulcers, which result from these bites, eventually heal, leaving small circular scars. The effects of infection with the adult worms have not been quantified, but the gross damage and subsequent loss of blood and tissue fluids is certainly partly responsible for the unthriftiness and anaemia associated with intestinal helminthiasis in the horse. As *S. vulgaris* is approximately half the size of *S. edentatus* and *S. equinus*, the blood-feeding losses may not be as severe.

Clinical signs: Anaemia, poor condition and performance, varying degrees of colic, temporary lameness, intestinal stasis, rarely intestinal rupture and death

Diagnosis: Colic due to verminous arteritis may be associated with a palpable, painful enlargement at the root of the mesentery.

Pathology: Lesions due to migrating larvae are most common in the cranial mesenteric artery and its main branches (Fig. 10.9), and

Fig. 10.9 *Strongylus vulgaris* larvae in the cranial mesenteric artery.

Fig. 10.10 Arteritis and thrombosis of cranial mesenteric artery caused by *Strongylus vulgaris* infection.

consist of thrombus formation provoked by larval damage to the endothelium, together with marked inflammation and thickening of the arterial wall (Fig. 10.10). True aneurysms with dilatation and thinning of the arterial wall, although uncommon, may be found, especially in animals which have experienced repeated infection. The arterial lesions heal quite markedly following treatment with anthelmintics, such as the macrocyclic lactones.

Triodontophorus

Members of the genus *Triodontophorus* are non-migratory large strongyles frequently found in large numbers in the colon and which contribute to the deleterious effects of mixed strongyle infection.

Pathogenesis: Like the other horse strongyles, the pathogenic effect of these worms is damage to the large intestinal mucosa from the feeding habits of the adult parasites. The base of the buccal cavity contains small teeth (see Fig. 1.39).

Clinical signs: Loss of condition, anaemia, weakness, diarrhoea

Pathology: Feeding worms lead to the formation of ulcers in the right dorsal colon. The ulcers may be deep and haemorrhagic and bunches of worms may be attached to them (Fig. 10.11).

Triodontophorus brevicauda

Common name: Non-migratory large strongyles

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Fig. 10.11 *Triodontophorus tenuicollis* adults feeding around the periphery of an ulcer in the ventral colon.

Family: Strongylidae

Subfamily: Strongylinae

Description, gross: Medium-sized worms, varying in size from around 9 to 25 mm.

Description, microscopic: The buccal capsule is subglobular and thick-walled with three large oesophageal teeth composed of two plates which are smooth except for three elevations on each and protrude into the buccal capsule. The anterior rim of the buccal capsule is thickened anteriorly and surrounded by six plate-like structures. The sub-median papillae are short, broad and conical. The external leaf crown consists of numerous slender elements protruding from the buccal collar, with an equal number of inner leaf crown elements. In the female, the vulva is close to the anus and the tail is very short. The large smooth egg is ovoid with almost similar poles and barrel-shaped side walls and contains a morula with very dark blastomeres. It measures 130–140 by 55–65 μm .

Hosts: Horse, donkey

Geographical distribution: Worldwide

Triodontophorus minor

Common name: Non-migratory large strongyles

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Strongylinae

Description, gross: Medium-sized worms, varying in length from around 9 to 15 mm.

Description, microscopic: The buccal capsule is subglobular and thick-walled with three large oesophageal teeth composed of two plates which are strongly denticulated and protrude into the buccal capsule. The anterior rim of the buccal capsule is thickened

anteriorly and surrounded by six plate-like structures. The cuticle is strongly serrated in the cervical region. The external leaf crown consists of 44–50 slender elements protruding from the buccal collar, with an equal number of inner leaf crown elements. In the female, the vulva is close to the anus and the tail is short. The eggs are similar to those of *T. brevicauda*.

Hosts: Horse, donkey

Geographical distribution: Worldwide

Triodontophorus nipponicus

Common name: Non-migratory large strongyles

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Strongylinae

Description, gross: Medium-sized worms, varying in size from about 9 to 15 mm.

Description, microscopic: The buccal capsule is subglobular and thick-walled with three large oesophageal teeth composed of two plates which are strongly denticulated, with three large denticulations, and protrude into the buccal capsule. The anterior rim of the buccal capsule is thickened anteriorly and surrounded by six plate-like structures. The cuticle is strongly serrated in the cervical region. The external leaf crown consists of 56–69 slender elements protruding from the buccal collar, with an equal number of inner leaf crown elements. In the female, the vulva is close to the anus and the tail is short. The eggs are similar to those of *T. brevicauda*.

Hosts: Horse, donkey

Geographical distribution: Worldwide

Triodontophorus serratus

Common name: Non-migratory large strongyles

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Strongylinae

Description, microscopic: The buccal capsule is subglobular and thick-walled with three large oesophageal teeth composed of two plates that protrude into the buccal capsule. The anterior rim of the buccal capsule is thickened anteriorly and surrounded by six plate-like structures. The mouth collar appears as an inflated round tube around the mouth. The external leaf crown consists of numerous slender elements protruding from the buccal collar, with an equal

number of inner leaf crown elements. In the female, the vulva is close to the anus and the tail is long. The eggs are similar to those of *T. brevicauda*.

Hosts: Horse, donkey

Geographical distribution: Worldwide

Triodontophorus tenuicollis

Common name: Non-migratory large strongyles

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Strongylinae

Description, microscopic: The buccal capsule is subglobular and thick-walled with three large oesophageal teeth composed of two plates which are finely denticulated and protrude into the buccal capsule. The anterior rim of the buccal capsule is thickened anteriorly and surrounded by six plate-like structures. The cuticle is strongly serrated in the cervical region. The external leaf crown consists of numerous slender elements protruding from the buccal collar, with an equal number of inner leaf crown elements. In the female, the vulva is close to the anus. The eggs are similar to those of *T. brevicauda*.

Hosts: Horse, donkey

Life cycle: As for *T. brevicauda*.

Geographical distribution: Worldwide

Cyathostomins ('small strongyles')

The group 'small strongyles' embraces over 40 species, popularly known as trichonemes, cyathostomes or cyathostomins. Fifteen species of small strongyles are commonly present in large numbers in horses. For many years there has been a great deal of confusion in the classification of this group of parasites and in a new revision it has been proposed that the genus *Trichonema* be discarded and replaced by four main genera, namely *Cyathostomum*, *Cylicocyclus*, *Cylicodontophorus* and *Cylicostephanus*, these being collectively referred to as cyathostomes or, more recently, cyathostomins. More detailed descriptions of the individual species within these genera, as listed in Table 10.1, are provided in Chapter 1. Other genera of unknown significance included in this group are *Poteriostomum*, *Craterostomum* and *Oesophagodontus*.

Since the majority of species involved are similar, both morphologically and behaviourally, they will be referred to in this text as cyathostomins or 'small strongyles'.

Pathogenesis and clinical signs: Small strongyles are extremely prevalent, and grazing horses usually carry a mixed burden of large and small strongyles. The major clinical signs associated with heavy infections in animals up to 2–3 years of age are unthriftiness, anaemia and sometimes diarrhoea. Marked clinical signs are less common in older animals, although general performance may be

Table 10.1 Cyathostomin species of the genera *Cyathostomum*, *Cylicocyclus*, *Cylicodontophorus* and *Cylicostephanus*.

impaired. In temperate countries an acute syndrome of catarrhal and/or haemorrhagic enteritis with severe diarrhoea, leading to emaciation and in some cases death, in horses and ponies in the spring has been reported; this is associated with the simultaneous mass emergence of cyathostome L₄ from the intestinal mucosa and submucosa. This may have aetiological and epidemiological similarities to type II ostertagiosis in young cattle and is often referred to as acute larval cyathostomosis.

Diagnosis: Diagnosis is based on the grazing history and clinical signs of loss of condition and anaemia. Although the finding of typical oval thin-shelled strongyle eggs on faecal examination may be a useful aid to diagnosis, it is important to remember that substantial worm burdens may be associated with faecal egg counts of only a few hundred eggs per gram (epg) due to low fecundity of adult worms, the long prepatent period or to the presence of many immature parasites. Frequently, the majority of eggs passed in the faeces of grazing horses will be Cyathostominae (small strongyles) as they are usually present in larger numbers than the Strongylinae (large strongyles). On postmortem, it may be possible to visualise the L₄ larvae in the intestinal mucosa using the transmural illumination technique (Fig. 10.12). On some occasions when heavy cyathostome infections in the spring cause severe diarrhoea, thousands

Fig. 10.12 Cyathostomin larva in the mucosa of the caecum visualized by transmural illumination.

Fig. 10.13 Small strongyles in fresh faeces

of bright-red cyathostome L₄, apparently unable to establish, may be present in the faeces (Fig. 10.13).

Pathology: Parasitic larval development of most species takes place entirely in the mucosa of the caecum and colon, but a few penetrate the muscularis and develop in the submucosa. The entry of larval cyathostomes (Fig. 10.14) into the lumina of the tubular glands generally provokes an inflammatory response together with marked goblet cell hypertrophy. Emergence of the bright-red L₄ into the gut lumen appears to be associated with massive infiltration of the gut mucosa with eosinophils. Many thousand L₄ may be present, but their pathogenic significance has been little studied. There are, however, reports of heavy natural infections of adult worms and larvae associated with catarrhal and haemorrhagic enteritis, with thickening and oedema of the mucosa, especially in animals of 6 months to 3 years of age.

Mature parasites are frequently present in large numbers in the lumen of the large intestine; during feeding those species with small buccal capsules take in only glandular epithelium, while large species may damage deeper layers of the mucosa. Although the erosions caused by individual parasites may be slight, when large numbers are present a desquamative enteritis may result.

Fig. 10.14 Developing small strongyle larvae in the mucosa of the caecum.

Epidemiology: Strongylosis is most frequently a problem in young horses reared on permanent horse pastures, although cases of severe disease may occur in adult animals kept in suburban paddocks and subjected to overcrowding and poor management. Although the pre-parasitic larval requirements of horse strongyles are similar to those of the trichostrongyles of ruminants, adult horses, unlike cattle, may carry substantial worm burdens and therefore have a considerable influence on the epidemiology of infection. Thus there are two sources of infection during the grazing season in temperate areas. First, there are infective larvae that developed during the previous grazing season and which have survived on pasture over winter. The second and probably more important source of infective larvae are the eggs passed in the current grazing season by horses, including nursing mares, sharing the same grazing area. Pasture larval levels increase markedly during the summer months when environmental conditions are optimal for rapid development of eggs to L₃ and may lead to the accumulation of large infections in the autumn.

At present there is little evidence for a consistent periparturient rise in faecal egg output in breeding mares due to a relaxation of immunity, since the egg rise in the spring occurs in both breeding and non-breeding animals and is often unrelated to parturition.

There is increasing evidence that many cyathostome L₃ ingested during the autumn show a degree of hypobiosis and remain in the large intestinal mucosa until the following spring. Mass emergence of these larvae results in the severe clinical signs described previously.

Treatment: Treatment for clinical strongylosis should not be necessary if prophylactic measures are adequate. Several broad-spectrum anthelmintics, including the benzimidazoles, pyrantel and the avermectins/milbemycins (macrocyclic lactones), are effective in removing lumen-dwelling adult and larval strongyles and these are usually marketed as in-feed or oral preparations. The macrocyclic lactones have the additional advantage of activity against larvae of horse bot flies (*Gasterophilus* spp.), which develop in the stomach. Some modern benzimidazoles and macrocyclic lactones are also efficient against both developing cyathostome larvae in the gut wall and some migrating stages of the large strongyles.

Control: Since horses of any age can become infected and excrete eggs, all grazing animals over 2 months of age should be treated every 4–8 weeks with an effective broad-spectrum anthelmintic. This regimen will also control infections with other intestinal parasites such as *Parascaris equorum* and *Oxyuris equi*. Any new animals joining a treated group should receive an anthelmintic and be isolated for 48–72 hours before being introduced. If possible, a paddock rotation system should be adopted so that nursing mares and their foals do not graze the same area in successive years. Avoid overstocking.

If horses are housed in the winter, treatment at that time with an anthelmintic effective against larval cyathostomes will reduce the risk of disease due to their mass emergence in the spring.

There is evidence that some species of cyathostomes are becoming resistant to benzimidazole compounds, pyrantel and piperazine, and to avoid this it is suggested that these should be used strategically alternated with chemically unrelated anthelmintics on an annual or a 6-monthly basis. Faecal samples from groups of horses should be examined at regular intervals to monitor drug efficiency. Selective chemotherapy, targeted at those horses with high faecal egg counts, would reduce the overall usage of anthelmintic and may reduce the selection pressure for development of resistant worms.

The introduction of pasture management techniques may be feasible for some enterprises, such as pasture cleaning twice a week

Fig. 10.15 Adult and larval small strongyles on the mucosa of the large intestine.

(vacuuming or sweeping) or the alternate grazing of pasture by ruminant livestock.

Cyathostomum spp.

Synonym: *Trichonema* spp.

Common names: Small strongyles, cyathostomins, cyathostomes, trichonemes

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Cyathostominae

Description, gross: Small (5–12 mm in length) bursate nematodes ranging in colour from white to dark red, the majority being visible on close inspection of the large intestinal mucosa or contents (Figs 10.15 and 10.16).

Fig. 10.16 Mixed infection of *Oxyuris equi* adults (white) and small strongyles in the colon.

Table 10.2 Geographical distribution of *Cyathostomum* spp.

| Species | Distribution | Comments |
|-------------------------|----------------------|----------------------------------|
| <i>C. alveatum</i> | Africa, Asia, Europe | Rare |
| <i>C. catinatum</i> | Cosmopolitan | Very common |
| <i>C. coronatum</i> | Cosmopolitan | Common |
| <i>C. labiatum</i> | Cosmopolitan | Common |
| <i>C. labratum</i> | Cosmopolitan | Common |
| <i>C. montgomeryi</i> | Africa | Rare. In zebra, horses and mules |
| <i>C. pateratum</i> | Cosmopolitan | Common |
| <i>C. saginatum</i> | Europe, Asia | Rare |
| <i>C. tetracanthrum</i> | Cosmopolitan | Rare |

Description, microscopic: The well-developed short buccal capsule is cylindrical, without teeth, and species differentiation is based on characteristics of the buccal capsule, and the internal and external leaf crowns. *Cyathostomum* have a moderately high mouth collar, with cephalic papillae not very prominent. The buccal capsule is broader than deep and has no dorsal gutter. Elements of the external leaf crown are larger, broader and fewer than elements of the internal leaf crown. Inner leaf crown is deep in the buccal capsule and has sclerotised extra-chitinous supports at or near the anterior edge of the buccal capsule (see Fig 1.45a). The dorsal ray of the male bursa is split to the origin of the externo-dorsal rays and the spicules are filiform, equal in length with 'pick'-shaped tips. In the female, the vulva is close to the anus. The tail may be straight or bent dorsally with a ventral bulge, anterior to the vulva. The eggs are medium-sized, a long ellipse, measuring about 100–110 by 40–45 µm. The shells are smooth and thin with almost similar poles and parallel side walls and contain a morula with several large blastomeres. It is not possible to distinguish between the eggs of the different species of cyathostomes.

Hosts: Horse, donkey

Geographical distribution: See Table 10.2.

***Cylicocycclus* spp.**

Synonym: *Trichonema* spp.

Common names: Small strongyles, cyathostomins, cyathostomes, trichonemes

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Cyathostominae

Description, gross: Small to medium-sized (10–25 mm in length) bursate nematodes ranging in colour from white to dark red, the majority being visible on close inspection of the large intestinal mucosa or contents.

Description, microscopic: The well-developed short buccal capsule is cylindrical, without teeth, and species differentiation is based on characteristics of the buccal capsule, and the internal

and external leaf crowns. *Cylicocycclus* have a high mouth collar with broad lateral papillae. Elements of the external leaf crown are larger, fewer and broader than those of the inner leaf crown, the latter being short, with thin rods at or near the anterior edge of the buccal capsule. The buccal capsule is short, broader than deep, with thin walls tapering anteriorly, with a hoop-shaped thickening around the posterior margin. A dorsal gutter is usually absent from the buccal capsule (see Fig 1.45b). In the male the dorsal ray is split to the origin of the externo-dorsal rays and the spicules are filiform, of equal length with pick-shaped tails. In females, the vulva is near the anus and the tail is usually straight but may be bent slightly dorsally.

Hosts: Horse, donkey and other equids

Geographical distribution: See Table 10.3.

***Cylicodontophorus* spp.**

Synonym: *Schultzitrichonema*

Common names: Small strongyles, cyathostomins, cyathostomes, trichonemes

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Cyathostominae

Description, gross: Small (7–14 mm in length) bursate nematodes ranging in colour from white to dark red, the majority being visible on close inspection of the large intestinal mucosa or contents.

Description, microscopic: The well-developed short buccal capsule is cylindrical, without teeth, and species differentiation is based on characteristics of the buccal capsule, and the internal and external leaf crowns. *Cylicodontophorus* have a high mouth collar, with inconspicuous lateral papillae and short and conical sub-median papillae. The buccal capsule is short, thick-walled, of nearly uniform thickness, and broader than deep. Inner leaf crown elements are longer, broader and less numerous than the external leaf crown

Table 10.4 Geographical distribution of *Cylicodontophorus* spp.

elements, and are inserted near the anterior edge of the buccal capsule (see Fig. 1.45c). The dorsal ray of the male bursa is split only to the proximal branch, and the spicules are filiform, equal in length with 'hook'-shaped tips. In the female, the tail is short with a sharp tip and a prominent ventral bulge may be present anterior to the vulva.

Hosts: Horse, donkey

Geographical distribution: See Table 10.4.

Cylicostephanus spp.

Synonyms: *Schultzitrichonema*, *Petrovinema*

Common names: Small strongyles, cyathostomins, cyathostomes

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Cyathostominae

Description, gross: Small (4–10 mm in length) bursate nematodes ranging in colour from white to dark red, the majority being visible on close inspection of the large intestinal mucosa or contents.

Description, microscopic: The well-developed short buccal capsule is cylindrical, without teeth, and species differentiation is based on characteristics of the buccal capsule, and the internal and external leaf crowns. *Cylicostephanus* have a depressed mouth collar, with inconspicuous lateral papillae and prominent sub-median papillae. The buccal capsule is slightly narrow anteriorly, with a wall of varying thickness, and with a dorsal gutter. External leaf crown elements are longer, broader and less numerous than the internal leaf crown elements, which are short thin rods inserted near the anterior edge of the buccal capsule (see Fig. 1.45d). The dorsal ray of the male bursa is split only to the proximal branch, and the spicules are filiform, equal in length with pick-shaped tips. In the female, the vulva is near the anus, and the tail is usually straight.

Hosts: Horse, donkey

Geographical distribution: See Table 10.5.

Poteriostomum imparidentatum

Common name: Non-migratory large strongyles

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Table 10.5 Geographical distribution of *Cylicostephanus* spp.

| Species | Distribution | Comments |
|-------------------------|-------------------------------------|-------------|
| <i>C. asymmetricus</i> | Africa, Asia, Europe, North America | Very rare |

| <i>C. ornatus</i> | Asia, Europe | Rare |
| <i>C. poculatus</i> | Cosmopolitan | Rare |
| <i>C. skrjabini</i> | Asia | Rare |

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Cyathostominae

Description, gross: Males are 9–14 mm and females 13–21 mm.

Description, microscopic: This genus is closely related to the genus *Cylicodontophorus*. The two genera are easily separated based on characteristics of the buccal capsule, especially the point of insertion of the internal leaf crown and the character of the dorsal ray. In *P. imparidentatum* six elements of the internal leaf crown are markedly longer than the others.

Hosts: Horse, donkey

Geographical distribution: Worldwide

Poteriostomum ratzii

Common name: Non-migratory large strongyles

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Cyathostominae

Description, gross: Males are 9–14 mm and females 13–21 mm.

Description, microscopic: This genus is closely related to the genus *Cylicodontophorus*. The two genera are easily separated based on characteristics of the buccal capsule, especially the point of insertion of the internal leaf crown and the character of the dorsal ray. In *P. ratzii* all elements of the internal leaf crown are of equal length.

Hosts: Horse, donkey

Geographical distribution: Worldwide

Craterostomum acuticaudatum

Synonyms: *Cylicostomum acuticaudatum*, *Cylicostomum mucronatum*, *Craterostomum mucronatum*

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Cyathostominae

Description, gross: Small worms, 6–11 mm long.

Description, microscopic: The buccal capsule is of greatest diameter in the middle, the wall being thickened behind the anterior edge. The dorsal gutter is strongly developed. The shallow oesophageal funnel has three small triangular teeth that do not project into the buccal cavity. Elements of the external leaf crown are large and transparent and less numerous than the short broad elements of the inner leaf crown that ring the anterior ridge of the buccal capsule. Sub-median papillae extend beyond the depressed mouth collar. In the female the tail is long and pointed and the vulva is relatively far from the anus.

Hosts: Horse, donkey

Geographical distribution: Africa, Asia, Europe

Craterostomum tenuicauda

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Cyathostominae

Description, gross: Small worms, 6–10 mm long

Description, microscopic: The buccal capsule is of greatest diameter in the middle, the wall being thickened behind the anterior edge. The dorsal gutter is strongly developed. The shallow oesophageal funnel has three small triangular teeth that do not project into the buccal cavity. The elements of the external leaf crown (nine) are large and transparent and less numerous than the short broad elements of the inner leaf crown (18) that ring the anterior ridge of the buccal capsule. Sub-median papillae are unnotched and extend beyond the depressed mouth collar. In the female, the tail is short and pointed and the vulva is relatively far from the anus.

Hosts: Horse, zebra

Geographical distribution: Africa, Asia

Pathogenesis: Not reported

Oesophagodontus robustus

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Family: Strongylidae

Subfamily: Cyathostominae

Description, gross: Male worms are 15–18 mm and females 19–24 mm. There is a slight constriction between the anterior end and the rest of the body.

Description, microscopic: The buccal capsule is shaped like a funnel with a thickened ring encircling its posterior margin. The oesophageal funnel has three lancet-like teeth that do not project into the buccal capsule. There is no dorsal gutter.

Hosts: Horse, donkey

Geographical distribution: Worldwide

Oxyuris equi

Common names: Equine pinworm, rat-tail

Predilection site: Caecum, colon and rectum

Phylum: Nematoda

Class: Secernentea

Superfamily: Oxyuroidea

Description, gross: The mature females are large, greyish-white, opaque worms with very long tapering tails that may reach 10–15 cm in length, whereas the mature males are generally less than 1.2 cm long (see Fig. 10.16). *Oxyuris equi* L₄ are 5–10 mm in length, have long tapering tails and are often attached orally to the intestinal mucosa.

Description, microscopic: There is a double oesophageal bulb (see Fig. 1.57) and the tiny males have caudal alae and a single pin-shaped spicule. In the female the vulva is situated anteriorly. *Oxyuris equi* eggs are ovoid, yellowish, thick-shelled, smooth and slightly flattened on one side with a transparent mucoid operculate plug at one end (see Fig. 4.4). Eggs measure 80–95 by 40–45 µm and contain a late-stage morula or a first larval stage when shed in faeces.

Hosts: Horse, donkey

Geographical distribution: Worldwide

Pathogenesis: Most of the pathogenic effects of *O. equi* in the intestine are due to the feeding habits of the L₄, which result in small erosions of the mucosa; in heavy infections, these may be widespread and accompanied by an inflammatory response. Normally, a more important effect is the perineal irritation and anal pruritis caused by the adult females during egg-laying and the adhesive egg masses. The resultant dull hair coat and loss of hair, as the horse rubs its tail against solid objects to relieve itching, is known as 'rat-tail'.

Clinical signs: The presence of parasites in the intestine rarely causes any clinical signs. However, intense pruritis around the anus causes the animal to rub on available solid objects, resulting in broken hairs, bare patches and inflammation, scarification and scaling of the skin over the rump and tail head. The intense itching often leads to restlessness and impaired feeding, causing some loss of condition.

Diagnosis: This is based on signs of anal pruritis and tail rubbing and the finding of greyish-yellow egg masses on the perineal skin

Fig. 10.17 Clumps of *Oxyuris equi* eggs around the rectum of a horse.

(Fig. 10.17). The large white long-tailed female worms are often seen in the faeces (Fig. 10.18), having been dislodged while laying their eggs. *Oxyuris equi* eggs are rarely found on faecal examination of samples taken from the rectum, but may be observed in material from the perineum or in faecal material taken from the ground. The condition needs to be differentiated from mange.

Pathology: Small erosions may occur in the mucosa in heavy infections accompanied by a mixed inflammatory cell response.

Epidemiology: Although the infective stage may be reached on the skin, more often flakes of material containing eggs are dispersed in the environment by the animal rubbing on stable fittings, fencing posts or other solid objects. Heavy burdens may build up in horses in infected stables and there appears to be little immunity to reinfection.

Fig. 10.18 Adult *Oxyuris equi* worms in faeces.

Treatment: Immature and adult *O. equi* are susceptible to many broad-spectrum anthelmintics and should be controlled by routine chemotherapy for the more important horse parasites. Effective anthelmintics include ivermectin, moxidectin, the benzimidazoles (fenbendazole, oxfendazole, oxibendazole) and pyrantel. Newly acquired horses should be treated routinely.

Where animals are showing clinical signs, the perineal skin and underside of the tail should be frequently cleaned (about every 4 days) using a disposable cloth to remove the egg masses prior to their development to L₃ larvae, in addition to anthelmintic treatment.

Control: A high standard of stable hygiene should be observed, such as the frequent removal of bedding and the provision of feeding racks and water troughs that cannot easily be contaminated by bedding.

Notes: Infection with the horse pinworm, *Oxyuris equi*, is extremely common. Although of limited pathogenic significance in the intestine, the female parasites may cause an intense anal pruritis during the process of egg-laying.

Probstmayria vivipara

Common name: Small equine pinworm

Predilection site: Colon

Phylum: Nematoda

Class: Secernentea

Superfamily: Oxyuroidea

Description, gross: Small slender nematodes, 2.0–3.0 mm, with long filamentous tails.

Description, microscopic: The mouth has six small lips and the buccal capsule is cylindrical and long. The oesophagus has an expanded posterior bulb. A large sucker-like excretory pore is present.

Hosts: Horse and various equids

Geographical distribution: Probably worldwide, except some regions of western Europe

Pathogenesis: It is generally considered to be non-pathogenic; although millions of these pinworms may be present, they have never given rise to any clinical signs.

Clinical signs: No associated clinical signs

Diagnosis: First-stage larvae may be found in the faeces or larvae and adult worms may be found on necropsy.

Pathology: No associated pathology

Epidemiology: Transmission is probably via coprophagia.

Treatment: The parasite is susceptible to most modern anthelmintics.

Control: Not usually required

Intestinal flukes

Several species of intestinal flukes belonging to the genera *Gastrodiscus* and *Pseudodiscus* are found in the large intestine of horses. Intermediate hosts are snails.

Pathogenicity: Adult flukes cause little damage to the intestine. Disease is usually caused by large numbers of immature flukes.

Clinical signs: Mild infections are subclinical. Heavy infections are accompanied by diarrhoea, anaemia, oedema, emaciation and marked weakness.

Diagnosis: Diagnosis is based on the presence of eggs in faeces or immature flukes in fluid faeces.

Pathology: Immature flukes are embedded in the mucosa, causing haemorrhage and necrosis. In heavy infections, there may be catarrhal and haemorrhagic enteritis.

Epidemiology: Infection is acquired by ingesting the intermediate hosts with vegetation.

Treatment: Flukicidal drugs, such as nitroxylnil, oxcyclozanide, closantel, triclabendazole or albendazole and netobimin, are active against the adult flukes; triclabendazole 10 mg/kg or closantel 7 mg/kg are active against immature flukes.

Control: Wet pastures or swamps where the intermediate hosts are found should be avoided.

Gastrodiscus aegyptiacus

Common name: Intestinal fluke

Predilection site: Small and large intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Gastrodiscidae

Description, gross: Adult flukes are pink in colour and measure 9–17 by 8–11 mm. The anterior is up to 4 mm and cylindrical, while the rest of the body is saucer-shaped, with the margins curved inwards (see Fig. 1.73).

Description, microscopic: The ventral surface is covered by a large number of regularly arranged papillae. The oral sucker has two posterolateral pouches; the posterior sucker is small and subterminal. Eggs are oval and measure 131–139 by 78–90 μm .

Final hosts: Horse, pig, warthog

Geographical distribution: Africa, India

Gastrodiscus secundus

Common name: Intestinal fluke

Predilection site: Large intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Gastrodiscidae

Final host: Horse

Geographical distribution: India

Pseudodiscus collinsi

Common name: Intestinal fluke

Predilection site: Large intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Description, gross: Adult flukes have a conical anterior end widening gradually to an oval leaf-like shape.

Description, microscopic: The conical body has conspicuous serrations along the anterior lateral margins. There is a ventral sucker and the oral sucker has paired pouch-like diverticula.

Final host: Horse

Geographical distribution: India

Protozoa

Entamoeba gedoelsti

Predilection site: Large intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Host: Horse

Description: Trophozoites are 7–13 μm in diameter. The nucleus has an eccentric endosome and a row of relatively coarse chromatin granules around its periphery. Cysts have not been reported.

Geographical distribution: Worldwide

Pathogenesis: Non-pathogenic

Clinical signs: No associated clinical signs

Diagnosis: Identification of trophozoites in caecal contents or faeces.

Epidemiology: Transmission is probably by ingestion of trophozoites. No cyst stage has been described.

Treatment and control: Not required

Entamoeba equi

Predilection site: Large intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Host: Horse

Description: Trophozoites are large and measure 40–50 by 23–29 μm . The nucleus has a small, oval, central endosome. Cysts are 15–27 μm and contain four nuclei.

Parasites of the respiratory system

Rhinoestrus purpureus

Common name: Horse nasal bot fly

Predilection site: Nasal passages

Class: Insecta

Family: Oestridae

Description, adults: A relatively small fly, 8–11 mm in length. The anterior thorax is characterised by a number of glossy black stripes. The head, thorax and abdomen are covered with small wart-like protruberances and a covering of short yellow–brown hairs. The head is broad, with small eyes. The legs are red and yellow–brown. The mouthparts are reduced to small knobs.

Description, larvae: The larvae resemble those of *Oestrus ovis* except that they have strongly recurved mouth hooks and a single row of 8–12 terminal hooklets. There are three larval stages, approximately 1, 3.5 and 20 mm in length, respectively.

Hosts: Horse, donkey, occasionally human

Geographical distribution: Russia, Ukraine, Central Asia

Pathogenesis: This species is a serious veterinary problem in areas such as Russia, and infestation by large numbers of larvae in the throat may result in a high level of mortality.

Clinical signs: Nasal discharge, rubbing, sneezing, unthriftiness, circling and lack of coordination. Secondary bacterial infections are common.

Diagnosis: Larvae may be observed in the nasal cavities, throat and base of the tongue.

Pathology: Catarrh, infiltration of inflammatory cells and squamous metaplasia, characterised by conversion of secretory epithelium to stratified squamous type, may be observed. Immune responses by the host to infestation may be recorded.

Epidemiology: Adults are on the wing in midsummer. Usually only one generation per year occurs, although a second may be observed in some areas.

Treatment: Where the numbers of larvae are small, it may not be economically viable to treat. However, in heavy infections closantel, nitroxylin, and the endectocides ivermectin, doramectin and moxidectin are highly effective, as are the organophosphates trichlorphon and dichlorvos.

Control: Area-wide control may be impractical; herd treatment may be given twice a year, the first at the beginning of summer to kill newly acquired larvae, and the second in midwinter to kill any overwintering larvae.

Dictyocaulus arnfieldi

Common name: Equine lungworm

Predilection site: Lungs

Phylum: Nematoda

Class: Secernentea

Fig. 10.19 *Dictyocaulus arnfieldi* first-stage larva showing the terminal protruberance.

Superfamily: Trichostrongyloidea

Description, gross: The adults are slender, thread-like and whitish, the adult males measuring around 3.5 cm and the females 6.5 cm in length. Their location in the trachea and bronchi and their size are diagnostic.

Description, microscopic: Male worms have a small non-lobulated bursa with short rays, with the mediolateral and posterolateral rays fused for half their length. The spicules are short, equal in length and slightly curved. The medium-sized, ellipsoidal, thin-walled eggs measure 80–100 by 50–60 µm and are embryonated. First-stage larvae emerge from the egg very early and measure 290–480 µm, with a posterior transparent protruberance (Fig. 10.19). The contents are granular in appearance.

Hosts: Donkey, other equids and occasionally the horse

Geographical distribution: Worldwide

Pathogenesis: The characteristic lesion is similar in both horses and donkeys and is somewhat different from bovine parasitic bronchitis.

Clinical signs: Despite the prevalence of patent *D. arnfieldi* infection in donkeys, overt clinical signs are rarely seen; however, on close examination slight hyperpnoea and harsh lung sounds may be detected. This absence of significant clinical abnormality may be partly a reflection of the fact that donkeys are rarely required to perform sustained exercise.

Infection is much less prevalent in horses. However, patent infections may develop in foals and these are not usually associated with clinical signs. In older horses, infections rarely become patent but are often associated with persistent coughing, nasal discharge and an increased respiratory rate.

Diagnosis: In donkeys, patent infections are common and L₁ are readily recovered from fresh faeces. In horses, although a history of donkey contact and clinical signs may be suggestive of *D. arnfieldi* infection, it is often not possible to confirm a diagnosis by demonstrating larvae in the faeces, as many infections do not reach patency. In practice, a presumptive diagnosis of lungworm infection in horses is often only possible in retrospect, when resolution of the clinical signs occurs after treatment.

Pathology: In the caudal lung lobes particularly, there are raised circumscribed areas of over-inflated pulmonary tissue 3.0–5.0 cm

in diameter. On section, at the centre of each lesion is a small bronchus containing lungworms and mucopurulent exudate. Microscopically, the epithelium is hyperplastic with an increase in the size and number of mucus-secreting cells while the lamina propria is heavily infiltrated and often surrounded by inflammatory cells, predominantly lymphocytes.

Epidemiology: Donkeys acquire infection as foals and yearlings and tend to remain infected, presumably through re-exposure, all their lives. Horses are thought to acquire infection mainly from pastures contaminated by donkeys during the summer months. Most commonly this occurs when donkeys are grazed as companion animals with horses. However, natural infection in horses can occur in the absence of donkeys. In horses, the prevalence of *D. arnfieldi* is difficult to establish since infections only occasionally achieve patency. *Pilobolus* fungi may play a role in the dissemination of *D. arnfieldi* larvae from faeces, as in *D. viviparus*.

Treatment: Successful treatment of both horses and donkeys has been reported using ivermectin or some benzimidazoles, such as fenbendazole and mebendazole.

Control: Ideally, horses and donkeys should not be grazed together, but if they are it is advisable to treat the donkeys, preferably in the spring, with a suitable anthelmintic. A similar regimen should be practised in donkey studs and visiting animals should be isolated in separate paddocks.

Echinococcus equinus

For more details see Parasites of the liver.

Parasites of the liver

Fasciola hepatica

Common name: Liver fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description, gross: Adult fluke are leaf-shaped, grey-brown in colour and around 2.5–3.5 cm in length (see Fig 1.70a).

Description, microscopic: The anterior end is conical and marked off by distinct shoulders from the body. The tegument is covered with backwardly projecting spines. An oral and ventral sucker may be readily seen.

Final hosts: Sheep, cattle, goat, horse, deer, human and other mammals

Intermediate hosts: Snails of the genus *Galba* (*Lymnaea*)

For more details see Chapter 9.

Echinococcus equinus

Synonym: *Echinococcus granulosus* (G4)

Common names: Dwarf dog tapeworm, hydatidosis

Predilection site: Mainly liver and lungs (intermediate hosts); small intestine (definitive host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: Hydatid cysts are large fluid-filled vesicles, 5–10 cm in diameter, with a thick concentrically laminated cuticle and an internal germinal layer.

Description, microscopic: The germinal layer produces numerous small vesicles or brood capsules, each containing up to 40 scolices, invaginated into their neck portions and attached to the wall by stalks. Brood capsules may become detached from the wall of the vesicle and float freely in the vesicular fluid and form 'hydatid sand'.

Final hosts: Dog, fox

Intermediate hosts: Horse, donkey

Geographical distribution: Mainly Europe

Pathogenesis and clinical signs: Infection in horses is generally not associated with clinical signs.

Epidemiology: Equine hydatidosis is commonest in Europe, and in other parts of the world most cases have been recorded in imported European horses. The strain is highly specific for the horse and the eggs do not develop in the sheep. The domestic dog and the red fox are the final hosts, and the cycle in countries of high prevalence depends on access by dogs to infected equine viscera. On mainland Europe, the most likely source is offal from horse abattoirs; in Britain the viscera of hunting horses, which are fed to foxhounds. The horse strain does not appear to be infective to humans.

Treatment: No treatment in horses

Control: This is based on the regular treatment of dogs to eliminate the adult tapeworms and on the prevention of infection in dogs by exclusion from their diet of animal material containing hydatids. This is achieved by denying dogs access to abattoirs and, where possible, by proper disposal of equine viscera. In some countries these measures have been supported by legislation, with penalties when they are disregarded.

Notes: Considerable phenotypic and genetic variability has been observed within the species *E. granulosus* and several strains have been identified based on molecular genotyping. New data demonstrate that 'E. granulosus' is an assembly of several, rather diverse strains and genotypes (designated G1–G10) that show fundamental differences, not only in their epidemiology but also in their pathogenicity to humans. *Echinococcus equinus* was formerly known as the horse strain (G4) of *E. granulosus*.

Parasites of the circulatory system

Elaeophora bohmi

Predilection site: Blood vessels

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Slender worms, males are about 4.5–6 cm and females 4–20 cm long.

Description, microscopic: Microfilariae are 230–290 µm with a long tail.

Final hosts: Horse and other equids

Intermediate hosts: Tabanid and other flies

Geographical distribution: Europe (in particular Austria), Middle East (Iran)

Pathogenesis: Found in the large veins and arteries, often of lower limbs where they usually induce very little pathological reaction.

Clinical signs: Infection is usually asymptomatic.

Diagnosis: This is not normally required. Infection is usually diagnosed as an incidental finding on postmortem examination of thickened blood vessels, or those containing nodules.

Pathology: Severe infection can cause thickening of the wall of arteries and veins, commonly those in the extremities, and nodules containing calcified worms may be present. The parasites selectively involve the media of the vessels, with the fibrous reaction that develops sometimes causing stenosis of the lumen. The worms are coiled and entwined among the tissue layers, provoking parasitic granulomas with intense eosinophilic and macrophage infiltration. In long-standing infections, the nodular and fibrous thickenings are visible in the vessel walls.

Epidemiology: Because of the innocuous nature of the infection in equines, the distribution of the species in these hosts is not completely known.

Treatment: Treatment is unknown, although repeated administration of diethylcarbamazine is effective, but the risk of fatalities from the presence of dead worms in the arteries should be recognised.

Control: Any reduction in vector numbers will reduce transmission.

Notes: These worms inhabit large blood vessels, but are only of local importance.

Schistosomes

Schistosomes are flukes found in the circulatory system. The sexes are separate, the small adult female lying permanently in a longitudinal groove, the gynaecophoric canal, in the body of the male. The genus has been divided into four groups – *haematobium*, *indicum*, *mansonii* and *japonicum* – but the genus as currently defined is paraphyletic so revisions are likely.

Indicum group

Schistosoma indicum

Predilection site: Portal, pancreatic, hepatic and mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The sexes are separate; the males are 5–19 mm long, and the females 6–22 mm long.

Description, microscopic: The eggs are oval with a terminal spine and measure 57–140 by 18–72 µm.

Final hosts: Cattle, sheep, goat, horse, donkey, camel

Intermediate hosts: Snails (*Indoplanorbis*)

Geographical distribution: India

Schistosoma nasalis

Synonym: *Schistosoma nasalae*

Common name: Snoring disease

Predilection site: Veins of nasal mucosa

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The sexes are separate; the male, which is broad and flat and about 1 cm long, carries the female in the hollow of its inwardly curved body.

Description, microscopic: The eggs measure 350–380 by 50–80 µm and are boomerang-shaped, with a terminal spine.

Final hosts: Cattle, goat, sheep, buffalo, horse

Intermediate hosts: Snails (*Lymnaea luteola*, *L. acuminata*, *Indoplanorbis exustus*)

Geographical distribution: India, Pakistan, Southeast Asia

Pathogenesis: In heavy infections there is a copious mucopurulent discharge, snoring and dyspnoea. The main pathogenic effects are associated with the eggs, which cause abscess formation in the mucosa. Fibrous granulomatous growths occur which may occlude the nasal passages.

Clinical signs: Coryza, sneezing, dyspnoea and snoring

Diagnosis: Infection is confirmed by the presence of the spindle-shaped eggs in the nasal discharge.

Pathology: The mucosa of the nasal sinuses is studded with small abscesses that contain the eggs of the worms, and later show much fibrous tissue and proliferating epithelium.

Epidemiology: The epidemiology is totally dependent on water as a medium for infection of both the intermediate and final hosts.

Schistosoma spindale

Predilection site: Mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The sexes are separate; the male, which is broad and flat and about 5–16 mm long, carries the female in the hollow of its inwardly curved body.

Description, microscopic: The eggs are spindle-shaped, measure 200–300 by 70–90 μm and have a lateral or terminal spine. There is no operculum.

Hosts: Cattle, horse, pig and occasionally dog

Intermediate hosts: Snails (*Planorbis*, *Indoplanorbis* spp., *Lymnaea* spp.)

Geographical distribution: Parts of Asia and the Far East

Japonicum group

Schistosoma japonicum

Common names: Blood fluke, bilharziosis

Predilection site: Portal and mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The sexes are separate; the male, which is broad and flat and 9.5–20 mm long, carries the female, which is 12–26 mm long, in the hollow of its inwardly curved body. The suckers lie close together near the anterior end. The cuticle is spiny on the suckers and in the gynaecophoric canal.

Description, microscopic: The eggs are short and oval, measuring 70–100 by 50–80 μm , and may have a small lateral subterminal spine. There is no operculum.

Final hosts: Cattle, horse, sheep, goat, dog, cat, rabbit, pig, rodents, human

Intermediate hosts: Snails belonging to the genus *Oncomelania*

Geographical distribution: South and East Asia

Other schistosomes

Schistosoma turkestanica

Synonym: *Orientobilharzia turkestanicum*

Predilection site: Mesenteric veins and small veins of the pancreas and liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: Small species, the male measuring around 4.2–8 mm and the female 3.4–8 mm in length.

Description, microscopic: The spirally coiled ovary is positioned in the anterior part of the body. In the male there are around 70–80 testes. The female uterus is short and contains only one egg at a time, which measures 72–77 by 16–26 μm with a terminal spine and a short appendage at the opposite end.

Final hosts: Cattle, buffalo, sheep, goat, camel, horse, donkey, mule and cat

Intermediate hosts: Snail (*Lymnaea euphratica*)

Geographical distribution: Asia, Middle East and parts of Europe

For more details on *Schistosoma* species see Chapters 1 and 8.

Trypanosomes

See Chapter 2 (Family Trypanosomatidae) for general description and Chapter 8 for detailed descriptions of individual species of trypanosomes and their control.

Trypanosoma brucei brucei

Common name: Nagana

Predilection site: Blood. *Trypanosoma brucei brucei* is also found extravascularly in, for example, the myocardium, central nervous system (CNS) and reproductive tract.

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Trypanozoon*

Description: *Trypanosoma brucei brucei* is pleomorphic in form and ranges from long and slender, up to 42 μm (mean 29 μm), to short and stumpy, 12–26 μm (mean 18 μm), the two forms often being present in the same blood sample. The undulating membrane is conspicuous, the kinetoplast is small and subterminal and the posterior end is pointed. In the slender form the kinetoplast is up to 4 μm from the posterior end, which is usually drawn out tapering almost to a point, and has a well-developed free flagellum. In the stumpy form the flagellum is either short or absent and the posterior end is broad and rounded with the kinetoplast almost terminal. Intermediate forms average 23 μm long and have a blunt posterior end and moderately long flagellum (see Fig. 2.6). A fourth form with a posterior nucleus may be seen in laboratory animals. In fresh unfixed blood films, the organism moves rapidly within small areas of the microscope field.

Hosts: Cattle, horse, donkey, zebu, sheep, goat, camel, pig, dog, cat, wild game species

Geographical distribution: Sub-Saharan Africa

Pathogenesis: In horses, *T. brucei brucei* infections may be acute or chronic, often accompanied by oedema of the limbs and genitalia.

Treatment: Horses are particularly susceptible to *T. brucei brucei* and suramin and quinapyramine methylsulphate are the drugs of choice (Table 10.6). Diminazene is relatively toxic to horses. Despite treatment, relapse from CNS infection is likely.

Trypanosoma brucei evansi

Synonyms: *Trypanosoma evansi*, *Trypanosoma equinum*

Common names: Surra, el debab, mbori, murrina, mal de Caderas, doukane, dioufar, thaga

Table 10.6 Drugs used in the treatment of *T. brucei brucei* infection.

| Drug | Recommended dose | Comments |
|------------------------------|-------------------------|---|
| Diminazene aceturate | 3–10 mg/kg i.m. | Ruminants, pig, horse. Contraindicated in dog and camel |
| Isometamidium | 0.25–1 mg/kg i.m. | Ruminants, horse, dog. Local reaction |
| Quinapyramine sulphate | 3–5 mg/kg i.m. | Horse only. Banned in ruminants |
| Quinapyramine methylsulphate | 5 mg/kg s.c. | Dog |
| Suramin | 7–10 mg/kg i.m. or i.v. | Horse, camel. Local and systemic reactions |

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Trypanozoon*

Description: *Trypanosoma brucei evansi* is identical to, and structurally indistinguishable in appearance from, the slender forms of *T. brucei brucei*. The mean length varies considerably, with typical forms 15–34 µm long (mean 24 µm). Most are slender or intermediate in shape, but stumpy forms occur sporadically. Strains that lack a kinetoplast visible with the light microscope have occasionally arisen spontaneously or can be produced by treatment with certain dyes, drugs or frozen storage.

Hosts: Horse, donkey, camel, cattle, zebu, goat, pig, dog, water buffalo, elephant, capybara, tapir, mongoose, ocelot, deer and other wild animals. Many laboratory and wild animals can be infected experimentally.

Geographical distribution: North Africa, Central and South America, central and southern Russia, parts of Asia (India, Burma, Malaysia, southern China, Indonesia, Philippines)

Pathogenesis: Depending on the virulence of the strain and the susceptibility of the individual host, the disease may be acute in horses, camels and dogs. Other domestic species, such as cattle, buffalo and pig, are commonly infected, but overt disease is uncommon and their main significance is as reservoirs of infection. The syndrome is similar to that caused by the tsetse-transmitted trypanosomes. Anaemia is caused mainly by extravascular haemolysis through erythrophagocytosis in the mononuclear phagocytic systems of the spleen, liver and lungs; as the disease becomes chronic there may be decreased haemoglobin synthesis. Leucopaenia and thrombocytopenia are caused by mechanisms that predispose leucocytes and platelets to phagocytosis. Immunological mechanisms in the pathogenesis lead to extensive proliferation of activated macrophages, which engulf or destroy erythrocytes, leucocytes, platelets and haematopoietic cells.

Clinical signs: All domestic animals are susceptible but the disease is only fatal in horses, camels and dogs. The disease is manifested by pyrexia, progressive anaemia, loss of condition and depression. Recurrent episodes of fever occur during the course of disease. Oedematous swellings, ranging from cutaneous plaques to frank oedema of the ventral abdomen and genitalia, and petechial haemorrhages

of the serous membranes are often observed. Abortions have been reported in buffaloes in Asia. Nervous signs may occur and include circling, incoordination, staggering, head pressing, paraplegia, paralysis and prostration.

Diagnosis: The clinical signs of the disease, although indicative, are not pathognomonic. Confirmation of clinical diagnosis depends on the demonstration of trypanosomes in the blood; if a herd or flock is involved a representative number of blood samples should be examined since, in individual animals, the parasitaemia may be in remission or in long-standing cases may be extremely scanty. Occasionally, when the parasitaemia is massive it is possible to detect motile trypanosomes in fresh films of blood. More usually, both thick and thin smears of blood are air-dried and examined later. Thick smears, de-haemoglobinised before staining with Giemsa or Leishman's stain, offer a better chance of finding trypanosomes, while the stained thin smears are used for differentiation of the trypanosome species.

More sensitive techniques utilise centrifugation in a microhaematocrit tube followed by microscopic examination of the interface between the buffy coat and the plasma; alternatively, the tube may be snapped, the buffy coat expressed on to a slide, and the contents examined under dark-ground or phase-contrast microscopy for motile trypanosomes. With these techniques the packed red cell volume is also obtained which is of indirect value in diagnosis if one can eliminate other causes of anaemia, especially helminthosis.

A number of serological tests have been described, including the indirect fluorescent antibody test (IFAT) and ELISA, and have been partially validated but require further evaluation and standardisation.

Pathology: The carcass is often pale, emaciated and there may be oedematous swellings in the lower part of the abdomen and genital organs with serous atrophy of fat. The liver, lymph nodes and spleen are enlarged and the viscera are congested. Petechiae may appear on lymph nodes, pericardium and intestinal mucosa. The liver is hypertrophic and congested with degeneration and necrosis of the hepatocytes, dilation of blood vessels and parenchymal infiltration of mononuclear cells. A non-suppurative myocarditis, sometimes associated with hydropericarditis, has been reported, accompanied by degeneration and necrosis of the myocardial tissue. Other lesions can include glomerulonephritis, renal tubular necrosis, non-suppurative meningo-encephalomyelitis, focal poliomyelitis, keratitis, ophthalmitis, orchitis, interstitial pneumonia and bone marrow atrophy. Splenic and lymph node hypertrophy occur during the acute phase but the lymphoid tissues are usually exhausted and fibrotic in the chronic stage.

Epidemiology: This species, although closely related to the salivarian trypanosome *T. brucei brucei*, is mechanically transmitted by biting insects; the usual vectors are horse flies (*Tabanus*) but *Stomoxys*, *Haematopota* and *Lyperosia* can also transmit the infection. No cyclical development occurs in the vector, with the trypanosomes remaining in the proboscis. In Central and South America the vampire bat is a vector and can transmit the disease (murrina).

Treatment and control: Suramin or quinapyramine (Trypacide) are the drugs of choice for treatment and also confer a short period of prophylaxis. For more prolonged protection a modified quinapyramine known as Trypacide Pro-Salt is also available. Unfortunately, drug resistance, at least to suramin, is not uncommon.

Notes: The original distribution of this parasite coincided with that of the camel, and is often associated with arid deserts and semi-arid steppes.

Trypanosoma congolense congolense

Common names: Nagana, paranagana, Gambia fever, ghindi, gobial

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Nannomonas*

Description: *Trypanosoma congolense congolense* is small, monomorphic in form and 8–20 µm long. The undulating membrane is inconspicuous, the medium-sized kinetoplast is marginal and the posterior end is blunt. There is no free flagellum (see Fig. 2.5). In fresh blood films the organism moves sluggishly, often apparently attached to red cells.

Hosts: Cattle, sheep, goat, horse, camel, dog, pig. Reservoir hosts include antelope, giraffe, zebra, elephant and warthog.

Geographical distribution: Sub-Saharan Africa

Pathogenesis: The signs caused by this species are similar to those caused by other trypanosomes, but the CNS is not affected. Anaemia is caused mainly by extravascular haemolysis through erythrophagocytosis in the mononuclear phagocytic systems of the spleen, liver and lungs but as the disease becomes chronic there may be decreased haemoglobin synthesis. Leucopaenia and thrombocytopaenia are caused by mechanisms that predispose leucocytes and platelets to phagocytosis. Immunological mechanisms in the pathogenesis lead to extensive proliferation of activated macrophages, which engulf or destroy erythrocytes, leucocytes, platelets and haematopoietic cells.

Clinical signs: Symptoms include intermittent fever, anaemia, oedema of the limbs and dependent parts, progressive weakness and loss of condition.

Treatment: Homidium salts, isometamidium and pyrimethidium can be used for treatment. Diminazene is relatively toxic to horses (Table 10.7).

Babesiosis/theileriosis

Two species, the small *Theileria equi* (formerly *Babesia equi*) and the large *B. caballi*, are of importance in horses.

Babesia caballi

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Table 10.7 Drugs used in the treatment of *T. congolense congolense* infection.

| Drug | Recommended dose | Comments |
|---------------------------------------|-------------------|---|
| Diminazene aceturate | 3–5 mg/kg i.m. | Ruminants, pig, horse. Contraindicated in dog and camel |
| Homidium bromide Homidium chloride | 1 mg/kg s.c. | Cattle, sheep, goat and horse. Prophylaxis for 6 weeks |
| Isometamidium | 0.25–1 mg/kg i.m. | Ruminants, horse, dog. Local reaction |
| Pyrimethidium bromide | 2–2.5 mg/kg i.m. | Cattle, sheep, horse, donkey. Prophylaxis for 4 months |

Description: Trophozoites within erythrocytes are pear-shaped, measuring 2–5 µm in length, commonly occurring in pairs joined at the posterior ends with the angle between the organisms acute. Round or oval forms 1.5–3 µm in diameter may also occur.

Hosts: Horse, donkey

Geographical distribution: Europe, Asia, Africa, South and Central America, southern USA, Australia: related to distribution of ticks

Pathogenesis: Death, if it occurs, is a result of organ failure, which in turn is due not only to destruction of the erythrocytes, with resultant anaemia, oedema and icterus, but also to the clogging of the capillaries of various organs by parasitised cells and free parasites. The stasis from this sludging causes degeneration of the endothelial cells of the small blood vessels, anoxia, and accumulation of toxic metabolic products, capillary fragility and eventual perivascular escape of erythrocytes and macroscopic haemorrhage. The incubation period is 6–10 days.

Clinical signs: The disease may be chronic or acute, and in either case can be mild or fatal. Haemoglobinuria is rare, but fever, anaemia and icterus are present. Gastroenteritis is common. Locomotor signs are usually present, and posterior paralysis may occur.

Diagnosis: Examination of blood films, stained with Romanowsky stains such as Giemsa, will reveal the parasites in the red cells. Species identification is essential with regard to choice of therapeutic drugs. The paired merozoites joined at their posterior ends are considered to be a diagnostic feature of *B. caballi*. Examinations should be made as early as possible, since the parasites begin to disappear from the peripheral blood after the fifth day.

The complement fixation test (CFT) is the primary screening test used for horses travelling between countries. Because the CFT may not identify all infected animals, especially those that have been treated, and because of anti-complementary reactions produced by some sera, the IFAT is used as a supplementary test. Test sera are inactivated for 30 minutes at 60°C and tested in dilutions of 1 : 5 to 1 : 5120. A lysis of 50% is recorded as positive, with the titre being the greatest serum dilution giving 50% lysis. A titre of 1 : 5 is regarded as positive. Anti-complementary samples are examined by the IFAT.

With the IFAT the recognition of a strong positive reaction is relatively simple, but any differentiation between weak positive and negative reactions requires considerable experience in interpretation. Each sample of serum is tested against an antigen of *B. caballi*. Test, positive and negative control sera are diluted from 1 : 80 to 1 : 1280. Sera diluted 1 : 80 or more that show strong fluorescence are usually considered to be positive, although due consideration is

also given to the patterns of fluorescence of the positive and negative controls.

Pathology: Principal lesions include splenomegaly with soft dark-red splenic pulp and prominent splenic corpuscles. The liver is enlarged and yellowish-brown and the gallbladder is distended with thick dark bile. The mucosa of the intestine is oedematous and icteric with patches of haemorrhage. Subcutaneous, subserous and intramuscular connective tissues are oedematous and icteric. The blood is thin and watery, and the plasma tinged with red.

Epidemiology: *Babesia caballi* is transmitted by a variety of tick species, including *Dermacentor*, *Hyalomma* and *Rhipicephalus*. Tick vectors include *Dermacentor reticulatus*, *D. variabilis*, *D. albipictus*, *D. silvarum*, *D. nitens*, *Hyalomma excavatum*, *H. scupense*, *Rhipicephalus bursa*, *R. sanguineus* and others according to geographical location. Young animals are less susceptible than old ones. Recovered horses may remain carriers for 10 months to 4 years.

Treatment: Treatment of equine piroplasmiasis is based on a combination of supportive and symptomatic treatment as well as chemotherapy. Supportive treatment is essential in the treatment of acute disease and may include blood transfusion, fluid therapy, vitamins and good nutrition. The chemotherapy of babesiosis in horses is difficult and, due to the toxicity of most effective drugs, care must be taken in the administration of the correct dosage.

The most commonly used drugs for chemotherapy of equine piroplasmiasis are as follows (Table 10.8).

- Imidocarb dipropionate, given intramuscularly at 2–3 mg/kg body weight in doses 24 hours apart, will usually be sufficient for sterilisation of *B. caballi* infections.
- Amicarbalide diisethionate produces clinical recovery at a dose rate of 9–10 mg/kg as a single dose, or as a divided dose over 24 hours. High doses may reportedly cause pronounced side effects.
- Diminazene aceturate 5 mg/kg given twice at 24-hour intervals produces clinical recovery.

Control: Immunity in horses after infection lasts for more than 1 year and horses are therefore protected in enzootic areas even with the seasonal fluctuation of the tick population. Tick control is essential. Special attention should be paid to the ears, region under the tail and between the hindlegs. Horses introduced into endemic areas are very susceptible and should therefore receive special attention.

Theileria equi

Synonyms: *Babesia equi*, *Nuttalia equi*

Predilection site: Blood

Phylum: Apicomplexa

Table 10.8 Drugs used in the treatment of *Babesia caballi* infection.

| Drug | Recommended dose | Frequency | Comments |
|----------------------------|------------------|-------------------------------|------------------------|
| Imidocarb dipropionate | 2–3 mg/kg i.m. | Two doses at 24-hour interval | Pain at injection site |
| Diminazene aceturate | 5 mg/kg i.m. | Two doses at 24-hour interval | Low therapeutic index |
| Amicarbalide diisethionate | 9–10 mg/kg i.m. | Single or repeat 24 hours | Low therapeutic index |

Fig. 10.20 Trophozoites of *Theileria equi*.

Class: Aconoidasida

Family: Theileriidae

Description: The merozoites in the erythrocytes are relatively small, 2–3 µm, rounded, amoeboid or most often pyriform, and are readily recognised in blood smears from acute cases. Apart from size, the piroplasms characteristically form a 'Maltese cross' of four organisms (Fig. 10.20).

Hosts: Horse, donkey

Geographical distribution: North, Central and South America, Africa, Asia, mainland Europe

Pathogenesis: Death, if it occurs, is a result of organ failure, which in turn is due not only to destruction of the erythrocytes, with resultant anaemia, oedema and icterus, but also to the clogging of the capillaries of various organs by parasitised cells and free parasites. The stasis from this sludging causes degeneration of the endothelial cells of the small blood vessels, anoxia, and accumulation of toxic metabolic products, capillary fragility and eventual perivascular escape of erythrocytes and macroscopic haemorrhage.

Clinical signs: The incubation period following an infective tick bite is 10–21 days. The first sign of disease is a rise in temperature followed by listlessness, depression, marked thirst, inappetence, lacrimation and blepharitis. The most characteristic sign is icterus. There is marked anaemia and more than half the erythrocytes are often destroyed leading to haemoglobinuria. Oedema of the head, legs and ventral part of the body is sometimes present, although posterior paralysis, sometimes seen in *B. caballi* infection, is absent. Affected animals are constipated, and pass small hard balls of faeces covered with yellow mucus. The animals lose condition fairly rapidly, and may become extremely emaciated. Haemorrhages are present on the mucosa of the nasal passages, vagina and third eyelid. The disease lasts 7–12 days but may be peracute with death occurring in 1–2 days, or may be chronic and last for weeks. Mortality is usually about 10% but may reach 50%. Recovery is slow.

Diagnosis: Examination of blood films, stained with Romanowsky stains such as Giemsa, will reveal the parasites in the red cells. Species identification is essential with regard to choice of therapeutic drugs. The tetrad or Maltese cross arrangement is a diagnostic feature of *T. equi*. Examinations should be made as early as possible since the parasites begin to disappear from the peripheral blood after the fifth day.

The CFT is the primary screening test used for horses travelling between countries. Because the CFT may not identify all infected animals, especially those that have been treated, and because of anti-complementary reactions produced by some sera, the IFAT is used as a supplementary test. Test sera are inactivated for 30 minutes at 60°C and tested in dilutions of 1 : 5 to 1 : 5120. A lysis of 50% is recorded as positive, with the titre being the greatest serum dilution giving 50% lysis. A titre of 1 : 5 is regarded as positive. Anti-complementary samples are examined by the IFAT.

With the IFAT the recognition of a strong positive reaction is relatively simple, but any differentiation between weak positive and negative reactions requires considerable experience in interpretation. Each sample of serum is tested against an antigen of *T. equi*. Test, positive and negative control sera are diluted from 1 : 80 to 1 : 1280. Sera diluted 1 : 80 or more that show strong fluorescence are usually considered to be positive, although due consideration is also given to the patterns of fluorescence of the positive and negative controls.

Pathology: Emaciation, icterus, anaemia and oedema are seen at postmortem examination. There are accumulations of fluid in the pericardial sac and body cavities, and the fat is gelatinous and yellow. The spleen is enlarged, with soft dark-brown pulp. The lymph nodes are swollen and sometimes inflamed. The liver is swollen, engorged and brownish-yellow, and the hepatic lobules are yellow in the centre and greenish-yellow round the edges. The kidneys are pale yellow and may contain petechial haemorrhages. There are petechial or ecchymotic haemorrhages on the mucosa of the intestine and stomach.

Epidemiology: *Theileria equi* is transmitted by a variety of tick species, including *Dermacentor*, *Hyalomma* and *Rhipicephalus*. Vectors are *Dermacentor reticulatus*, *D. albipictus*, *Hyalomma marginatum* (*H. detritum*), *H. scupense*, *Rhipicephalus bursa* in Russia and former Soviet states; *R. evertsi* in equatorial Africa; *H. anatolicum* and *H. marginatum* in Greece; *H. dromedarii* and *R. sanguineus* in central Asia. The vectors in the USA include *D. variabilis*, *D. albipictus*, *D. (Anocentor) nitens* and *R. sanguineus*; and in South America *D. (A.) nitens*.

Treatment: Imidocarb dipropionate given intramuscularly at 2–3 mg/kg body weight in doses 24 hours apart will bring about recovery from *T. equi* infections, but not sterilisation of infection. The use of four doses of 4 mg/kg body weight at 72-hour intervals is reported to sterilise *T. equi* infections, but this high-dose therapy may cause severe side effects, such as extreme restlessness, sweating and signs of abdominal pain. Treated horses may become seronegative to CFT but remain positive to IFAT and infective to tick vectors. Treatment with amicarbalide diisethionate produces clinical recovery at a dose of 9–10 mg/kg as a single dose, or as a divided dose over 24 hours. High doses may reportedly cause pronounced side effects. Diminazene aceturate 6–12 mg/kg body weight given twice in a 48-hour period may be required for clinical recovery (Table 10.9).

Notes: There is no cross-immunity between *T. equi* and *B. caballi*. Young animals are less seriously affected than adults and mixed infections of these parasites can occur.

Neorickettsia risticii

Synonym: *Ehrlichia risticii*

Common names: Equine monocytic ehrlichiosis, Potomac horse fever, ditch fever, Shasta River crud, equine ehrlichial colitis

Predilection site: Reproductive tract

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: *Neorickettsia risticii* is a Gram-negative obligate intracellular bacterium, 0.6–1.5 µm in size, with a trophism for monocytes. The organism is not visible in monocytes in blood films from clinical cases.

Hosts: Horse, rarely dog, cat

Life cycle: Details of the life cycle are incomplete but infection to horses appears to involve ingestion of metacercarial stages of trematodes or inadvertent ingestion of aquatic insect stages.

Geographical distribution: USA

Pathogenesis: Potomac horse fever is an acute enterocolitis syndrome producing mild colic, fever and diarrhoea in horses of all ages, as well as abortion in pregnant mares.

Following ingestion within the insect or trematode, the organism is taken up by cells of the monocyte/macrophage series and the organisms accumulate in the reticuloendothelial cells in the wall of the large colon. The infection of enterocytes of the small and large intestine results in acute colitis, which is one of the principal clinical signs. Other signs vary from transient mild fever to severe diarrhoea, which become apparent after 12–18 days. Colic of variable severity and abdominal distension may precede the onset of diarrhoea in about 25% of cases. As well as blood and lymphoid tissue, the organisms have been detected in macrophages, crypt endothelial cells and mast cells in the wall of the colon, caecum and small intestine, where it is thought that a localised endotoxaemia may lead to electrolyte imbalance. A bluish 'toxic ring' surrounding the teeth may be present and affected horses may also exhibit mild to moderate tachypnoea and tachycardia. Mild to severe laminitis has been reported following the onset of diarrhoea. Infection has also been associated with abortion in mares.

Clinical signs: Fever, depression, leucopaenia, dehydration, laminitis and diarrhoea

Diagnosis: A provisional diagnosis is often based on the presence of typical clinical signs and the seasonal and geographic occurrence of the disease. Examination of peripheral blood smears is of no value

Table 10.9 Drugs used in the treatment of *Theileria equi* infection.

| Drug | Recommended Dose | Frequency | Comments |
|----------------------------|---------------------------|---|------------------------|
| Imidocarb dipropionate | 2–3 mg/kg i.m. or 4 mg/kg | Two doses at 24-hour interval or four doses at 72-hour interval for sterility | Pain at injection site |
| Diminazene aceturate | 6–12 mg/kg i.m. | Two doses at 48-hour interval | Low therapeutic index |
| Amicarbalide diisethionate | 9–10 mg/kg i.m. | Single or repeat 24 hours | Low therapeutic index |

as infected monocytes are present in small numbers in the blood. A definitive diagnosis should be based on isolation or detection of *N. risticii* from the blood or faeces of infected horses. Although serological tests such as IFAT or ELISA exist, serological testing is of limited value as a diagnostic tool, although many infected horses have high antibody titres at the time of infection. Because of the high prevalence of false-positive titres, interpretation of the IFAT in individual horses is difficult. Isolation of the agent in cell culture, although possible, is time-consuming and not routinely available in many diagnostic laboratories. A recently developed real-time polymerase chain reaction (PCR) assay allows the detection of *N. risticii* DNA within 2 hours, making this a much more feasible test for routine diagnostic examination. To enhance the chances of detection of *N. risticii*, the assay should be performed on a blood as well as a faecal sample, as the presence of the organism in blood and faeces may not necessarily coincide.

Pathology: On postmortem, there are few or no gross pathological changes although histological changes include focal degeneration of endothelial cells in the colon leading to small ulcerative lesions and patchy hyperaemia in the large intestine. There is marked depletion of goblet cells and dilation of intestinal crypts.

Epidemiology: Disease is seen in spring, summer and early autumn and is associated with pastures bordering creeks or rivers. *Neorickettsia risticii* has been identified in freshwater snails and isolated from trematodes released from the snails. DNA has been detected in 13 species of immature and adult caddisflies (Trichoptera), mayflies (Ephemeroptera), damselflies (Odonata, Zygoptera), dragonflies (Odonata, Anisoptera) and stoneflies (Plecoptera). Transmission studies using *N. risticii*-infected caddisflies have reproduced the clinical disease. One route of exposure is believed to be inadvertent ingestion of aquatic insects that carry *N. risticii* in the metacercarial stage of a trematode. The incubation period is 10–18 days. Clinically ill horses are not contagious and can be housed with susceptible horses.

Treatment: Oxytetracycline administered at a dose of 6.6 mg/kg i.v. for 5 days is highly effective if given early in the clinical course of the disease. Supportive therapy with fluids, electrolytes, non-steroidal anti-inflammatory drugs (NSAIDs) and antidiarrhoeals may also be indicated in animals exhibiting signs of enterocolitis. Laminitis, if it develops, is usually severe and often refractory to treatment.

Control: Several inactivated whole-cell vaccines based on the same strain of *N. risticii* are commercially available, although they are only marginally protective in the field. Reduction of snail numbers in rivers and ditches may be attempted to lessen sources of infection.

Notes: The causative agent, formerly known as *Ehrlichia risticii*, has recently been renamed *Neorickettsia risticii* because of its lesser genetic relationships to other *Ehrlichia* groups.

Anaplasma phagocytophilum

Synonym: *Ehrlichia equi*

Common name: Equine granulocytic ehrlichiosis

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: Blood smears stained with Giemsa or Wright's stains reveal one or more loose aggregates (morulae or inclusion bodies, 1.5–5 µm in diameter) of blue–grey to dark-blue coccoid, coccobacillary or pleomorphic organisms within the cytoplasm of neutrophils.

Hosts: Sheep, cattle, dog, horse, deer, rodents, human

Geographical distribution: USA, South America, Europe

Pathogenesis: Equine granulocytic ehrlichiosis is an infectious, non-contagious, seasonal disease. Severity of signs varies with age of the animal and duration of the illness. Signs may be mild. Horses less than 1 year old may have a fever only. Horses 1–3 years old develop fever, depression, mild limb oedema and ataxia. Adults exhibit the characteristic signs of fever, partial anorexia, depression, reluctance to move, limb oedema, petechiation and jaundice. The fever, which is highest during the first 1–3 days (39.5–40°C), persists for 6–12 days. Rarely, myocardial vasculitis may cause transient ventricular arrhythmias. Any concurrent infection can be exacerbated. Cytoplasmic inclusion bodies are few during the first 48 hours and increase to 30–40% of circulating neutrophils at days 3–5 of infection.

Clinical signs: Fever, depression, limb oedema, jaundice and ataxia

Diagnosis: Demonstration of the characteristic cytoplasmic inclusion bodies in blood smears is diagnostic. PCR can detect *A. phagocytophilum* DNA in unclotted blood or buffy coat smears. An IFAT can detect rising antibody titres to *A. phagocytophilum*.

Pathology: Gross petechiation, ecchymoses and oedema develop in the subcutis and fascia. Vasculitis is regional, with the subcutis and fascia of the legs predominantly affected.

Epidemiology: In endemic areas the disease is seasonal, occurring during periods of peak tick activity. In the USA, transmission to horses is by the tick *Ixodes pacificus* (western black-legged tick).

Treatment: Oxytetracycline and tetracycline 7 mg/kg i.v. for 8 days has eliminated the infection. Horses with severe ataxia and oedema may benefit from short-term corticosteroid treatment (dexamethasone 20 mg for 2–3 days).

Control: Recovered horses are solidly immune for more than 2 years. There is no vaccine.

Notes: The causal rickettsial agent was initially termed *Ehrlichia equi*, but based on DNA sequence relationships the organism is now referred to as *Anaplasma phagocytophilum*.

Parasites of the nervous system

Thelazia lacrymalis

Common name: Equine eyeworm

Predilection site: Eye, conjunctival sac and lacrimal duct

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Small, thin, yellowish-white worms about 1.0–2.0 cm long. Males are 8–12 mm and females 14–18 mm in length.

Description, microscopic: A mouth capsule is present and the cuticle has prominent striations at the anterior end. In the male, the tail is blunt and recurved with caudal alae.

Final hosts: Horse and other equids

Intermediate hosts: Muscid flies, particularly *Musca*, *Fannia* and *Morellia*

Geographical distribution: Europe, North and South America and parts of Asia

Pathogenesis: In many hosts, moderate eyeworm infection causes little pathogenic disease. Lesions are caused by the serrated cuticle of the worm and most damage results from movement by the active young adults, causing lacrimation, followed by conjunctivitis. In heavy infections the cornea may become cloudy and ulcerated. There is usually complete recovery in about 2 months, although in some cases areas of corneal opacity can persist. Infection may predispose the host to secondary bacterial infection.

Clinical signs: Often infection can be inapparent but heavy infestations can cause lacrimation, conjunctivitis and photophobia. Flies are usually clustered around the eye because of the excessive secretion. In severe cases the eyes may be swollen, with keratitis and corneal ulceration with a purulent exudate.

Diagnosis: This is based on observation of the parasites in the conjunctival sac. Examination of the lacrimal secretion may reveal first-stage larvae.

Pathology: Invasion of the lacrimal gland and ducts may cause inflammation and necrotic exudation leading to occlusion and reduced tear production. Mechanical irritation of the conjunctiva produces inflammation, while damage to the cornea leads to opacity, keratitis and corneal ulceration.

Epidemiology: *Thelazia lacrymalis* is very common in some areas and infestation occurs seasonally, linked to periods of maximum fly activity. The parasite can survive in the eye for several years, but since it is only the young adult that is pathogenic a reservoir of infection may persist in symptomless carrier animals. Only heavy infections cause symptoms. Survival of larvae also occurs in the pupal stages of flies during the winter.

Treatment: Fenbendazole 10 mg/kg orally for 5 days is effective. Ivermectin given directly into the conjunctival sac may also have some effect, but is not effective when given orally. Mechanical removal with forceps following the application of an ocular local anaesthetic is also useful. In cases of secondary bacterial infection the use of antibiotic eye preparations may be indicated.

Control: Prevention is difficult because of the ubiquitous nature of the fly vectors. Fly control measures aimed at protecting the face, such as headbands, aids in the control of eyeworm infection.

Halicephalobus delitrix

Synonyms: *Micronema delatrx*, *Halicephalobus gingivalis*

Phylum: Nematoda

Class: Secernentea

Superfamily: Rhabditoidea

Pathogenesis: This saprophagous free-living nematode inhabits decaying organic matter, such as manure, and can be highly pathogenic. It has been found in the brain, spinal cord and meninges and in granulomatous tissues of the nares and maxilla of horses. It can also infect humans.

Toxoplasma gondii

For more details see Parasites of the locomotory system.

Sarcocystis neurona

Common name: Equine protozoal myeloencephalitis

Predilection site: Brain, spinal cord

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: Meronts present in the cytoplasm of neural cells, leucocytes and giant cells in the grey and white matter of the brain and spinal cord are 5–35 by 5–20 µm and contain 4–40 merozoites when mature.

Intermediate host: Horse

Final host: Opossum (*Didelphis virginiana*). Armadillos, skunks, raccoons, sea otters, seals and domestic cats have all been implicated but their significance is not known.

Geographical distribution: North, Central and South America

Pathogenesis: The organism causes wide-ranging neurological signs associated with infection of any part of the CNS.

Clinical signs: Clinical signs include circling; cranial nerve signs of muscle atrophy, facial paralysis; unilateral vestibular disease; cervical spinal cord disease (wobbler syndrome); monoplegia with muscle atrophy; gait abnormalities, pruritis; cauda equine syndrome.

Diagnosis: Diagnosis is based on clinical signs, analysis of cerebrospinal fluid, response to antiprotozoal therapy and negative response to corticosteroid therapy. Postmortem diagnosis is confirmed by demonstration of the organisms in CNS lesions. A Western blot test for *S. neurona* antibody in cerebrospinal fluid has been developed.

Pathology: There is focal discoloration, haemorrhage and malacia of CNS tissue. On histopathology, the parasites are found in association with mixed inflammatory cellular responses, and neuronal degeneration. Meronts in various stages of maturation, or free merozoites, are commonly seen within the cytoplasm of neurones or macrophages, neutrophils, eosinophils, more rarely capillary endothelial cells and myelinated axons.

Epidemiology: The North American opossum is thought to be one definitive host with transmission to horses via sporocysts in faeces. The life cycle may also involve opossums scavenging on bird carcasses containing an identical organism, *Sarcocystis falcatula*, a parasite of several North American bird species. In this respect, horses may be acting as an abnormal aberrant host. The disease is sporadic,

although multiple cases have been reported on farms or racing establishments but there is no evidence of horse-to-horse transmission. The disease occurs most frequently in young adult breeding stock.

Treatment: The treatment of choice appears to be trimethoprim–sulphadiazine 15 mg/kg twice daily combined with pyrimethamine 0.25 mg/kg daily in feed. This may be followed by intermittent therapy with the same drugs at 20 mg/kg and 1 mg/kg, respectively, once every 1–2 weeks.

Control: The source of the infection is probably opossum faeces so measures to prevent feed contamination should be considered. A vaccine based on chemically inactivated cultured merozoites has shown promise in ameliorating the neurological effects of infection.

Parasites of the reproductive/urogenital system

Trypanosoma equiperdum

Synonym: *Trypanosoma brucei equiperdum*

Common name: Dourine

Predilection site: Reproductive tract

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Trypanozoon*

Description: The organism is identical to, and structurally indistinguishable in appearance from, *T. brucei evansi*. The organism is polymorphic, with slender, intermediate and stumpy forms. The mean length varies considerably, with typical forms 15–34 µm long (mean 24 µm). The undulating membrane is conspicuous and the kinetoplast small and subterminal. Strains that lack a kinetoplast visible with the light microscope have occasionally arisen spontaneously or can be produced by treatment with certain dyes, drugs or frozen storage.

Hosts: Horse, donkey

Geographical distribution: Mediterranean basin, South Africa, Middle East, South America

Pathogenesis: The disease is marked by stages of exacerbation, tolerance or relapse that vary in duration and which may occur once or several times before death or recovery. The signs most frequently noted are pyrexia, tumefaction and local oedema of the genitalia and mammary glands, oedematous cutaneous eruptions, knuckling of the joints, incoordination, facial paralysis, ocular lesions, anaemia and emaciation. A pathognomonic sign is the oedematous plaque consisting of an elevated lesion in the skin, up to 5–8 cm in diameter and 1 cm thick. The plaques usually appear over the ribs, although they may occur anywhere on the body, and usually persist for between 3 and 7 days. They are not a constant feature. In long-standing cases, the external genitalia may be fibrosed. The incubation period is 2–12 weeks and the disease runs a chronic course over 6 months to 2 years.

Clinical signs: The first sign is oedema of the genitalia and there is slight fever, inappetance and a mucous discharge from the urethra and vagina. Circumscribed areas of the mucosa of the vulva or penis may become depigmented. The second stage of the disease is

characterised by urticaria and appears after 4–6 weeks. Circular, sharply circumscribed urticarial plaques about 3 cm in diameter arise on the sides of the body, remain for 3–4 days, and then disappear. The plaques may develop again later. Muscular paralysis develops beginning with the muscles of the nostrils and neck, extending to the hindlimbs and finally to the rest of the body. The animal shows incoordination and then complete paralysis. Dourine is usually fatal unless treated, but mild strains of the parasite may occur in some regions.

Diagnosis: Demonstration of the trypanosomes from the urethral or vaginal discharges, the skin plaques or the peripheral blood is generally not possible, although centrifugation of these fluids may help to find the pathogens. The clinical disease is typical in endemic areas to allow diagnosis. Infected animals can be detected with the CFT but cross-reaction with *T. evansi* and *T. brucei* are common. An IFAT is used as a confirmatory test for dourine or to resolve inconclusive results obtained by CFT.

Pathology: At postmortem examination, gelatinous exudates are present under the skin. In the stallion, the scrotum, sheath and testicular tunica are thickened and infiltrated. In some cases, the testes are fibrosed and may be unrecognisable. In the mare, the vulva, vaginal mucosa, uterus, bladder and mammary glands may be thickened with gelatinous infiltration. The lymph nodes, particularly in the abdominal cavity, are hypertrophied, softened and, in some cases, haemorrhagic. There is pronounced anaemia and oedematous infiltration of the perineal tissues and ventral abdominal wall and hydrothorax, hydropericardium and ascites are often pronounced. The spinal cord of animals with paraplegia is often soft, pulpy and discoloured, particularly in the lumbar and sacral regions.

Epidemiology: Dourine is the only trypanosome that is not transmitted by an invertebrate vector. Organisms present in the equine reproductive tract are transmitted during coitus and very rarely by biting flies. As trypanosomes are not continually present in the genital tract throughout the course of the disease, transmission of the infection does not necessarily take place at every copulation involving an infected animal. Transmission of infection from mare to foal can occur via the mucosa, such as the conjunctiva. Mares' milk has been shown to be infectious. *Trypanosoma equiperdum* occurs in donkeys but the disease is asymptomatic. Oedema on the genitals is not obvious and skin plaques only occur in less than 10% of infected donkeys. Sperm and vaginal discharges contain large numbers of parasites and are therefore a significant reservoir of the pathogen.

Treatment: Quinapyramine sulphate (3–5 mg/kg s.c.) is one of the few compounds effective against *T. equiperdum*. In many countries, chemotherapy is prohibited and strict border controls are required before importation of horses and donkeys.

Control: Strict control of breeding and movements of horses together with quarantine and slaughter in clinical outbreaks has a marked effect on the incidence of disease. Detection and slaughter of carrier equines leads to eventual eradication. In-contact animals are declared free after three consecutive monthly negative CFTs.

Notes: *Trypanosoma equiperdum* causes the most important venereal disease in horses and is responsible for great losses wherever it occurs.

Animals other than equids can be infected experimentally. Rat-adapted strains can be maintained indefinitely; infected rat blood can be satisfactorily cryopreserved. Antigens for serological tests are commonly produced from infected laboratory rats.

Klossiella equi

Predilection site: Kidney

Phylum: Apicomplexa

Class: Conoidasida

Family: Klossiellidae

Description: Meronts in endothelial cells of Bowman's capsule in the kidneys are 8–12 µm in diameter with 20–30 nuclei. Second-generation meronts found in epithelial cells of the proximal convoluted tubules are 15–23 µm in diameter and contain 15–20 merozoites. Gamogony and sporogony occur in the epithelial cells of the thick limb of Henle's loop. The microgamonts form 4–10 microgametes. Sporonts, 20–23 µm in diameter, have about 40 buds on their periphery before becoming sporoblasts, 35–45 µm in diameter. Each sporoblast divides by multiple fission forming 10–15 or more nuclei, which condense and come to lie along the periphery of the sporoblast. The sporocysts each contain 10–15 sporozoites and are themselves contained in a sac formed by the host cell.

Hosts: Horse, donkey, zebra

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Non-pathogenic and not usually associated with clinical signs.

Diagnosis: Sporocysts may be detected in urine sediments or trophozoite stages may be found on postmortem in the kidney. The site and location are pathognomonic.

Pathology: Only heavily parasitised kidneys have gross lesions, which appear as tiny grey foci on the cortical surface. Microscopically these foci are areas of necrosis, with perivascular infiltration of inflammatory cells, especially lymphocytes, with an increase in interstitial fibroblasts.

Epidemiology: Sporocysts are passed in the urine and infection takes place by the ingestion of the sporulated sporocysts.

Treatment and control: Not required

Notes: This species is apparently quite common throughout the world but seldom seen.

Parasites of the locomotory system

Trichinella spiralis

Synonym: *Trichina spiralis*

Common name: Muscle worm

Predilection site: Small intestine, muscle

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichinelloidea

Description, gross: Because of their short lifespan, the adult worms are rarely found in natural infections. The male is about 1.5 mm and the female 3.5–4.0 mm long.

Description, microscopic: The oesophagus is at least one-third of the total body length and the tail in the male has two small cloacal flaps, but no copulatory spicule nor a spicule sheath. In the female, the uterus contains developing larvae and the vulva is in the mid-oesophageal region. *Trichinella* infection is most easily identified by the presence of coiled larvae in striated muscle (see Fig. 1.63). These larvae measure about 800–1000 µm in length. The cysts are lemon-shaped, 0.3–0.8 by 0.2–0.4 mm in size and often transparent.

Hosts: Pig, rat, horse, human, and most mammals

Geographical distribution: Worldwide, with the apparent exceptions of Australia, Denmark and Great Britain

For more details see Chapter 11.

Toxoplasma gondii

Predilection site: Muscle, lung, liver, reproductive system, CNS

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: Tachyzoites are found developing in vacuoles in many cell types, for example fibroblasts, hepatocytes, reticular cells and myocardial cells. In any one cell there may be 8–16 organisms, each measuring 6.0–8.0 µm. Tissue cysts, measuring up to 100 µm in diameter, are found mainly in the muscle, liver, lung and brain and may contain several thousand lancet-shaped bradyzoites.

Pathogenesis: *Toxoplasma* has been recorded in horses but there are few, if any, clinical reports of disease.

For more details see Chapter 9.

Sarcocystiosis

Sarcocystis is one of the most prevalent parasites of grazing animals.

Diagnosis: Most cases of *Sarcocystis* infection in horses are only revealed at postmortem, when the grossly visible sarcocysts in the muscle are discovered. Examination of faeces from dogs on the farm for the presence of sporocysts may be helpful in the diagnosis.

Pathology: For the two species reported in horses, microscopic inspection has revealed minimal host reaction in infected tissues.

Epidemiology: Little is known of the epidemiology, but from the high prevalence of symptomless infections observed in abattoirs it is clear that where dogs are kept in close association with horses or their feed, then transmission is likely. Acute outbreaks are probably most likely when horses, which have been reared without dog contact, are subsequently exposed to large numbers of the sporocysts from dog faeces. The longevity of the sporocysts shed in the faeces is not known.

Treatment: There is no effective treatment for *Sarcocystis* infection in horses.

Control: The only control measures possible are those of simple hygiene. Farm dogs should not be housed in, or allowed access to, fodder stores, nor should they be allowed to defecate in pens where horses are housed. It is also important that they are not fed uncooked meat.

Sarcocystis equicanis**Synonym:** *Sarcocystis bertrami***Predilection site:** Muscle**Phylum:** Apicomplexa**Class:** Conoidasida**Family:** Sarcocystiidae**Description:** Tissue cysts are segmented, up to 10 mm long with a smooth wall less than 1 µm thick with no radial striations. A small number of 0.4–2.0 µm protrusions are evident on electron microscopy.**Intermediate host:** Horse**Final host:** Dog**Geographical distribution:** Worldwide**Pathogenesis:** The pathogenic effects associated with *S. equicanis* in the horse have not been investigated.**Clinical signs:** Infection has not been associated with clinical signs in the final or intermediate host.***Sarcocystis fayeri*****Predilection site:** Muscle**Phylum:** Apicomplexa**Class:** Conoidasida**Family:** Sarcocystiidae**Description:** Tissue cysts are up to 900 by 70 µm. The cyst wall is 1–2 µm thick and radially striated.**Intermediate host:** Horse**Final host:** Dog**Geographical distribution:** Worldwide**Pathogenesis:** Few pathogenic effects are associated with *S. fayeri* in the horse, although a few cases of severe myositis have been reported.**Clinical signs:** Occasional myalgia has been reported.**Parasites of the integument*****Onchocerca reticulata*****Common names:** Kasen summer mange, equine dhobie itch**Predilection site:** Connective tissue, flexor tendons and suspensory ligament of the fetlock**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Filarioidea**Description, gross:** Slender whitish worms, males measuring 15–20 cm and females over 50 cm long**Description, microscopic:** Microfilariae are 330–370 µm and possess a long whiplash tail.**Final hosts:** Horse, donkey**Intermediate hosts:** *Culicoides* spp. (biting midges)**Geographical distribution:** Worldwide**Pathogenesis:** The connective tissue of the flexor tendons and suspensory ligament of the fetlocks is the preferential site. Following inoculation of L₃ by the midge vector *Culicoides*, the arrival of the parasites in their final site results in host reaction in the form of a painless diffuse swelling. This gradually increases in size to become a palpable soft lump, and then regresses to leave a calcified focus, the skin over the area remaining intact. In the lower limbs the reaction to the presence of the parasite leads to the formation of soft painless swellings succeeded by small fibrous nodules.**Clinical signs:** Apart from the initial mild reaction, no clinical signs attributable to the adult worms have been demonstrated. The microfilariae are reported to cause a chronic dermatitis of horses, being severe in summer and disappearing during the winter.**Diagnosis:** Infection may be confirmed by examination of thick skin sections taken from the predilection sites. The piece of skin is placed in warm saline for about 8–12 hours and teased to allow emergence of the microfilariae. These are readily recognised by their sinuous movements in a centrifuged sample of the saline. Fluid from scarified skin can also be examined for the presence of microfilariae.**Pathology:** The ventral skin lesions are indistinguishable from those of *Culicoides* sensitivity. Gross lesions include alopecia, scaling, crusting and leucoderma. Secondary excoriations and ulcerative dermatitis are induced by self-trauma.**Epidemiology:** The general prevalence of equine onchocercosis is high, most surveys in the USA having shown rates of more than 50%, though the highest so far recorded in Britain is 23%. The accumulation of microfilariae in the definitive host is highest during the seasons of greatest midge activity.**Treatment:** Not usually required. Ivermectin has good activity against the microfilariae stages and will provide relief in cases of onchocercal dermatitis.**Control:** Generally not indicated. Insecticidal sprays or repellents may reduce attacks by biting midges.**Notes:** Although onchocercosis is an important filarial infection in human medicine, most species in domestic animals are relatively harmless.***Parafilaria multipapillosa*****Synonym:** *Filaria haemorrhagica***Common names:** Summer bleeding disease, summer sores**Predilection site:** Subcutaneous and intermuscular connective tissue**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Filarioidea**Description, gross:** Slender white worms 3.0–7.0 cm in length. Adult males measure 28 mm, females 40–70 mm.**Description, microscopic:** Anteriorly, there are numerous papillae and circular ridges in the cuticle. In the female the vulva is situated anteriorly near the simple mouth opening.

The small embryonated eggs (around $55 \times 30 \mu\text{m}$) have a thin flexible shell and are laid on the skin surface where they hatch to release the microfilariae or L_1 ; these are about $200 \mu\text{m}$ in length and have a rounded posterior extremity.

Final hosts: Horse, donkey

Intermediate hosts: Horn flies, *Haematobia atripalpis* and other *Haematobia* spp. in Europe

Geographical distribution: North Africa, eastern and southern Europe, Asia and South America

Pathogenesis: Infection results in the formation of subcutaneous nodules, which break open and ooze blood (Fig. 10.21). Their distribution in the harness areas may make the animals unsuitable for work.

Clinical signs: Clinically, the condition is characterised by matting of the hair due to blood and tissue fluid exudates from ruptured nodules. The lesions are more prominent in the summer and particularly when the animals are hot, so that they appear to be 'sweating blood'. Occasionally, lesions are mistaken for injuries caused by thorns and barbed wire.

Diagnosis: The presence of nodules in the skin ('bleeding points') are pathognomonic. Larvated eggs or microfilariae can be demonstrated by microscopic examination of smears taken from the haemorrhagic exudate of fresh lesions. An ELISA is also available in some countries for serodiagnosis.

Pathology: Nodules formed in the cutaneous and intermuscular connective tissue are 1–2 cm in diameter, enlarge in the summer months, burst open and haemorrhage and heal by scarring.

Epidemiology: Disease is usually only apparent in the warmer seasons in temperate regions, whereas in hot tropical areas lesions are often seen after the rainy season. Although the condition tends to disappear in cold weather, it will periodically reappear during warmer months for up to 4 years in individual animals.

Treatment: This is difficult, but oral ivermectin or moxidectin may be tried.

Control: Fly control measures will be beneficial.

Fig. 10.21 Flank of a horse showing subcutaneous nodules induced by *Parafilaria multipapillosa*.

Setaria equina

Common name: Abdominal worm

Predilection site: Peritoneum, pleural cavity

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: The adults are long and slender, reaching 8–10 cm (males) and 13–15 cm (females). The posterior end is spirally coiled.

Description, microscopic: The microfilariae present in the blood are sheathed and measure about 190–256 μm in length.

Final hosts: Horse, donkey

Intermediate host: Mosquitoes

Geographical distribution: Worldwide

Pathogenesis: The adult worms live in the abdominal body cavity. Occasionally, the adults invade the lungs and eyes. The worms in their normal site are usually harmless and are only discovered at necropsy. Migrating larvae can cause an encephalomyelitis in horses and can also invade the eye and induce blindness.

Clinical signs: There are no clinical signs when the worms are in their normal site, but when nervous tissue is involved there is locomotor disturbance and in severe cases lumbar paralysis.

Diagnosis: Infection with the adult worms is only accidentally discovered in the living animal by the finding of microfilariae in routine blood smears. In cases of cerebrospinal setariosis, confirmatory diagnosis is only possible by microscopic examination of the spinal cord, since the parasites exist only as larval forms in their aberrant site.

Pathology: Migrating larvae affecting the CNS may cause areas of damage seen as brown foci or streaks grossly. The lesions show microcavitation and variable haemorrhage. There is loss of myelin and fragmentation of axons locally with eosinophils, neutrophils and macrophages present along with a mild meningitis and vascular cuffing.

Epidemiology: Since the worms are usually innocuous their epidemiology has received little study. The prevalence is higher in warmer countries, where there is longer seasonal activity of the mosquito vectors.

Treatment: There is no treatment for setarial paralysis. Ivermectin has been reported to be effective against adult *S. equina*.

Control: This would depend on control of the mosquito vectors, which is unlikely to be applied specifically for this parasite.

Notes: The members of this genus are usually harmless inhabitants of the peritoneal and pleural cavities.

Rhabditis strongyloides

Synonym: *Peloderma strongyloides*

Phylum: Nematoda

Class: Secernentea

Superfamily: Rhabditoidea

Pathogenesis: Another saprophagous free-living nematode found in decaying organic matter. Exposure to this environment, such as damp straw bedding, can induce a pruritic erythematous dermatitis in the skin and gingivae of horses. Cases have also been reported in cattle, pigs, dogs and occasionally in humans.

Diagnosis: Examination of skin scrapings may reveal nematode larvae with a rhabditiform oesophagus. Culture of larvae to adults on nutrient agar will assist in diagnosis.

Hypoderma diana

Common name: Deer warble

Predilection site: Subcutaneous connective tissue

Class: Insecta

Family: Oestridae

Description, larvae: The mature larvae are thick and somewhat barrel-shaped, tapering anteriorly. When mature they are 25–30 mm in length and most segments bear short spines.

Hosts: Deer, occasionally horse and sheep

Notes: *Hypoderma diana* is capable of infecting many species of deer, but does not infect cattle. However, it has been reported in horses and donkeys.

ECTOPARASITES

LICE

Bovicola equi

Synonyms: *Damalinea equi*, *Trichodectes parumpilosus*, *Werneckiella equi equi*

Common name: Horse louse

Predilection site: Upper epidermal layers of the neck, flanks and tail base

Class: Insecta

Order: Phthiraptera

Suborder: Ischnocera

Family: Trichodectidae

Description: These lice are up to 1–2 mm long and reddish-brown in colour. The relatively large head is as wide as the wingless body, and rounded anteriorly. The mouthparts are ventral. This species has a three-segmented antenna and a single claw on the tarsi (see Fig. 3.69).

Host: Horse

Geographical distribution: Worldwide

Pathogenesis: *Bovicola equi* may cause intense irritation, resulting in rubbing and scratching, with matting and loss of hair and sometimes self-excoriation, involving almost the entire body in extreme cases. It is possible that heavy louse infestations in equines are themselves symptomatic of some other disorder, such as disease or, more likely, simple neglect. If neglected and left ungroomed, the

undisturbed louse population will multiply more rapidly. In addition, animals in a debilitated condition will fail to shed their winter coats and hence retain very large numbers of lice.

This species may act as a vector of equine infectious anaemia.

Clinical signs: Restlessness, rubbing and damage to the coat will suggest that lice are present, and when the hair is parted the parasites will be found. *Bovicola equi* appears as small yellowish specks in the hair, and the small pale eggs are readily found scattered throughout the coat. Other symptoms include a rough coat, skin infections, loss of hair and weight loss.

Diagnosis: The lice and their eggs may be seen within the hair and on the skin when the coat is parted. The lice may be removed and identified under a light microscope.

Pathology: The pathology of louse infestation is extremely variable. Infestations may induce alopecia, dermal irritation, papulocrustous dermatitis and self-excoriation.

Epidemiology: The mouthparts of *B. equi* are adapted for biting and chewing, and allow them to feed on the outer layers of the hair shafts, dermal scales and blood scabs. They also feed on the exudates resulting from their irritant effect. *Bovicola equi* is capable of rapid population expansion.

Equine pediculosis spreads by contact and via contaminated grooming equipment, blankets, rugs and saddlery. Severe infestations spread over the entire body, and the numbers are greatest in winter and early spring when the winter coat is at its most dense. Longer-haired animals and breeds are more prone to infestation by this species. As in cattle, the shedding of the winter coat is important in ridding animals of the greater part of their louse burden in spring. In hot countries the skin temperature of the animal's back may be high enough to kill lice in the exposed, fine-coated areas.

Treatment: Currently pyrethroid-based insecticides, applied as non-systemic pour-on formulations, are usually used to control lice, as many older drugs are no longer available. All the horses in the establishment should be treated. Because eggs are relatively resistant to insecticides, treatment should be repeated every 7–14 days to kill newly hatched lice. Systemic treatments, such as the avermectins, are not approved for treatment of lice on horses. Essential oils (such as tea tree or lavender oil) groomed into the coat may be highly effective in reducing equine louse infestations.

Control: Grooming equipment should be scalded, blankets and rugs thoroughly washed, and saddlery thoroughly cleaned. Ideally, animals should have individual grooming equipment, and saddlery should not be interchanged, but this may not be economically feasible within some establishments. Regular and thorough grooming is, of course, the essence of control.

Haematopinus asini

Common name: Horse sucking louse

Predilection site: Skin of head, neck, back, brisket and between the legs

Class: Insecta

Order: Phthiraptera

Suborder: Ischnocera

Family: Haematopinidae

Description: *Haematopinus asini* is 3–3.5 mm long and yellow-brown as an adult. The lice have three pairs of legs and a long narrow head with piercing mouthparts adapted for sucking blood and tissue fluids. The lice are found only on equines. All the species of *Haematopinus* are large lice, about 4–5 mm in length. They possess prominent angular processes, known as ocular points or temporal angles, behind the antennae. Eyes are absent. The thoracic sternal plate is dark and well developed. The legs are of similar sizes, each terminating in a single large claw that opposes the tibial spur. Distinct sclerotised paratergal plates are visible on abdominal segments 2 or 3 to 8.

Hosts: Horse, donkey

Geographical distribution: Worldwide

Pathogenesis: On horses, *H. asini* is most commonly found on the head, neck, back and inner surface of the upper legs. Symptoms include heavy dandruff and greasy skin and eventually bald spots with raw red centres. Light infestations may be asymptomatic but, if present in sufficient numbers, they have been known to cause anaemia, weight loss and loss of vitality and appetite. Outbreaks of equine lice tend to be more frequent in the early spring, since the accumulated dirt in the barn and tack room, plus dander from the shedding of winter coats, provides an ideal environment for them. In horses, lice are often associated with poor grooming and management. Thin, aged, stressed or physically compromised horses seem to be more susceptible. Heavy lice infestations may in themselves be symptomatic of some other disorder such as disease or, more likely, simple neglect. Animals in a debilitated condition may harbour very large numbers of lice and the louse population will rapidly multiply on neglected ungroomed animals.

Clinical signs: *Haematopinus* spp. irritate their hosts by taking small but frequent blood meals. Each time they feed, they puncture the skin in a different place. As in other animals, equine lice may cause intense irritation, resulting in rubbing and scratching, with matting and loss of hair and sometimes excoriation, involving almost the whole body in extreme cases. Animals are restless and lose condition, and in heavy *Haematopinus* infestations there may also be anaemia. Loss of condition and weight may increase the susceptibility of the host animal to other diseases.

Diagnosis: Restlessness, rubbing and damage to the coat would suggest that lice are present, and when the hair is parted the parasites will be found. These lice are large and yellow-brown, and very easily seen, and in temperate countries on warm sunny days will often move on to the surface of the coat.

Pathology: The pathology of louse infestation is extremely variable. Low infestations may induce alopecia, irritation, papulocrustous dermatitis and self-excoriation. The blood-feeding of *Haematopinus* may cause anaemia.

Epidemiology: In normal light infestations, lice occupy sites in the dense hair of the mane, the base of the tail, the submaxillary space, and also on the fetlocks of rough-legged breeds. From these sites spread occurs over the whole body, and the numbers are greatest in winter and early spring when the winter coat is at its most dense. As in cattle, the shedding of the winter coat is important to rid animals of the greater part of their louse burden in spring. In hot conditions the skin temperature of the animal's back may be high enough to kill lice in the exposed, fine-coated areas. Equine pediculosis spreads by contact and via contaminated grooming equipment, blankets, rugs and saddlery.

Treatment: As for *B. equi*

Control: As for *B. equi*

MITES

Demodex equi

Predilection site: Hair follicles and sebaceous glands

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Demodicidae

Description: Species of *Demodex* have an elongate tapering body, up to 0.1–0.4 mm in length, with four pairs of stumpy legs ending in small blunt claws in the adult (see Fig. 3.100). Setae are absent from the legs and body. The legs are located at the front of the body and, as such, the striated opisthosoma forms at least half the body length.

Host: Horse

Geographical distribution: Worldwide, but not reported in Australia

Pathogenesis: In the horse demodectic mange is rare, but may occur as either the squamous or the pustular type, affecting initially the muzzle, forehead and periocular area.

Clinical signs: Scaling and alopecia, with or without papules and pustules, largely on the face, shoulders, neck and limbs. Pruritus is absent. Demodicosis in horses has been reported in association with chronic corticosteroid treatment.

Diagnosis: For confirmatory diagnosis, deep scrapings are necessary to reach the mites deep in the follicles and glands. This is best achieved by taking a fold of skin, applying a drop of liquid paraffin, and scraping until capillary blood appears.

Pathology: Lesions in horses, evident as patchy alopecia and scaling or as nodules, usually begin on the head and neck, but may rapidly spread to involve most of the body.

Epidemiology: Probably because of its location deep in the dermis, it is difficult to transmit *Demodex* between animals unless there is prolonged contact. Such contact occurs most commonly at suckling.

Treatment: There is little information regarding the treatment of equine demodicosis. Investigation and treatment of underlying systemic disease should be performed. Amitraz is contraindicated in horses because it can cause severe colic and death.

Control: Not usually required

Notes: A second species, *D. caballi*, which infests the eyelids and muzzle has been described in horses; whether this is a true species or a morphological variant has not been established.

Sarcoptes scabiei

Common name: Scabies

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Sarcoptidae

Pathogenesis: When present, sarcoptic mange can be severe. There may be intense pruritus due to hypersensitivity. Early lesions appear on the head, neck and shoulders as small papules and vesicles that later develop into crusts. As alopecia and crusting spread, the skin becomes lichenified, forming folds. If untreated, lesions may extend over the whole body, leading to emaciation, general weakness and anorexia.

Treatment: If suspected, organophosphate insecticides or lime–sulphur solution can be applied by spray or dipping. Treatment should be repeated at 12- to 14-day intervals at least three to four times. Alternatively, the oral administration of ivermectin or moxidectin 200 µg/kg can be attempted. Several treatments are required, 2–3 weeks apart, and it is important to treat all contact animals.

Notes: This mange is now uncommon in horses. In Britain, for example, only two cases have been recorded since 1948. In both cases there was strong evidence that the infection had been acquired from other domestic species.

More detailed description can be found in the section Ectoparasites in Chapters 3 and 11.

Psoroptes ovis

Synonyms: *Psoroptes equi*, *Psoroptes cuniculi*, *Psoroptes cervinus*, *Psoroptes bovis*

Common name: Scab mite

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Psoroptidae

Pathogenesis: Infestation is rare in horses. When present, pruritic lesions may be seen on thickly haired regions of the body, such as under the forelock and mane, at the base of the tail, between the hindlegs and in the axillae. Lesions start as papules and alopecia and develop into thick haemorrhagic crusts.

Treatment: As for sarcoptic mange.

More detailed description can be found in Chapter 3 and the section Ectoparasites in Chapter 9.

Chorioptes bovis

Synonyms: *Chorioptes ovis*, *Chorioptes equi*, *Chorioptes caprae*, *Chorioptes cuniculi*

Predilection site: Skin; particularly the legs, feet, base of tail and upper rear surface of the udder

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Psoroptidae

Fig. 10.22 Characteristic leg lesions of chorioptic mange in a horse.

Pathogenesis: In horses, chorioptic mange due to *C. bovis* is occasionally observed. The mites are restricted to the pasterns, and occur as crusty lesions with thickened skin on the legs below the knees and hocks, and are most prevalent in rough-legged animals and in those with heavy feather (Fig. 10.22). Though the mites are active only superficially, their movement causes irritation and restlessness, especially at night when animals are housed, and minor injuries may occur in the fetlock region from kicking against walls.

Notes: The names *Chorioptes ovis*, *Chorioptes equi*, *Chorioptes caprae* and *Chorioptes cuniculi* used to describe the chorioptic mites found on sheep, horses, goats and rabbits, respectively, are now all thought to be synonyms of *Chorioptes bovis*.

More detailed description can be found in the section Ectoparasites in Chapters 3 and 8.

Several non-obligate ectoparasites are found on horses and are listed in the host–parasite checklists at the end of this chapter. More detailed descriptions of these parasites can be found in Chapter 17.

HOST–PARASITE CHECKLISTS

In the following checklists, the codes listed below apply.

Helminths

N, nematode; T, trematode; C, cestode; A, acanthocephalan.

Arthropods

F, fly; L, louse; S, flea; M, mite; Mx, maxillopod; Ti, tick.

Protozoa

Co, coccidia; Bs, blood sporozoa; Am, amoeba; Fl, flagellate; Ci, ciliate.

Miscellaneous ‘protozoal organisms’

B, blastocyst; Mi, microsporidian; My, *Mycoplasma*; P, Pneumocystidomycete; R, *Rickettsia*.

Horse parasite checklist. Continued

| Section/host system | Helminths | | Arthropods | | Protozoa | |

Parasites of pigs

ENDOPARASITES

Parasites of the digestive system

MOUTH

Entamoeba suigingivalis

Predilection site: Mouth

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites are small, 7–12 µm, and have no cysts.

Host: Pig

Geographic distribution: Worldwide

Notes: There is some debate over whether this is a valid species, and may be synonymous with *E. gingivalis*.

OESOPHAGUS

Gongylonema pulchrum

Synonym: *Gongylonema scutatum*

Common name: Gullet worm

Predilection site: Oesophagus, rumen

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: A long, slender, whitish worm, the males being about 5.0 cm and the females up to about 14.0 cm in length.

Description, microscopic: Worms are easily distinguished microscopically by the presence of longitudinal rows of cuticular bosses in the anterior region of the body. Asymmetrical cervical alae are prominent.

Final hosts: Sheep, goat, cattle, pig, buffalo, horse, donkey, deer, camel, human

Intermediate hosts: Coprophagous beetles, cockroaches

For more details see Chapter 9.

STOMACH

Hyostrogylus rubidus

Common name: Red stomach worm

Predilection site: Stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: Slender reddish worms when fresh, males measuring around 5–7 mm and females 6–10 mm in length (see Fig. 1.16). The body cuticle is both transversely and longitudinally striated with 40–45 longitudinal striations.

Description, microscopic: A small cephalic vesicle is present and the spicules resemble *Ostertagia* in ruminants, but have only two distal branches. The bursa of the male is well developed and the dorsal lobe small. There is a well-developed telamen and short spicules. The vulva of the female opens in the posterior third of the body. Eggs are medium-sized, 71–78 by 35–42 µm, strongyle type and are often difficult to differentiate from those of *Oesophagostomum*. They are ovoid with almost similar rounded poles and slightly barrel-shaped side walls. The eggshell is colourless with a thin wall and in fresh faeces contains a minimum of 32 blastomeres.

Hosts: Pig, wild boar; occasionally found in rabbits

Geographical distribution: Worldwide

Pathogenesis: Similar to ostertagiosis, with penetration of the gastric glands by the L₃ and replacement of the parietal cells by rapidly dividing undifferentiated cells which proliferate to give rise to nodules on the mucosal surface. The pH becomes elevated in heavy infections and there is an increase in mucus production and a

Fig. 11.1 Inflamed pig stomach infected with *Hyostrongylus rubidus*.

catarrhal gastritis. Sometimes there is ulceration and haemorrhage of the nodular lesions (Fig. 11.1), but more commonly light infections occur and these are associated with decreased appetite and poor feed conversion rates.

Clinical signs: Light infections are often asymptomatic. Heavy infections can lead to inappetence, vomiting, anaemia, and loss of condition and body weight. Diarrhoea may or may not occur.

Diagnosis: This is based on a history of access to permanent pig pastures and the clinical signs. Confirmatory diagnosis is by examination of faeces for eggs; larval identification following faecal culture may be necessary, particularly to differentiate *Hyostrongylus* from *Oesophagostomum*. At necropsy, the small reddish worms can be seen in the mucous exudates on the gastric mucosa. Other stomach worms, the spiruroid nematodes, are larger (>13 mm).

Pathology: During the course of larval development there is dilation of infected gastric glands and hyperplasia of the glandular epithelium of both infected and neighbouring glands. The lamina propria is oedematous with infiltration by lymphocytes, plasma cells and eosinophils. Larvae are found in the gastric glands with adults mainly on the surface. During the course of development the hyperplasia causes the formation of pale nodules, which may become confluent in heavy infections, leading to the formation of a thickened convoluted mucosa. There may be focal or diffusely eroded areas and occasionally ulceration of the glandular mucosa.

Epidemiology: Because of the preparasitic larval requirements, infection is confined to pigs with access to pasture or those kept in straw yards. It is therefore more common in breeding stock, particularly gilts. The free-living larvae are particularly sensitive to desiccation and low temperatures. The epidemiology, at least in temperate zones, is similar to that of *Ostertagia* in ruminants, with seasonal hypobiosis a feature. Adult pigs often act as a reservoir of infection.

Treatment: When *Hyostrongylus* infection is diagnosed, particularly in breeding stock, it is important to use a drug such as a modern benzimidazole or a macrocyclic lactone, which will remove hypobiotic larvae.

Control: The same principles apply as for the control of parasitic gastroenteritis in ruminants. For example, in temperate areas there should be an annual rotation of pasture with other livestock

or crops. The timing of the move to other pastures may be dependent on other farming activities; if it can be delayed until October or later and accompanied by an anthelmintic treatment, then eggs from any worms which survive the treatment are unlikely to develop due to the unfavourable winter temperatures. A second treatment, again using a modern benzimidazole or a macrocyclic lactone, is recommended 3–4 weeks later to remove any residual infection. It may be advantageous to treat pregnant pigs before farrowing.

Notes: This parasite is responsible for a chronic gastritis in pigs, particularly gilts and sows.

Ollulanus tricuspis

Predilection site: Stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: This is a very small trichostrongyle (0.7–1.0 mm long). Males are 0.7–0.8 mm and females 0.8–1 mm long.

Description, microscopic: It is identified microscopically by the spiral coil of the head. The male bursa is well developed and the spicules are stout and each is split into two for a considerable distance. The female has a tail with three or four short cusps. The vulva is in the posterior part of the body and there is only one uterus and ovary.

Hosts: Cats, wild felids; occasionally found in pigs, foxes and domestic dogs

Geographical distribution: Mainly occurs in Europe, North and South America, Australasia and the Middle East

Pathogenesis: A chronic gastritis has been reported in the pig.

Clinical signs: Occasional vomiting and emaciation.

Diagnosis: Diagnosis of ollulanosis is seldom made because of their small size and lack of eggs and larvae in the faeces. Examination of vomit, following an emetic, for the presence of worms is a useful approach. At necropsy, recovery and identification of the very small worms from the gastric mucosa should lead to a diagnosis.

Pathology: The worms lie beneath the mucus on the surface of the stomach, or partly in the gastric glands, and their presence may lead to mucosal lymphoid hyperplasia and elevated numbers of globule leucocytes in the gastric epithelium. Heavy infections result in hyperplasia of the gastric glands causing the stomach mucosa to become convoluted and thrown into folds.

Epidemiology: The parasite is common in some parts of the world, particularly in cat colonies and cats that roam. The parasite can replicate in the stomach without any need for external egg or larval phases and can spread via vomit. The disease spreads mainly among starving stray cats and from them to other hosts.

Treatment: Not reported in the pig, although benzimidazoles or ivermectin should be effective.

Control: This is mainly achieved through the implementation of good hygiene procedures and prevention of contact with cats.

Ascarops strongylina

Synonym: *Arduenna strongylina*

Predilection site: Stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Small slender worms, the males measuring up to 15 mm and the reddish females 22 mm in length. They live on the stomach wall under a layer of mucus.

Description, microscopic: A cervical ala is located only on the left side of the body. The wall of the pharynx contains several spiral supports. Eggs are small, thick-shelled, 34–39 by 20–22 μm , and are embryonated when passed.

Final hosts: Pig, wild boar

Intermediate hosts: Coprophagous beetles (*Aphodius*, *Onthophagus*, *Gymnopleurus*)

Geographical distribution: Worldwide

Pathogenesis: *Ascarops strongylina* is not severely pathogenic, the main effect being a catarrhal gastritis, particularly in young animals.

Clinical signs: Clinical signs are usually absent, although in heavy infections softening of faeces and inappetence may occur.

Diagnosis: Diagnosis of a particular genus is difficult by faecal examination, but the presence of the small elongate eggs in the faeces of animals showing signs of gastritis will give a tentative indication of spiruroidosis.

Pathology: On postmortem, the gastric mucosa is sometimes reddened and oedematous.

Epidemiology: The epidemiology depends on the presence and abundance of the intermediate beetle hosts. Infection is more prevalent in outdoor pigs at pasture.

Treatment: Treatment has not been considered with this genus.

Control: Not usually required

Ascarops dentata

Synonym: *Arduenna dentata*

Predilection site: Stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description: Similar to *A. strongylina* but much bigger, male worms measuring 3.5 cm and female worms 5.5 cm in length. The buccal capsule has two teeth anteriorly.

Geographical distribution: Malaysia, Southeast Asia

All other details are essentially similar to *A. strongylina*.

Gnathostoma hispidum

Predilection site: Stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Thick-bodied worms, the males being 1.5–2.5 cm and the females 2.0–4.5 cm long. The presence of the worms in gastric nodules is sufficient for generic diagnosis.

Description, microscopic: The whole body is covered with spines. The left spicule is longer than the right. Eggs are oval, 72–74 by 39–42 μm , with a thin cap at one pole (Fig. 11.2).

Final hosts: Pig, rarely human

Intermediate hosts: *Cyclops* spp. and related freshwater crustaceans

Geographical distribution: Europe, Asia, Africa

Pathogenesis: The most obvious effect of gnathostomosis is the presence of fibrous growths on the stomach wall. Ulceration and necrosis of the stomach wall are often present. In some cases a number of larvae will migrate from the stomach to other organs, most commonly the liver, in which they burrow, leaving necrotic tracks in the parenchyma. It occurs erratically in humans as a cause of visceral larva migrans.

Clinical signs: *Gnathostoma* infection is usually inapparent. Severe infections may produce a marked gastritis leading to inappetence and weight loss.

Diagnosis: The infection in the living animal can only be diagnosed by the finding of the greenish oval eggs, which have a thin cap at one pole, in the faeces. Often, however, eggs are not present in faeces.

Pathology: Fibrous growths are of variable size, the largest being 3–4 cm in diameter, and are cavitated, amounting to thick-walled cysts containing several worms and fluid.

Fig. 11.2 *Gnathostoma hispidum* egg.

Epidemiology: It should be noted that the final hosts are also eligible second intermediate hosts, so that, for example, the pig may harbour L₃ in its liver and muscles as well as adult worms in its stomach.

Treatment: Treatment has not been fully investigated.

Control: With the ubiquity of the first and second intermediate hosts, complete control cannot be achieved, but partial limitation is possible by thorough cooking of all food.

Gnathostoma doloresi

Predilection site: Stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description: Adult male worms are 2.6–2.8 cm and female worms 3–4 cm long. The entire body surface has numerous transverse rows of backwardly directed cuticular spines. Anteriorly, the spines are broad and short, with several unequal teeth, becoming gradually smaller with single-pointed spines posteriorly. The spicules are unequal, stout and curved and taper evenly from root to tip.

Geographical distribution: Asia

All other details are essentially similar to *G. hispidum*.

Physocephalus sexalatus

Predilection site: Stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Small slender worms, the males measuring about 10–12 mm and the females up to 22 mm in length.

Description, microscopic: The wall of the pharynx contains a single spiral support. The cervical papillae are asymmetrically located. Eggs are small, an elongated ellipse, thick-shelled, measure around 34–39 by 15–17 µm and are embryonated when passed.

Final hosts: Pig, camel; occasionally rabbit, hare

Intermediate hosts: Coprophagous beetles

Geographical distribution: Widely distributed in many parts of the world

Pathogenesis: The parasites lie on the surface of the stomach wall under a layer of mucus. *Physocephalus sexalatus* is not severely pathogenic, the main effect being a catarrhal gastritis, particularly in young piglets.

Clinical signs: In many infections, obvious clinical signs are absent; in heavy infections, softening of faeces and inappetence may occur.

Diagnosis: As for other spiruroid parasites.

Pathology: At necropsy, the gastric mucosa is sometimes reddened and oedematous. The tiny worms can be seen in the mucus covering the gastric mucosa.

Epidemiology: Infection occurs where the intermediate hosts are plentiful. Transmission may also occur through paratenic hosts, such as amphibians or birds.

Treatment: Not reported

Control: Measures that restrict dung beetle populations feeding on pig faeces will be beneficial.

Notes: *Physocephalus sexalatus* is not considered to be of great economic or pathogenic importance.

Simondsia paradoxa

Synonym: *Spiroptera cesticillus*

Predilection site: Stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Small slender worms. The females measure up to about 20 mm and males 12–15 mm in length.

Description, microscopic: Females have large lateral alae and a large ventral and dorsal tooth. The gravid female has a characteristic form, the posterior end of the body being a rounded sac filled with eggs. The male has a spirally coiled tail. The small eggs are oval or ellipsoid, 20–29 µm, and are embryonated when laid.

Final hosts: Pig, occasionally rabbit and hare

Intermediate hosts: Beetles

Geographical distribution: Predominantly a parasite of tropical and subtropical regions; also occurs in parts of Europe

Pathogenesis: *Simondsia paradoxa* is not severely pathogenic, the main effect being a catarrhal gastritis. In addition, there can be some fibrous reaction around the nodules in the stomach wall.

Clinical signs: Infections are usually asymptomatic.

Diagnosis: Diagnosis of a particular genus is difficult by faecal examination, but the presence of the small elongate eggs in the faeces of animals showing signs of gastritis will give a tentative indication of spiruroidosis.

Pathology: Females are present in nodules 6–8 mm in diameter.

Epidemiology: Infection is likely to be more common in outdoor pigs where the intermediate hosts are more abundant.

Treatment: Treatment is generally not considered.

Control: Attempts to control these spiruroids are unlikely to be successful because of the ready availability of the intermediate hosts.

Trichostrongylus axei

Synonym: *Trichostrongylus extenuatus*

Common name: Stomach hairworm

Predilection site: Stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are small, hair-like, light brownish-red and difficult to see with the naked eye. Males measure around 3–6 mm and females 4–8 mm in length.

Hosts: Cattle, sheep, goat, deer, horse, donkey, pig and occasionally human

Geographical distribution: Worldwide

Pathogenesis: *Trichostrongylus axei* may occasionally be found in the stomach of pigs, but is considered to be of minor importance.

SMALL INTESTINE

Globocephalus urosubulatus

Synonyms: *Globocephalus longemucronatus*, *Globocephalus samoensis*

Common name: Pig hookworm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ancylostomatoidea

Description, gross: A very small, stout, whitish worm, 4–9 mm long.

Description, microscopic: The mouth opens subdorsally and the buccal capsule is globular but with an absence of chitinous structures in the buccal capsule. It has neither teeth nor plates. The male bursa is well developed and the spicules are slender. Eggs are medium-sized, ovoid, smooth, with a thin colourless shell. They measure 50–60 by 26–35 µm and only have six to eight blastomeres.

Hosts: Pig, wild boar

Geographical distribution: North and South America, Europe, Africa and Asia

Pathogenesis: Not known but thought to be generally of little pathological significance, although heavy infections may affect piglets severely.

Clinical signs: Generally asymptomatic, although heavily infected piglets may be anaemic and show weight loss and emaciation.

Diagnosis: Identification of eggs in the faeces, or adult worms found in the small intestine on postmortem.

Pathology: Not described

Epidemiology: Not reported

Treatment: Most modern benzimidazoles and macrocyclic lactones are likely to be effective.

Control: Frequent removal of faeces and bedding on dry straw or concrete will help reduce the risk of infection.

Ascaris suum

Common names: Large roundworm, white spot

Predilection site: Small intestine

Fig. 11.3 *Ascaris suum* adult worms.

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: *Ascaris suum* is by far the largest nematode of the pig; the white/cream-coloured rigid females are up to 40 cm long and the males up to 25 cm in length (Fig. 11.3), and could only be confused with *Macracanthorhynchus* where this occurs.

Description, microscopic: The eggs are ovoid and yellowish-brown, with a thick shell, the outer layer of which is irregularly mamillated (see Fig. 4.5). They measure 50–75 by 40–55 µm and the contents consist of granules and unsegmented cells. The egg is larvated when passed in the faeces and the thick multilayered egg-shell enables the egg to survive desiccation and freezing in the environment for several years. Occasionally the population of worms will comprise only females and unfertilised eggs can appear in the faeces. Where an outer albuminous layer is present it is thinner than that of a fertilised egg.

Hosts: Pig, wild boar, rarely sheep, cattle, human

Geographical distribution: Worldwide

Pathogenesis: The migrating larval stages in large numbers may cause numerous small haemorrhages, emphysema and a transient pneumonia, but it is now recognised that many cases of so-called 'Ascaris pneumonia' may be attributable to other infections, or to piglet anaemia. In the liver, the migrating larvae can cause 'milk spot' or 'white spot', which appears as cloudy whitish spots of up to 1.0 cm in diameter on the surface of the liver, and represents the fibrous repair of inflammatory reactions to the passage of larvae in the livers of previously sensitised pigs (Fig. 11.4). Livers showing 'milk spot' lesions may be condemned at meat inspection. The adult worms in the intestine cause little apparent damage to the mucosa, but occasionally, if large numbers are present, there may be obstruction, and rarely a worm may migrate into the bile duct causing obstructive jaundice and carcass condemnation. Experimental infections have shown that in young pigs the important effect of alimentary ascariasis is economic, with poor feed conversion and slower weight gains, leading to an extension of the fattening period by 6–8 weeks.

Clinical signs: The main effect of the adult worms in pigs is to cause production loss in terms of diminished weight gain. Otherwise,

Fig. 11.4 Milk spot lesions in the liver associated with *Ascaris suum*.

clinical signs are absent except in the occasional case of intestinal or biliary obstruction. Heavy infections may increase the susceptibility of young pigs to other bacterial and viral pathogens. In piglets under 4 months old, larval activity during the pulmonary phase of migration may cause a clinically evident pneumonia, which is usually transient and rapidly resolving. In sheep and cattle exposed to contaminated grazing, there may be acute dyspnoea, tachypnoea and coughing following acute challenge with migrating larvae in the lungs.

Diagnosis: Diagnosis is based on clinical signs, history of disease and, in infections with the adult worm, on the presence in faeces of the yellow–brown ovoid eggs with thick mamillated shells. Being dense, the eggs float more readily in saturated solutions of zinc sulphate or magnesium sulphate than in the saturated sodium chloride solution that is used in most faecal examination techniques. Low counts of *A. suum* eggs in faeces (<200 eggs per gram) may represent false positives due to the coprophagic activity of pigs. At necropsy, the large worms in the small intestine are easy to recognise.

Pathology: Larval migration induces lesions in the liver and lungs. In the lungs, gross lesions are limited largely to numerous focal haemorrhages scattered over and through the pulmonary parenchyma. There may be some oedema, congestion and alveolar emphysema. Microscopically, there is an eosinophilic bronchiolitis. Bronchioles are surrounded by macrophages and eosinophils, and the bronchiolar wall is infiltrated by eosinophils, which are also present, with necrotic debris, in the lumen. Larvae are usually readily found in tissue sections and may be present in alveoli, alveolar ducts, bronchioles or bronchi, and in more chronic cases are found within eosinophilic granulomas. Lesions in the liver result in considerable economic loss from condemnation at meat inspection. Haemorrhagic tracks are present near portal areas and throughout lobules, visible through the capsule as pin-point red areas, sometimes slightly depressed and surrounded by a narrow pale zone. These lesions collapse, healing by fibrosis, which extends around portal tracts and extends out more diffusely emphasising lobular outlines. Granulomatous foci containing giant cells, macrophages and eosinophils may centre on the remnants of larvae trapped and destroyed in the liver. The inflammatory infiltrates in livers of animals exposed to larval ascarids may become severe and diffuse, and this is reflected in the gross appearance of the liver, which has

Fig. 11.5 A knot of *Ascaris suum* in the small intestine of an infected pig.

extensive ‘milk spots’ and prominent definition of lobules. The liver is firm, and heavy scars may become confluent, obliterating some lobules and extending out to exaggerate interlobular septa throughout the liver.

The pathogenicity of adult ascarids in the intestine is poorly defined. Heavy infections may obstruct the gut, being visible as rope-like masses through the intestinal wall (Fig. 11.5). Ascarids may occasionally pass to the stomach and be vomited or migrate up the pancreatic or bile ducts. Sometimes biliary obstruction and icterus, or purulent cholangitis, may ensue. Rarely, intestinal perforation occurs. On histology, there may be substantial hypertrophy of the muscularis externa and elongation of the crypts of Lieberkühn, though height of villi is not significantly reduced. Hypertrophy and exhaustion of the goblet-cell population and increased infiltrates of eosinophils and mast cells are also observed in infected intestines.

Epidemiology: Young suckling piglets can become infected early after birth through the ingestion of embryonated eggs that are attached to the underbelly of the sow. Prevalence of infection is usually highest in pigs of around 3–6 months of age. A partial age immunity operates in pigs from about 4 months of age onwards and this, coupled with the fact that the worms themselves have a limited lifespan of several months, would suggest that the main source of infection is the highly resistant egg on the ground, a common characteristic of the ascaridoidea. Hence ‘milk spot’, which is economically very important since it is a cause of much liver condemnation, presents a continuous problem in some pig establishments. This condition has been widely noted to have a distinct seasonality of occurrence, appearing in greatest incidence in temperate areas during the warm summer months, and almost disappearing when the temperatures of autumn, winter and spring are too low to allow development of eggs to the infective stage. Also, earthworms are generally more active and available during the summer months. Sows and boars act as reservoirs of light infection. *Ascaris suum* may occasionally infect cattle, causing an acute, atypical, interstitial pneumonia that may prove fatal. In most cases reported the cattle have had access to housing previously occupied by pigs, sometimes several years before, or to land fertilised with pig manure. In lambs, *A. suum* may also be a cause of clinical pneumonia as well as ‘milk spot’ lesions, resulting in condemnation of livers. In most cases lambs

have been grazed on land fertilised with pig manure or slurry, such pasture remaining infective for lambs even after ploughing and cropping. Young adults of *A. suum* are occasionally found in the small intestine of sheep. There are a few recorded cases of patent *A. suum* infection in humans but cross-infection is not of epidemiological significance.

Treatment: The intestinal stages are susceptible to most of the anthelmintics in current use in pigs, and the majority of these, such as the benzimidazoles, are given in the feed over several days. In cases of suspected *Ascaris* pneumonia, injectable levamisole and ivermectin may be more convenient. For 3–4 days after treatment the faeces should be removed from the pens and destroyed, as they will often contain large numbers of eggs and expelled/disintegrating worms.

Control: In the past, elaborate control systems have been designed for ascariasis in pigs, but with the appearance of highly effective anthelmintics these labour-intensive systems are rarely used. The chief problem in control is the great survival capacity of the eggs. In housed pigs, strict hygiene in feeding and bedding, with frequent hosing/steam cleaning of walls, floors and feeding troughs, will limit the risk of infection. Some disinfectants and chemical solutions will limit infectivity. In pigs on free range the problem is greater, and where there is serious ascariasis it may be necessary to discontinue the use of paddocks for several years, since the eggs can survive cultivation. It is good practice to treat in-pig sows at entry to the farrowing pen, and young pigs should receive anthelmintic treatment when purchased or on entry to the finishing house and 8 weeks later; boars should be treated every 3–6 months. Washing of the skin of sows prior to their removal to the farrowing pen should reduce contamination with embryonated eggs.

Notes: The type species, *Ascaris lumbricoides*, occurs in humans and at one time it was not differentiated from *A. suum*, so that the pig was thought to present a zoonotic risk for humans. With species distinction now possible, *A. lumbricoides* is accepted as specific for humans and some species of primates.

Strongyloides ransomi

Common name: Threadworm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Rhabditoidea

Description, gross: Slender hair-like worms 3.4–4.5 mm long (see Fig. 1.51). Only females are parasitic.

Description, microscopic: The long oesophagus may occupy up to one-third of the body length and the uterus is intertwined with the intestine giving the appearance of twisted thread. Unlike other intestinal parasites of similar size the tail has a blunt point. *Strongyloides* eggs are oval, thin-shelled and small, 45–55 by 26–35 µm. They have a very fine wall and always contain a thick, short, first-stage larva (see Fig. 4.5).

Host: Pig

Geographical distribution: Worldwide

Pathogenesis: Skin penetration by infective larvae may cause an erythematous reaction. Mature parasites are found in the duodenum and proximal jejunum and if present in large numbers may cause inflammation with oedema and erosion of the epithelium. This results in catarrhal enteritis with impairment of digestion and absorption. Infection in young piglets can result in retarded growth.

Clinical signs: In light infections, animals show no clinical signs. In heavy infections, there is bloody diarrhoea, anaemia, anorexia and emaciation, and sudden death may occur. During the migratory phase there may be coughing, abdominal pain and vomiting.

Diagnosis: Demonstration of larvated eggs in faeces or the adults in scrapings from the intestine on postmortem is diagnostic.

Pathology: The adult female worms burrow into the intestinal wall and establish in tunnels in the epithelium at the base of the villi in the small intestine, causing an inflammatory response. In large numbers they may cause villous atrophy, with a mixed mononuclear inflammatory cell infiltration of the lamina propria. Crypt epithelium is hyperplastic and there is villous clubbing.

Epidemiology: *Strongyloides* infective larvae are not ensheathed and are susceptible to extreme climatic conditions. However, warmth and moisture favour development and allow the accumulation of large numbers of infective stages. Adult breeding stock may be infected with dormant larvae in their subcutaneous fat. Pregnancy and farrowing appear to stimulate the re-emergence of these larvae, which then may infect piglets via the colostrum. This appears to be the major route of infection in young piglets and, in only 7 days after birth, piglets may be passing eggs in their faeces.

Treatment: Specific control measures for *Strongyloides* infection are rarely called for. The benzimidazoles, levamisole and the macrocyclic lactones may be used for the treatment of clinical cases and a single dose of ivermectin 4–16 days prior to farrowing has been shown to suppress larval excretion in the milk of sows.

Control: Strict hygiene and cleaning of pens before farrowing helps limit levels of infection. Treating the sows before farrowing can also help reduce infections in piglets.

Trichinella spiralis

Synonym: *Trichina spiralis*

Common name: Muscle worm

Predilection site: Small intestine, muscle

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichinelloidea

Description, gross: Because of their short lifespan, the adult worms are rarely found in natural infections. The male is about 1.5 mm and the female 3.5–4.0 mm long.

Description, microscopic: The oesophagus is at least one-third of the total body length and the tail in the male has two small cloacal flaps, but no copulatory spicule nor a spicule sheath. In the female,

Fig. 11.6 Encysted larvae of *Trichinella spiralis* in muscle.

the uterus contains developing larvae and the vulva is in the mid-oesophageal region. *Trichinella* infection is most easily identified by the presence of coiled larvae in striated muscle (Fig. 11.6; see also Fig. 1.63). These larvae measure about 800–1000 μm in length. The cysts are lemon-shaped, 0.3–0.8 by 0.2–0.4 mm in size, and often transparent.

Hosts: Pig, rat, horse, human and most mammals

Geographical distribution: Worldwide, with the apparent exceptions of Australia, Denmark and Great Britain

Pathogenesis: The adults occur in the glandular crypts of the proximal small intestine and their larvae in the striated muscles; the diaphragmatic, intercostal and masseter muscles and the tongue are considered to be the main predilection sites. Infection in domestic animals is invariably light, and clinical signs do not occur. However, when hundreds of larvae are ingested, as occasionally happens in humans and presumably also in predatory animals in the wild, including cats and dogs, the intestinal infection is often associated with catarrhal enteritis and diarrhoea, and 1–2 weeks later the massive larval invasion of the muscles causes acute myositis, fever, eosinophilia and myocarditis. Periorbital oedema and ascites are also common in humans, sometimes accompanied by vomiting, diarrhoea, fever and myocarditis. Unless treated with an anthelmintic and anti-inflammatory drugs, such infections may frequently be fatal as a consequence of paralysis of respiratory muscles, but in persons who survive this phase the clinical signs start to abate after 2–3 weeks.

Clinical signs: These are variable and depend on the host and the level of infection. Signs are usually non-specific and resemble those of other diseases, such as diarrhoea, fever, muscular pain, dyspnoea and peripheral eosinophilia. *Trichinella spiralis* infection in young pigs can induce inappetance, weakness and diarrhoea. Older pigs are generally more tolerant of infection.

Diagnosis: This is not relevant in live domestic animals. At meat inspection, heavy larval infections may occasionally be just seen with the naked eye as tiny greyish-white spots. For routine purposes small samples of pig muscle (taken from the preferential predilection sites) of about 1 g are squeezed between glass plates, the apparatus being called a compressorium, and examined for the presence of larvae by direct low-power microscopic examination or projection onto a screen using a trichinoscope. Alternatively,

Fig. 11.7 Larvae of *Trichinella spiralis* following digest in pepsin/HCl.

small portions of diaphragm tissue may be digested in pepsin/HCl and the sediment examined microscopically for the presence of larvae (Fig. 11.7). The digestion method is now the preferred approach in most countries as it is less expensive and labour-intensive to perform. For mass screening purposes, designed to determine the incidence of trichinellosis in pigs within regions or for some high-volume slaughterhouses, immunodiagnostic tests have been used. Of these, the antibody-detection enzyme-linked immunosorbent assay (ELISA) or enzyme immunoassay appears to be the test of choice.

Pathology: The adults occur in the glandular crypts of the proximal small intestine where there is little associated pathology. Larvae are found in the striated muscles, with the diaphragmatic, intercostal and masseter muscles and the tongue considered to be the main predilection sites. On microscopic examination, the larvae lie in a bulging clear segment of muscle fibre, which may be loosely encircled by eosinophils, lymphocytes, plasma cells and macrophages. In a heavy infection, a large proportion of the muscle fibres in the predilection muscles may be infected with larvae and surrounded by reactive zones. As the cellular reaction subsides, muscle fibres surrounded by the larvae have the appearance of a fibrous capsule. Once larvae become encysted, there is muscle fibre degeneration and mineralisation, which does not appear to affect larval viability, as larvae can survive for up to 20 years.

Epidemiology: It is important to realise that trichinellosis is basically an infection of animals in the wild and that the involvement of humans in these circumstances is accidental. The epidemiology of trichinellosis depends on two factors. First, animals may become infected from a wide variety of sources, predation and cannibalism being perhaps the most common. Others include feeding on carrion, since the encapsulated larvae are capable of surviving for several months in decomposing flesh, and the ingestion of fresh faeces from animals with a patent infection. It is also thought that transport hosts, such as crustaceans and fish, feeding on drowned terrestrial animals, may account for infection in some aquatic mammals such as seals.

The second factor is the wide host range of the parasite, infecting various carnivores and omnivorous mammals. In temperate areas rodents, brown bear, badger and wild pig are most commonly involved; in the Arctic, polar bear, wolf and fox; in the tropics, lion, leopard, bushpig, hyena, jackal and warthog. In these sylvatic

or feral cycles, humans and their animals are only occasionally involved. For example, the consumption of polar bear meat may cause infection in Inuit and sled-dogs, while in Europe the hunting and subsequent ingestion of wild pigs may also produce disease in humans and their companion animals.

The domestic or synanthropic cycle in the human and the pig is an 'artificial' zoonosis largely created by feeding pigs on food waste containing the flesh of infected pigs; more recently, tail biting in pigs has been shown to be a mode of transmission. Rats in piggeries also maintain a secondary cycle, which may on occasions pass to pigs or vice versa from the ingestion of infected flesh or faeces. Infection in humans is acquired from the ingestion of raw or inadequately cooked pork or its by-products, such as sausages, ham and salami. It is also important to realise that smoking, drying or curing pork does not necessarily kill larvae in pork products. Horse meat has increasingly been implicated in the transmission of *Trichinella* to humans.

In areas such as Poland, Germany and the USA, human trichinosis acquired from pork has, until recently, been an important zoonosis. Over the past few decades, prohibition of feeding uncooked food waste to pigs, improved meat inspection and public awareness have greatly diminished the significance of the problem. In Britain and other countries in Europe and in the USA, the numbers of outbreaks are few and sporadic.

The decreasing prevalence is also reflected in the fact that inapparent infection in humans, as shown by the presence of *T. spiralis* larvae in muscle samples at necropsy, has decreased from 10% to not recorded in Britain, and from 20% to under 5% in the USA over the past 60 years.

Treatment: Although rarely called for in animals, the adult worms and the larvae in muscles are susceptible to several of the benzimidazole anthelmintics, such as in-feed treatment with flubendazole in pigs.

Control: Probably the most important factor in the control of trichinellosis is a legal requirement that swill or waste human food intended for consumption by pigs must be boiled (100°C for 30 minutes). In fact, this practice is mandatory in many countries to limit the potential spread of other diseases, such as foot and mouth disease and swine fever.

Other essential steps include the following.

- 1 Meat inspection plays an essential role in monitoring the detection of infected carcasses. Such carcasses must be condemned.
- 2 Measures to eliminate rodents and other wild animals from piggeries and slaughterhouses.
- 3 Prevention of exposure of pigs to dead animal carcasses, particularly of rats and pigs.
- 4 Regulations to ensure that larvae in pork are destroyed by cooking or freezing. In the USA, for example, any pork or pork products, other than fresh pork, must be treated by heating or freezing before marketing and it is likely also that irradiation might soon be introduced as a further method of control.
- 5 Consumer education, and particularly the recognition that pork or pork products or the flesh of carnivorous game should be thoroughly cooked before consumption. It is worth noting that the larvae of *Trichinella nativa* that occurs in wild carnivores and seals in some arctic and sub-arctic regions is very resistant to freezing.

Notes: The taxonomy of the genus has been controversial until very recently. It is composed of several sibling species that cannot be

differentiated morphologically but molecular typing, and other criteria, have now identified eight species of *Trichinella* (for more details see Table 1.7).

Macracanthorhynchus hirudinaceus

Common name: Thorny-headed worm

Predilection site: Duodenum and proximal small intestine

Phylum: Acanthocephala

Family: Oligacanthorhynchidae

Description, gross: Adults resemble *Ascaris suum*, but taper posteriorly. The anterior of the worm possesses a retractable proboscis, which is covered with recurved hooks (see Fig. 1.64). The males are up to 10 cm and the females around 40–60 cm in length and slightly pinkish in colour when fresh. The white worms are thick (5–10 mm wide), flattened and the cuticle is transversely wrinkled (occasionally misdiagnosed as a tapeworm).

Description, microscopic: There is no alimentary canal. The large egg is oval and symmetrical with a thick greyish dark-brown pitted shell and contains the **acanthor** larva when laid. The egg measures 90–110 by 50–65 µm. The larva has a small circle of minute hooks at the anterior.

Final hosts: Pig, wild boar, occasionally dog, wild carnivores and human

Intermediate hosts: Various dung beetles and water beetles

Geographical distribution: Worldwide, but absent from certain areas, for example parts of western Europe

Pathogenesis: Mild infections are not very pathogenic, but heavy infections may retard growth rates and cause emaciation.

Clinical signs: Low-level infections are usually asymptomatic. Heavy infections may cause inappetence and weight loss.

Diagnosis: This is based on finding the typical eggs in the faeces. At necropsy the worms superficially appear similar to *Ascaris suum*, but when placed in water the spiny proboscis is protruded, thus aiding differentiation.

Pathology: *Macracanthorhynchus hirudinaceus* penetrates deep into the intestinal wall with its proboscis and produces inflammation and may provoke granuloma formation at the site of attachment in the wall of the duodenum and small intestine. Heavy infections may induce a catarrhal enteritis and, rarely, penetration of the intestinal wall, which can result in a fatal peritonitis.

Epidemiology: Infection is seasonal, being partly dependent on the availability of the intermediate hosts. The eggs are able to remain viable in the environment for several years. Infection tends to be more prevalent in pigs of around 1–2 years of age.

Treatment: Although there is little information on treatment, levamisole, ivermectin and doramectin are reported to be effective.

Control: Pigs should be prevented from access to the intermediate hosts. In modern management systems this may be easily achieved, but where pigs are kept in small sties the faeces should be regularly removed to reduce the prevalence of the dung beetle intermediate hosts.

Fig. 11.8 Egg of *Fasciolopsis buski*.

Fasciolopsis buski

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description, gross: Large, thick, elongate–oval fluke without shoulders, broader posteriorly, and variable in size but usually measuring 30–75 by 8–20 mm. The ventral sucker is situated near the anterior extremity and is much larger than the oral sucker. The cuticle bears spines that are frequently lost in the adult fluke.

Description, microscopic: Eggs are oval, yellowish-brown, thin-shelled with an operculum, and measure 125–140 by 70–90 μm (Fig. 11.8). They resemble those of *Fasciola*.

Final hosts: Pig, dog and human

Intermediate hosts: Flat spiral-shelled freshwater snails of *Planorbis*, *Hippeutis* and *Segmentina* species

Geographical distribution: India, Pakistan, Southeast Asia and China

Pathogenesis: The parasite is mainly of importance as a cause of disease in humans. It is located in the small intestine where it can cause severe ulceration of the intestinal mucosa in heavy infections in humans. Lesions are less severe in the pig and dog.

Clinical signs: Infection causes abdominal pain, diarrhoea, oedema, ascites and occasionally intestinal obstruction leading to malnutrition and death in humans. Symptoms are less severe in pigs and dogs.

Diagnosis: Diagnosis is confirmed by faecal identification of the eggs, which have to be differentiated from those of *Fasciola* spp.

Pathology: Heavier infections produce ulceration of the intestinal mucosa.

Epidemiology: The intermediate snail hosts feed on certain plants, namely water caltrop (*Trapa natans*) and water chestnut (*Eleocharis tuberosa*), which are cultivated for food and often fertilised with human faeces. The cercariae encyst on the tubers or nuts of these

plants, and cause infection if eaten raw. Pigs also become infected through eating these plants.

Treatment: Albendazole (10 mg/kg) and praziquantel (15 mg/kg) are both effective.

Control: The disease is easily preventable by avoiding raw or uncooked aquatic plants in endemic areas. The introduction of good sanitation facilities limits contamination of local watercourses and ponds.

Notes: *Fasciolopsis buski* is primarily a parasite of humans, but can occur in the pig and dog, which may act as reservoir hosts.

Postharmostomum suis

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Brachylaemidae

Description, gross: The body is smooth, elongate and around 4–8 mm in length.

Description, microscopic: The small, oval, light-brown egg measures 30–35 by 15–17 μm .

Final host: Pig

Intermediate hosts: Land snails, particularly species of *Xerophilina*

Geographical distribution: North Africa

Pathogenesis: The parasite ingests blood but is not considered to be very pathogenic.

Coccidiosis

Although some 10 species of coccidia have been described from pigs, their importance is not clear. *Cystispora suis* is a cause of a naturally occurring severe enteritis in young piglets aged 1–2 weeks. *Eimeria deblickei* has been described as causing clinical disease and severe pathology; *E. polita*, *E. scabra* and *E. spinosa* cause moderate to mild diarrhoea in piglets (Table 11.1).

The source of infection appears to be oocysts produced by the sow during the periparturient period, the piglets becoming initially infected by coprophagia; the second phase of diarrhoea is initiated

Table 11.1 Predilection sites and prepatent periods of coccidia species in pigs.

| Species | Predilection site | Prepatent period (days) |
|---|---------------------------|-------------------------|
| <i>Cystispora suis</i> (syn. <i>Isoospora suis</i>) | Small intestine | 5 |
| <i>Eimeria deblickei</i> | Small intestine | 6–7 |
| <i>Eimeria polita</i> | Small intestine | 7–8 |
| <i>Eimeria scabra</i> | Small and large intestine | 7–11 |
| <i>Eimeria spinosa</i> | Small intestine | 7 |
| <i>Eimeria porci</i> | Small intestine | 5–7 |
| <i>Eimeria neodeblickei</i> | Unknown | 10 |
| <i>Eimeria perminuta</i> | Unknown | ? |
| <i>Eimeria suis</i> | Unknown | 10 |

by reinvasion from tissue stages. Diagnosis of the condition is difficult unless postmortem material is available since clinical signs occur prior to the shedding of oocysts and are very similar to those caused by other pathogens such as rotavirus.

Diagnosis of coccidial infections is based on history and clinical signs and, in patent infections, on the presence of oocysts of the pathogenic species in the faeces. Oocysts may not be shed during the diarrhoeal phase so faecal counts are not always of value.

Treatment for all species of *Eimeria* (and *Cystisospora*) has generally relied on the use of a sulphonamide–trimethoprim product combined with electrolyte and fluid therapy. Treatment with several anticoccidial drugs, such as halofuginone, salinomycin, toltrazuril and diclazuril given orally to affected animals, has been reported to be effective, although such treatments may not be licensed or approved in many countries. Control of coccidiosis is based on reducing environmental contamination by improved hygiene. Pens should be kept clean and dry. Ammonia-based disinfectants can be used after thoroughly cleaning farrowing pens by high-pressure hosing or steam disinfection. Overcrowding of piglets and faecal contamination of food and water should be avoided. Prevention has been achieved by the in-feed administration of amprolium to sows during the periparturient period, from 1 week prior to farrowing until 3 weeks post farrowing, where such treatments are still licensed or approved.

Cystisospora suis

Synonym: *Isospora suis*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are spherical to subspherical, 17–25 by 16–22 μm (mean 20.6 \times 18.1 μm), and the wall is colourless and thin. There is no micropyle or residuum and when sporulated the oocysts contain two sporocysts each with four sporozoites. The two sporocysts are ellipsoidal, 13–14 by 8–11 μm , without a Stieda body but with a sporocyst residuum. The four sporozoites in each sporocyst are sausage-shaped with one pointed end (Fig. 11.9).

Fig. 11.9 Oocysts of *Cystisospora suis*.

Host: Pig

Life cycle: Meronts are found in the epithelial cells of the villi of the small intestine, usually in the distal third and below the host cell nucleus. First-generation meronts are present 2–3 days after infection. Second-generation meronts are present 4 days and mature gamonts 5 days after infection. The prepatent period is 4–6 days and the period of patency 3–13 days.

Geographical distribution: Worldwide

Pathogenesis: Infection can occur in all types of farrowing facilities and under all types of management systems. Piglets with clinical infection develop a characteristic non-haemorrhagic disease that is unresponsive to routine antibiotic therapy. Scours tend to occur in individuals from about 6 days of age, but most of the litter scours at 8–10 days of age. The diarrhoea ranges from white to pasty cream faeces through to a watery diarrhoea. Affected piglets tend to be stunted and hairy. Severely affected piglets become dehydrated, continue to suckle but weight gains are reduced. Mortality is generally low to moderate. *Cystisospora suis* can cause infection on its own or in combination with other enteropathogens, such as enterotoxigenic *Escherichia coli*, rotavirus and transmissible gastroenteritis virus.

Clinical signs: The main clinical sign is diarrhoea, often biphasic, which varies in its severity from white to pasty cream faeces through to a watery diarrhoea.

Diagnosis: Diagnosis of the condition is difficult unless postmortem material is available, since clinical signs occur prior to the shedding of oocysts and are very similar to those caused by other pathogens such as rotavirus.

Pathology: Lesions caused by *C. suis* in young piglets are present in the jejunum and ileum and are associated with the development stages of the parasite. The affected intestine is inflamed and reddened (Fig. 11.10). Microscopic changes include villous atrophy, villous fusion, crypt hyperplasia and necrotic enteritis.

Treatment: Treatment with toltrazuril (1 mL of 5% suspension) given orally to affected piglets at 4 days of age has proved effective.

Fig. 11.10 *Cystisospora suis* infection in a piglet.

Eimeria deblickei**Predilection site:** Small intestine**Phylum:** Apicomplexa**Class:** Conoidasida**Family:** Eimeriidae

Description: Oocysts are ellipsoid or ovoid, 15–23 by 11–18 μm (mean $18.8 \times 14.3 \mu\text{m}$), with a smooth and colourless wall (see Fig. 4.36). There is a polar granule but no micropyle or oocyst residuum. Sporocysts are elongate ovoid, 13–20 by 5–7 μm , with a large Stieda body and a large sporocyst residuum. The sporozoites are vermiform, and each contains two large clear globules.

Host: Pig

Life cycle: The endogenous stages are located in the distal part of the columnar epithelial cells of the tips of the villi in the small intestine posterior to the bile duct. First-generation meronts mature at 2 days and second-generation meronts at 4 days; gamonts mature about 5 days after infection. The prepatent period is 6–7 days and the patent period approximately 5 days. Oocyst sporulation time is 5–7 days.

Geographical distribution: Worldwide

Pathogenesis: *Eimeria deblickei* has been described as causing clinical disease and severe pathology in young piglets. Older animals are seldom, if ever, affected.

Clinical signs: Diarrhoea, inappetence, emaciation, depressed growth and occasional mortality in young piglets.

Pathology: Catarrhal inflammation of the jejunum is seen. On postmortem there may be enteritis and large numbers of meronts and gamonts may be found in mucosal scrapings. On histopathology, there may be villous atrophy, villous fusion and crypt hyperplasia.

Eimeria polita**Predilection site:** Small intestine**Phylum:** Apicomplexa**Class:** Conoidasida**Family:** Eimeriidae

Description: Oocysts are ellipsoidal or broad ovoid, 20–33 by 14–22 μm (mean $25.9 \times 18.1 \mu\text{m}$), with a slightly rough yellowish-brown wall (see Fig. 4.36). There is no micropyle or oocyst residuum, although a polar granule may be present. Sporocysts are ellipsoidal to ovoid, 13–19 by 5–9 μm , and each has a Stieda body and a residuum. The sporozoites are elongate with one or two clear globules, and lie lengthwise head to tail in the sporocysts. The mature meronts are about 14–24 by 11–23 μm and contain 15–30 merozoites. Macrogametes are 16–29 by 15–25 μm and microgamonts 16–29 by 13–29 μm and possess a residuum.

Host: Pig

Life cycle: The endogenous stages occur in the epithelium at the tips of the villi in the jejunum and ileum. There are thought to be two generations of meronts. Gamonts and gametes are found in the

same area of the intestine and mature 8–9 days after infection. The prepatent period is 7–8 days and the patent period 6–8 days.

Geographical distribution: Worldwide

Pathogenesis: *Eimeria polita* is thought to be moderately pathogenic. Mixed infections are common and several coccidial species may be involved in causing diarrhoea in young piglets.

Clinical signs: Heavy infections may cause diarrhoea, inappetence, weight loss, unthriftiness, dehydration and death.

Pathology: On postmortem there may be enteritis and large numbers of meronts and gamonts may be found in mucosal scrapings. On histopathology, there may be villous atrophy, villous fusion and crypt hyperplasia.

Eimeria scabra**Predilection site:** Small and large intestine**Phylum:** Apicomplexa**Class:** Conoidasida**Family:** Eimeriidae

Description: Oocysts are ovoid or ellipsoidal, 24–42 by 20–24 μm (mean $31.9 \times 22.5 \mu\text{m}$), with a thick rough striated wall, yellow-brown in colour (see Fig. 4.36). There is a micropyle and polar granule, but no oocyst residuum. Sporocysts are ovoid, 14–18 by 7–9 μm , each with a prominent Stieda body and sporocyst residuum. The sporozoites are elongate with two clear globules and lie lengthwise head to tail in the sporocysts. First-generation meronts are 16 by 13 μm in size at 3 days post infection and contain 16–24 merozoites. Second-generation meronts are 16 by 12 μm (5 days), containing 14–22 merozoites; third-generation meronts are 21 by 16 μm in size (7 days) and contain 14–28 merozoites. The macrogametes are 18 by 12 μm and the microgamonts 17 by 13 μm .

Host: Pig

Life cycle: The endogenous stages are found in the epithelial cells of the villi, and the necks of the crypts in the posterior small intestine, and also in the caecum and colon. There are three generations of meronts. The first-generation meronts mature at 3 days, second-generation meronts mature at 5 days and a third generation of meronts matures 7 days after infection. The prepatent period is 7–11 days and the patent period 4–8 days. Sporulation time is 9–12 days.

Geographical distribution: Worldwide

Pathogenesis: Not generally considered pathogenic, but it may cause mild diarrhoea in piglets.

Clinical signs: Occasional diarrhoea

Pathology: On postmortem there may be enteritis and large numbers of meronts and gamonts may be found in mucosal scrapings. On histopathology, there may be villous atrophy, villous fusion and crypt hyperplasia.

Eimeria spinosa**Predilection site:** Small intestine**Phylum:** Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, 17–24 by 12–19 μm (mean $20.6 \times 16.2 \mu\text{m}$), with a thick, rough, brown wall with long spines. There is a polar granule but no micropyle or oocyst residuum (see Fig. 4.36). Sporocysts are elongate ovoid, 10–14 by 5–7 μm , each with a prominent Stieda body and residuum. The sporozoites are elongate, and lie lengthwise head to tail in the sporocysts and each has a clear globule at the large end.

Host: Pig

Life cycle: All the endogenous stages are found in the villous epithelial cells of the jejunum and ileum. The number of meront generations is not known. The prepatent period is 7 days. The sporulation time is 9–10 days.

Geographical distribution: Worldwide

Pathogenesis: *Eimeria spinosa* has been described as causing clinical disease in young piglets. Older animals are generally not affected.

Clinical signs: Diarrhoea, inappetence, emaciation, depressed growth and occasional mortality in young piglets.

Pathology: Similar to *E. scabra*.

The following species of *Eimeria* found in pigs are considered non-pathogenic.

Eimeria porci

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, 18–27 by 13–18 μm (mean $21.6 \times 15.5 \mu\text{m}$), colourless to yellowish-brown, with an indistinct micropyle, a polar granule but no oocyst residuum (see Fig. 4.36). Sporocysts are ovoid, 8–12 by 6–8 μm . Each has a Stieda body and a sporocyst residuum. The sporozoites are elongate and lie at either end of the sporocysts, or lie lengthwise head to tail. Each has an indistinct clear globule.

Host: Pig

Life cycle: The endogenous stages occur in the epithelial cells of the lower jejunum and ileum below the host cell nucleus. There are two meront generations. The first occurs 1–3 days, and the second 3–6 days after infection. Young gamonts can be recognised 5 days after infection. The prepatent period is 5–7 days and the patent period 6 days. Sporulation time is 9 days.

Geographical distribution: Worldwide

Eimeria neodebliecki

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoid, 17–26 by 13–20 μm (mean $21.2 \times 15.8 \mu\text{m}$), and the wall is smooth and colourless; there is no micropyle or oocyst residuum but there is a polar granule (see Fig. 4.36). Sporocysts are elongate or broadly ovoid (9–14 by 5–8 μm); each has a Stieda body and a sporocyst residuum. The sporozoites are vermiform and lie lengthwise head to tail in the sporocysts and each has two clear globules.

Host: Pig

Life cycle: Details of the life cycle are unknown. The prepatent period is 10 days and the patent period 6 days. The sporulation time is 13 days.

Geographical distribution: Worldwide

Eimeria perminuta

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid to subspherical, 12–15 by 10–13 μm (mean $13.3 \times 11.7 \mu\text{m}$), yellow in colour, and the wall has a rough surface. A polar granule is present but no micropyle or oocyst residuum (see Fig. 4.36). Sporocysts are ellipsoidal to broadly ovoid, 6–8 by 4–6 μm , each with a Stieda body and residuum. Sporozoites are elongate with two clear globules and lie lengthwise head to tail in the sporocysts.

Host: Pig

Life cycle: Details of the life cycle are unknown. The sporulation time is 10–12 days.

Geographical distribution: Worldwide

Eimeria suis

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal, 15–23 by 12–18 μm (mean $18.2 \times 14.0 \mu\text{m}$), with a smooth and colourless wall. There is a polar granule but no micropyle or oocyst residuum (see Fig. 4.36). Sporocysts are elongate ovoid, 8–12 by 4–6 μm , each with a prominent Stieda body and a sporocyst residuum. The sporozoites are elongate and lie lengthwise head to tail in the sporocysts and each has a clear globule at the broad end.

Host: Pig

Life cycle: Details of the life cycle are not known. The prepatent period is 10 days and the patent period 6 days. The sporulation time is 5–6 days.

Geographical distribution: Worldwide

Oocyst descriptions of these *Eimeria* species, including diagrammatic drawings, are provided in Chapter 4.

Cryptosporidium parvum

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Description: Mature oocysts are ovoidal or spheroidal, 5.0 by 4.5 µm (range 4.6–5.4 × 3.8–4.7 µm) and a length/width ratio of 1.19.

Hosts: Cattle, sheep, goat, horse, pig, deer, human

Geographical distribution: Worldwide

Pathogenesis: Most pig cryptosporidial infections are asymptomatic, with the majority of infections occurring in pigs aged 6–12 weeks.

Clinical signs: Clinically the disease is characterised by anorexia and diarrhoea, often intermittent, which may result in poor growth rates. Vomiting and diarrhoea have been reported in young piglets with combined rotavirus and *Cryptosporidium* infections.

Pathology: The meronts and gamonts develop in a parasitophorous envelope apparently derived from the microvilli and so the cell disruption seen in other coccidia does not apparently occur. However, mucosal changes are obvious in the ileum where there is stunting, swelling and eventually fusion of the villi. This has a marked effect on the activity of some of the membrane-bound enzymes.

Epidemiology: The epidemiology of infection has not been studied although it is likely to be similar to *C. parvum* infection in other hosts. Piglets are likely to become infected without showing clinical signs but become sources of infection for other piglets that follow. The primary route of infection is direct animal to animal via the faecal–oral route.

Notes: Recent molecular characterisations have shown that there is extensive host adaptation in *Cryptosporidium* evolution, and many mammals or groups of mammals have host-adapted *Cryptosporidium* genotypes that differ from each other in both DNA sequence and infectivity. Genetic and biological characterisation studies have identified two distinct host-adapted strains of *Cryptosporidium* in pigs. Pig genotype I is now considered to be *Cryptosporidium suis*.

Further details of *C. parvum* are given in Chapter 8.

Cryptosporidium suis

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Host: Pig

Description: Oocysts, passed fully sporulated, are ellipsoid, 4.4–4.9 by 4.0–4.3 µm (mean 4.6 × 4.2 µm), with a length/width ratio of 1.35.

Giardia intestinalis

Synonyms: *Giardia duodenalis*, *Giardia lamblia*, *Lamblia lamblia*

Predilection site: Small intestine

Phylum: Fornicata

Class: Treponadea

Family: Giardiidae

Hosts: Human, cattle, sheep, goat, pig, alpaca, dog, cat, guinea pig, chinchilla

Geographical distribution: Worldwide

Pathogenesis: Infection in pigs is considered non-pathogenic

Notes: The current molecular classification places isolates into eight distinct assemblages. Some authors give separate specific names to organisms isolated from different hosts, although species specificity of many isolates is unknown. Phylogenetic data suggest that *G. intestinalis* is a species complex composed of several species that are host-specific.

Further details of this species are given in Chapters 2 and 8.

LARGE INTESTINE

Oesophagostomum

Six species of *Oesophagostomum* have been described from pigs, of which the most commonly encountered species is *O. dentatum* (Table 11.2).

Oesophagostomum dentatum

Common name: Nodular worm

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: Adult worms are white in colour, 8–14 mm long. Males are 8–10 mm and females 11–14 mm (Fig. 11.11).

Description, microscopic: The cephalic vesicle is prominent, but cervical alae are practically absent. The nine elements of the leaf

Table 11.2 Species of *Oesophagostomum*.

| Species | Host | Geographical distribution |
|---|----------------|---------------------------|
| <i>Oesophagostomum dentatum</i> | Pig | Worldwide |
| <i>Oesophagostomum quadrispinulatum</i> | Pig, wild boar | Worldwide |
| <i>Oesophagostomum brevicaudum</i> | Pig | North America |
| <i>Oesophagostomum longicaudum</i> | Pig | Europe |
| <i>Oesophagostomum georgianum</i> | Pig | North America |
| <i>Oesophagostomum granatensis</i> | Pig | Europe |

Fig. 11.11 *Oesophagostomum dentatum* adult worms.

crown project forward and the internal leaf crown has 18 elements. The buccal capsule is shallow with parallel sides and the oesophagus is club-shaped with a narrow anterior end. In the female, the tail is relatively short. Eggs are ovoid, smooth with almost similar rounded poles and strongly barrel-shaped side walls. The shell is thin and colourless. They measure around 60–80 by 35–45 μm and contain 8–16 blastomeres in fresh faeces. L_3 are less than 600 μm with a tail less than 60 μm .

Host: Pig

Geographical distribution: Worldwide

Pathogenesis: *Oesophagostomum* infections in the pig are not often associated with clinical disease. Occasional diarrhoea, depression in weight gain and poor food conversion may occur, especially during the period of emergence of larvae and maturation of worms in the lumen of the large intestine. Burdens of about 3000 to 20,000 adult worms are associated with subclinical disease experimentally. Occasionally, infection with *Oesophagostomum*, particularly mucosal damage precipitated by larval encystment, may predispose to necrotic enteritis in association with anaerobic flora and perhaps *Balantidium*.

Clinical signs: Pregnant sows show inappetence, become very thin, and following farrowing milk production is reduced with effects on litter performance.

Diagnosis: Diagnosis is based on postmortem findings and faecal egg counts. Mixed infections with nodular worms and *Hyostromylus* occur frequently in pigs at pasture and their eggs are difficult to distinguish, requiring faecal culture to distinguish L_3 .

Pathology: In heavy infections there is thickening of the large intestinal wall with catarrhal enteritis. Nodule formation with *O. dentatum* is small compared with other species.

Epidemiology: Infection is more prevalent in older pigs, which are generally less susceptible to the pathogenic effects compared with younger pigs. Survival of free-living L_3 on the pasture and hypobiotic L_4 in the host occur during autumn and winter; the hypobiotic larvae complete their development in the spring often coincident

with farrowing. Transmission may also occur by flies, which can carry L_3 on their legs.

Treatment: Adult worms are susceptible to benzimidazoles, levamisole and macrocyclic lactones. Anthelmintic treatment does not always affect the larvae within the nodules and repeat treatments several weeks apart are required to reduce the worm population.

Control: Infections with *Oesophagostomum* are more likely to occur in outdoor pigs kept on pasture. Good management practices, such as provision of clean pastures, rotation, mixed or alternate grazing and strategic dosing regimens, should be considered.

Trichuris suis

Synonym: *Trichocephalus suis*

Common name: Whipworms

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: The adults are whitish and about 3–5 cm long with a thick broad posterior end tapering rapidly to a long filamentous anterior end that is characteristically embedded in the mucosa (Fig. 11.12).

Description, microscopic: The male tail is coiled and possesses a single spicule in a protrusible sheath. The sheath is variable in shape and in the extent of its spinous armature. The female tail is curved. The characteristic eggs are lemon-shaped, 50–68 by 21–31 μm , with a thick smooth shell and a conspicuous transparent protruding polar plug at both ends; in the faeces these eggs appear yellow or brown in colour. The contents are granular, unsegmented and brownish.

Hosts: Pig, wild boar

Geographical distribution: Worldwide

Pathogenesis: Most infections are light and asymptomatic. Occasionally, when large numbers of worms are present, they cause a

Fig. 11.12 *Trichuris suis* on the surface of the large intestine.

haemorrhagic colitis and/or a diphtheritic inflammation of the caecal mucosa. This results from the subepithelial location and continuous movement of the anterior end of the whipworm as it searches for blood and fluid. In pigs, heavy infections are thought to facilitate the invasion of potentially pathogenic spirochaetes.

Clinical signs: Despite the fact that pigs have a high incidence of light infections, the clinical significance of this genus is generally negligible, although isolated outbreaks have been recorded. Sporadic disease due to heavy infection is occasionally seen and is associated with an acute or chronic inflammation of the caecal mucosa with watery diarrhoea that often contains blood. Anaemia may be present.

Diagnosis: Since the clinical signs are not pathognomonic, diagnosis may depend on finding numbers of lemon-shaped *Trichuris* eggs in the faeces. However, since clinical signs may occur during the prepatent period, diagnosis in food animals may depend on necropsy.

Pathology: In severe cases, the mucosa of the large intestine is inflamed, haemorrhagic with ulceration and formation of diphtheritic membranes.

Epidemiology: The most important feature is the longevity of the eggs, which may survive for 3 or even 4 years as a reservoir of infection in piggeries. Generally pigs of around 2–4 months of age are the most heavily infected.

Treatment: The benzimidazoles or levamisole by injection are effective against adult *Trichuris*, but less so against the larval stage. Some benzimidazoles need to be administered over several days. Doramectin is also effective, as is in-feed medication with dichlorvos (where available).

Control: Prophylaxis is rarely necessary. Attention should be given to areas where eggs might continue to survive for long periods. Such areas should be thoroughly cleaned and disinfected or sterilised by wet or dry heat.

Notes: The adults are usually found in the caecum but are only occasionally present in sufficient numbers to be clinically significant.

Intestinal flukes

Several species of intestinal fluke belonging to the genera *Gastrodiscus* and *Gastrodiscoides* have been reported in pigs. Further details on the life cycle, epidemiology, treatment and control of intestinal flukes are provided in Chapter 10.

Gastrodiscus aegyptiacus

Common name: Intestinal fluke

Predilection site: Small and large intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Gastrodiscidae

Description, gross: Adult flukes are pink in colour and measure 9–17 by 8–11 mm. The anterior is up to 4 mm and cylindrical, while

the rest of the body is saucer-shaped, with the margins curved inwards (see Fig. 1.73).

Description, microscopic: The ventral surface is covered by a large number of regularly arranged papillae. The oral sucker has two posterolateral pouches; the posterior sucker is small and subterminal. Eggs are oval and measure 131–139 by 78–90 μm .

Final hosts: Horse, pig, warthog

Intermediate hosts: Snails of the genus *Bulinus* and *Cleopatra*

Geographical distribution: Africa, India

Gastrodiscus hominis

Synonym: *Gastrodiscoides hominis*

Common name: Intestinal fluke

Predilection site: Large intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Gastrodiscidae

Description: Adult flukes are pink in colour when fresh and measure 8–14 by 5–8 mm, with a conical anterior body and large disc-shaped posterior body lacking tegumental papillae.

Final hosts: Pig, human

Geographical distribution: Asia

Flagellate protozoa

Flagellate protozoa are commonly found in pig faeces but are generally considered non-pathogenic. The life cycle is similar for all species found in pigs. Transmission is thought to occur by ingestion of trophozoites from faeces. All are generally only identified from smears taken from the large intestine of fresh carcasses.

Tritrichomonas suis

Synonyms: *Trichomonas suis*, *Tritrichomonas foetus*

Predilection site: Nasal passages, stomach, caecum, colon

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is characteristically elongate or spindle-shaped, but may occasionally be pyriform or rotund, 9–16 by 2–6 μm (mean $11 \times 3 \mu\text{m}$), with three anterior flagella which are approximately equal in length and each ending in a round or spatulate knob. The undulating membrane runs the full length of the body and has four to six folds and its marginal filament continues as a posterior free flagellum (see Fig. 2.11). An accessory filament is present. The costa runs the full length of the body, and fine subcostal granules are present. The axostyle is a hyaline rod with a bulbous capitulum and extends beyond the body as a cone-shaped projection

narrowing abruptly to a short tip. There is a chromatic ring around its point of exit. The parabasal body is usually a single, slender, tube-like structure, and the nucleus is ovoid or elongated and has a large conspicuous endosome surrounded by a relatively clear halo.

Host: Pig

Geographical distribution: Worldwide

Pathogenesis: Occurs commonly and is considered non-pathogenic. The organism can cause abortion in sows when experimentally introduced into the reproductive tract.

Notes: *Tritrichomonas suis* is now thought to be synonymous with *Tritrichomonas foetus*, which has been found worldwide and is an important cause of infertility, abortion and endometritis in cattle (see Chapter 8). *Tritrichomonas foetus* is also associated with large bowel diarrhoea in cats (see Chapter 12).

Tetratrichomonas buttreyi

Synonym: *Trichomonas buttreyi*

Predilection site: Caecum, colon

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is ovoid or ellipsoidal, 4–7 by 2–5 μm (mean $6 \times 3 \mu\text{m}$). Cytoplasmic inclusions are frequently present. There are three or four anterior flagella, which vary in length from a short stub to more than twice the length of the body, and each ends in a knob or spatulate structure. The undulating membrane runs the full length of the body and has three to five undulations ending in a posterior free flagellum. The accessory filament is prominent and the costa relatively delicate. The axostyle is relatively narrow, has a spatulate capitulum and extends 3–6 μm beyond the body. There is no chromatic ring at its point of exit. A pelta is present. The nucleus is frequently ovoid ($2\text{--}3 \times 1\text{--}2 \mu\text{m}$) but is variable in shape and has a small endosome.

Hosts: Cattle, pig

Geographical distribution: Worldwide

Trichomitus rotunda

Synonym: *Trichomonas buttreyi*

Predilection site: Caecum, colon

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is typically broadly pyriform, but may occasionally be ovoid or ellipsoidal. It measures 7–11 by 5–7 μm (mean $9 \times 6 \mu\text{m}$). Cytoplasmic inclusions are frequently present. The three anterior flagella are approximately equal in length and each terminates in a knob or spatulate structure. The blepharoplast appears to consist of a single granule. The undulating membrane together with the costa extends about 50–75% the length of the body and

its undulation pattern varies from smooth to tightly telescoped or coiled waves. The posterior free flagellum is generally shorter than the body. The axostyle is a narrow, straight, non-hyaline rod with a crescent or sickle-shaped capitulum extending about 4 μm beyond the body. The nucleus is practically spherical, 2–3 μm in diameter, with an endosome surrounded by a clear halo. The parabasal body is 2–3 by 0.4–1.3 μm and is composed of two rami forming a 'V'. Each ramus has a parabasal filament.

Host: Pig

Geographical distribution: Worldwide

Chilomastix mesnili

Synonyms: *Chilomastix suis*, *Chilomastix hominis*, *Macrostoma mesnili*

Predilection site: Caecum, colon

Phylum: Fornicata

Class: Retortamonadea

Family: Retortamonadorididae

Description: Trophozoites are pear-shaped, 6–24 by 3–10 μm , with a spiral groove crossing the middle half of the body and three anterior flagella. A slit-like cytostome, enclosing a fourth flagellum, is located in the anterior portion of the body. The lemon-shaped cysts are 6–10 μm in diameter and contain a single nucleus and cytostome (Fig. 11.13).

Hosts: Human, apes (chimpanzee, orangutan) monkeys (macaques), pig

Geographical distribution: Worldwide

Pathogenesis: Non-pathogenic

Diagnosis: Identification of trophozoites, or cysts in large intestinal contents or faeces.

Treatment and control: Not required

Fig. 11.13 Cysts of *Chilomastix mesnili*.

Other intestinal protozoa

Entamoeba suis

Predilection site: Large intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites are 5–25 µm in diameter. The nucleus varies in appearance. The endosome is central and usually quite large and sometimes fills the nucleus but may be small with a homogeneous ring of peripheral chromatin. The cytoplasm is granular and vacuolated. The cysts are 4–17 µm in diameter and contain a single nucleus and chromatin granules of varying shape and size.

Host: Pig

Geographical distribution: Worldwide

Pathogenesis: Non-pathogenic

Diagnosis: Identification of trophozoites or cysts in large intestinal contents or faeces.

Treatment and control: Not required

Iodamoeba buetschlii

Synonyms: *Iodamoeba wenyonii*, *Iodamoeba suis*, *Entamoeba williamsi*, *Endolimax williamsi*

Predilection site: Large intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites are 4–20 µm with blunt pseudopods that form slowly. The nucleus is large and contains a large nuclear endosome rich in chromatin surrounded by a layer of globules. The cysts are irregular in form, ranging from 5 to 14 µm and contain a single nucleus and a large glycogen body.

Hosts: Pig, human, apes (chimpanzee, gorilla), monkeys

Geographical distribution: Worldwide

Pathogenesis: Non-pathogenic

Notes: *Iodamoeba buetschlii* is the commonest amoeba found in pigs, and is also commonly found in monkeys and humans.

Endolimax nana

Synonyms: *Amoeba limax*, *Entamoeba nana*, *Endolimax intestinalis*, *Endolimax suis*, *Endolimax ratti*

Predilection site: Large intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites are 6–15 µm with granular vacuolated cytoplasm and a nucleus which contains an irregular endosome composed of chromatin granules. Mature cysts are oval, 8–10 µm long, and contain four nuclei.

Hosts: Human, apes, monkeys, pig, rat

Geographical distribution: Worldwide

Pathogenesis: Non-pathogenic

Notes: *Endolimax nana* is common in humans, primates and pigs.

Balantidium coli

Predilection site: Large intestine

Phylum: Ciliophora

Class: Litostomatea

Family: Balantidiidae

Description: An actively motile organism, up to 300 µm, whose pellicle possesses rows of longitudinally arranged cilia (Fig. 11.14; see also Fig. 2.2). At the anterior end there is a funnel-shaped depression, the peristome, which leads to the cytostome or mouth; from this, food particles are passed to vacuoles in the cytoplasm and digested. Internally there are two nuclei, a reniform macronucleus and adjacent micronucleus, and two contractile vacuoles, which regulate osmotic pressure. Cysts are spherical to ovoid, 40–60 µm in diameter (Fig. 11.15).

Hosts: Pig, human, camel, monkey, dog (rarely), rat

Geographical distribution: Worldwide

Pathogenesis: Normally non-pathogenic, these protozoa may, for reasons unknown, occasionally cause ulceration of the mucosa and accompanying dysentery in the pig. *Balantidium* may be a secondary invader within lesions of the large intestine.

Fig. 11.14 *Balantidium coli*.

Fig. 11.15 *Balantidium coli* cysts.

Clinical signs: Occasionally causes diarrhoea or dysentery.

Diagnosis: *Balantidium* is easily recognised by microscopic examination of intestinal contents or by histological examination of intestinal lesions.

Pathology: The organisms are found in enormous numbers in the lumen of the large intestine with normal caecal mucosa (Fig. 11.16). However, the organism may be found within mucosal ulcers initiated by other infections. It produces hyaluronidase, which might help to enlarge the lesions by attacking the intercellular ground substance.

Epidemiology: *Balantidium coli* probably exists as a commensal in the large intestine of most pigs. Humans may occasionally become clinically affected through contamination of foodstuffs or hands with pig faeces. Transmission occurs by ingestion of cysts or trophozoites. The cysts are resistant to environmental conditions and

Fig. 11.16 Large numbers of *Balantidium coli* in the lumen of the large intestine.

can survive for weeks in pig faeces. The pig is the usual source of infection for humans and dogs.

Treatment: Tetracyclines are effective.

Control: Routine hygiene measures to prevent ingestion of cysts or faeces should prevent infection.

Parasites of the respiratory system

NASAL PASSAGES

Tritrichomonas suis

For more details see section Large intestine.

LUNGS

Metastrongylus

Description, gross: Slender white worms, up to 6.0 cm in length; the host, site and long slender form are sufficient for generic identification. Individual species are differentiated on the size and shape of the male spicules.

Description, microscopic: The ellipsoid eggs have rough thick shells, are 45–57 by 38–41 μm in size and are larvated when laid.

Pathogenesis: The adult worms are found in the lumen of small bronchi and bronchioles, especially those of the posterior lobes of the lungs and provoke a chronic catarrhal and eosinophilic bronchiolitis and bronchitis. Purulent staphylococcal infection in the lungs has been noted in many cases of metastrongylosis. The worms are also believed to be responsible for the occasional transmission of swine influenza virus but conclusive proof is not available.

Clinical signs: Most infections are light and asymptomatic, particularly in older pigs. However, in heavy infections in young animals, coughing can be marked, and is accompanied by dyspnoea and nasal discharge. Secondary bacterial infection may complicate the signs, inducing inappetence and loss of weight.

Diagnosis: For faecal examination saturated magnesium sulphate should be used as the flotation solution because of the heavy density of the eggs. The small, rough-shelled, larvated eggs are characteristic, but it should be noted that *Metastrongylus* is often present in normal pigs, and pulmonary signs may be due to microbial infection rather than lungworms. Egg output may be sporadic in older pigs. The disease is most often encountered in pigs on pasture, though an occasional outbreak has occurred in yarded pigs. Disease history and clinical signs are also an aid to diagnosis.

Pathology: During the prepatent period areas of pulmonary consolidation, bronchial muscular hypertrophy and peribronchial lymphoid hyperplasia develop, often accompanied by areas of overinflation. When the worms are mature, and eggs are aspirated into the smaller air passages and parenchyma, consolidation increases and emphysema is more marked. Hypersecretion of bronchiolar mucus also occurs during this stage. About 6 weeks after infection, chronic bronchitis and emphysema are established and small

greyish nodules may be found in the posterior part of the diaphragmatic lobes; these may aggregate to form larger areas and are slow to resolve.

Epidemiology: Metastrongylosis shows a characteristic age distribution, being most prevalent in pigs of 4–7 months old. It can be of high prevalence in wild boar. The parasite is common in most countries, although outbreaks of disease do not often occur, probably due to the fact that most systems of pig husbandry do not allow ready access to earthworms by pigs. Though it is often suggested that *Metastrongylus* may transmit some of the porcine viruses, and may enhance the effect of pathogens already present in the lungs, the role of the worm is not conclusively proven.

Treatment: Many anthelmintics, including the modern benzimidazoles, levamisole and the macrocyclic lactones, are highly effective.

Control: When pig husbandry is based on pasture, control is extremely difficult because of the ubiquity and longevity of the earthworm intermediate host. On farms where severe outbreaks have occurred, pigs should be housed, dosed and the infected pasture cultivated or grazed with other livestock.

Metastrongylus apri

Synonym: *Metastrongylus elongatus*

Common name: Pig lungworm

Predilection site: Lung

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description, gross: The adult male is up to 25 mm and the female up to 58 mm long.

Description, microscopic: The male bursa is relatively small and the spicules are filiform and each ends in a single hook. The vulva of the female is near the anus. The posterior is curved ventrad. The medium-sized eggs are ellipsoidal with a thick greyish shell with a slightly crenated rough surface. Eggs measure around 50–63 by 33–42 µm and contain a fully developed first-stage larva when laid.

Final hosts: Pig and wild boar; has been recorded in sheep, deer and in other ruminants

Intermediate hosts: Earthworms: *Lumbricus terrestris*, *Lumbricus rubellus*, *Diplocardia* spp., *Eisenia austriaca*, *Dendrobaena rubida*, *Helodrilus foetidus*, *H. caliginosus*

Geographical distribution: Worldwide

Metastrongylus pudendotectus

Synonym: *Metastrongylus brevivaginat*

Common name: Pig lungworm

Predilection site: Lung

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description, microscopic: Differs from *M. apri* in having a larger bursa, and smaller spicules with double hooks in the male. The female tail is straight. Eggs measure about 57–63 by 39–42 µm.

Final hosts: Pig and wild boar

Intermediate hosts: Earthworms: *Lumbricus terrestris*, *Lumbricus rubellus*

Geographical distribution: Worldwide

Metastrongylus salmi

Common name: Pig lungworm

Predilection site: Lung

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description, microscopic: Differs from the other two species in the length and shape of the male spicules.

Geographical distribution: Parts of Africa, Indo-China, USA

Echinococcus granulosus

For more details see Parasites of the liver.

Parasites of the liver

Ascaris suum

For more details on ‘milk spot’ liver caused by migrating larvae, see section Small intestine.

Toxocara canis

Migrating larvae of this species can also cause ‘milk spot’ liver in pigs. For more details see Chapter 12.

Fasciola hepatica

Common name: Liver fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description, gross: Adult fluke are leaf-shaped, grey–brown in colour and around 2.5–3.5 cm in length.

Description, microscopic: The anterior end is conical and marked off by distinct shoulders from the body. The tegument is covered

with backwardly projecting spines. An oral and ventral sucker may be readily seen.

Final hosts: Sheep, cattle, goat, horse, deer, human and other mammals

Intermediate hosts: Snails of the genus *Galba* (*Lymnaea*)

Geographical distribution: Worldwide

For more details see Chapter 9.

Fasciola gigantica

Common name: Tropical large liver fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description: The adult fluke is larger than *F. hepatica*, the body is more transparent, and can reach 7.5 cm in length and 1.5 cm in breadth. The shape is more leaf-like, the conical anterior end is very short and the shoulders, characteristic of *F. hepatica*, are barely perceptible. The gut caeca are more highly branched than in *F. hepatica*.

Final hosts: Cattle, buffalo, sheep, goat, pig, camel, deer, human

Intermediate hosts: Snails of the genus *Lymnaea*

Geographical distribution: Africa, Asia

For more details see Chapter 9.

Echinococcus granulosus

Subspecies: *granulosus*

Common names: Dwarf dog tapeworm, hydatidosis

Predilection site: Mainly liver and lungs (intermediate hosts); small intestine (definitive host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description: Hydatid cysts are large fluid-filled vesicles, 5–10 cm in diameter, with a thick concentrically laminated cuticle and an internal germinal layer. The germinal layer produces numerous small vesicles or brood capsules each containing up to 40 scolices, invaginated into their neck portions and attached to the wall by stalks. Brood capsules may become detached from the wall of the vesicle and float freely in the vesicular fluid and form 'hydatid sand'.

Final hosts: Dog and many wild canids

Intermediate hosts: Domestic and wild ruminants, human and primates, pig and lagomorphs

Geographical distribution: Worldwide

Pathogenesis: Hydatid cysts generally cause no clinical signs in pigs. Pressure atrophy of the liver and ascites may be found in heavy infections. Dyspnoea and coughing may be observed in heavily infected lungs.

For more details see Chapter 9.

***Taenia hydatigena* (metacestode)**

Synonyms: *Taenia marginata*, *Cysticercus tenuicollis*

Predilection site: Abdominal cavity, liver (intermediate hosts); small intestine (definitive hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description: The mature metacestode (*Cysticercus tenuicollis*) is about 5–8 cm in diameter and contains a single invaginated scolex (bladderworm) with a long neck.

Final hosts: Dog, fox, weasel, stoat, polecat, wolf, hyena

Intermediate hosts: Sheep, cattle, deer, pig, horse

Geographical distribution: Worldwide

Notes: The correct nomenclature for the intermediate host stage is 'metacestode stage of *Taenia hydatigena*' rather than '*Cysticercus tenuicollis*'.

For more details see Chapter 9.

Parasites of the pancreas

Eurytrema pancreaticum

Synonyms: *Distoma pancreaticum*, *Eurytrema ovis*

Common name: Pancreatic fluke

Predilection site: Pancreatic ducts and occasionally the bile ducts and the duodenum

Phylum: Platyhelminthes

Class: Trematoda

Family: Dicrocoeliidae

Description: Oval, leaf-shaped, reddish-brown flukes measuring around 8–16 by 5–8.5 mm. The body is thick and the juvenile flukes are armed with spines which are often absent by the adult stage. The oral sucker is larger than the ventral sucker and the pharynx and oesophagus are short. The testes are positioned horizontally just behind the ventral sucker. A tubular cirrus sac is present. The uterus completely occupies the posterior body.

Hosts: Cattle, buffalo, sheep, goat, pig, camel and human

Intermediate hosts: Land snails, particularly of the genus *Bradybaena*; grasshoppers of the genus *Conocephalus* or tree crickets (*Oecanthus*)

Geographical distribution: Eastern Asia and South America

Parasites of the circulatory system

Schistosomes

Schistosomes are flukes found in the circulatory system. The sexes are separate, the small adult female lying permanently in a longitudinal groove, the gynaecophoric canal, in the body of the male (see Fig. 1.81). The genus has been divided into four groups – *haematobium*, *indicum*, *mansoni* and *japonicum* – but the genus as currently defined is paraphyletic so revisions are likely.

Indicum group

Schistosoma spindale

Common names: Blood fluke, bilharziosis

Predilection site: Mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description: The male measures about 5–16 mm and the female around 7.2–16.2 mm in length.

Final hosts: Cattle, horse, pig and occasionally dog

Intermediate hosts: Snails (*Planorbis*, *Indoplanorbis* spp., *Lymnaea* spp.)

Geographical distribution: Parts of Asia and the Far East

Japonicum group

Schistosoma japonicum

Common names: Blood fluke, bilharziosis

Predilection site: Portal and mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description: The male, which is broad and flat and about 9.5–20 mm long, carries the female, which is 12–26 mm long, in the hollow of its inwardly curved body. The suckers lie close together near the anterior end. The cuticle is spiny on the suckers and in the gynaecophoric canal. This characteristic and the vascular predilection site are sufficient for generic identification.

Final hosts: Cattle, horse, sheep, goat, dog, cat, rabbit, pig, human

Intermediate hosts: Snails belonging to the genus *Oncomelania*

Geographical distribution: South and East Asia

Other schistosomes

Schistosoma incognitum

Common names: Blood fluke, bilharziosis

Synonym: *Schistosoma suis*

Predilection site: Mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, microscopic: The eggs measure about 90 by 41 μm , and are yellowish-brown, sub-oval with one side flattened, with a small stout spine inclining towards the flattened margin.

Final hosts: Pig, dog

Intermediate hosts: Snails (*Radix* spp.)

Geographical distribution: Indian subcontinent

For more general details of *Schistosoma* species see Chapter 8.

Trypanosomes

See Chapter 2 (Family Trypanosomatidae) for general description and Chapter 8 for detailed descriptions of individual species of trypanosomes and their control.

Trypanosoma brucei brucei

Common name: Nagana

Predilection site: Blood. *Trypanosoma brucei brucei* is also found extravascularly in, for example, the myocardium, central nervous system (CNS) and reproductive tract.

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Trypanozoon*

Description: *Trypanosoma brucei brucei* is pleomorphic in form and ranges from long and slender, up to 42 μm (average 29 μm), to short and stumpy, 12–26 μm (mean 18 μm), the two forms often being present in the same blood sample. The undulating membrane is conspicuous, the kinetoplast is small and subterminal and the posterior end is pointed (see Fig. 2.6).

Hosts: Cattle, horse, donkey, zebu, sheep, goat, camel, pig, dog, cat, wild game species

Geographical distribution: Sub-Saharan Africa

Treatment: The two drugs in common use in cattle are isometamidium and diminazene aceturate and both should be suitable for use in pigs. These are usually successful except where trypanosomes have developed resistance to the drug or in some very chronic cases. Treatment should be followed by

surveillance, since reinfection, followed by clinical signs and parasitaemia, may occur within a week or two. Alternatively, the animal may relapse after chemotherapy due to a persisting focus of infection in the tissues or because the trypanosomes are drug-resistant.

Trypanosoma congolense congolense

Common names: Nagana, paranagana, Gambia fever, ghindi, gobial

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Nannomonas*

Description: *Trypanosoma congolense congolense* is small, monomorphic in form and 8–20 µm long. The undulating membrane is inconspicuous, the medium-sized kinetoplast is marginal and the posterior end is blunt. There is no free flagellum (see Fig. 2.5). In fresh blood films the organism moves sluggishly, often apparently attached to red cells.

Geographical distribution: Sub-Saharan Africa

Treatment: In infected cattle, the two drugs in common use are diminazene aceturate (Berenil) and homidium salts (Ethidium and Novidium) and are appropriate for use in pigs infected with *T. congolense*. As with *T. brucei*, these drugs are usually successful except where trypanosomes have developed resistance to the drug or in some very chronic cases.

Trypanosoma simiae

Synonyms: *Trypanosoma congolense simiae*, *Trypanosoma rodhaini*, *Trypanosoma porci*

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Nannomonas*

Description: Tryptomastigotes are polymorphic, 12–24 µm long. Around 90% of the forms are long and stout with a conspicuous undulating membrane; around 7% are long and slender with an inconspicuous undulating membrane; and around 3% are short with an inconspicuous undulating membrane. A free flagellum is usually absent.

Hosts: Pig, camel, sheep, goat

Geographical distribution: Central Africa

Epidemiology: *Trypanosoma simiae* is mainly a parasite of warthogs transmitted by tsetse flies, in which the parasites develop in the midgut and proboscis. Tsetse flies also transmit the parasite to pigs, but transmission between pigs is usually mechanically by biting flies.

Treatment: In pigs, *T. simiae* is the most important trypanosome pathogen and the rapid onset of death again gives little chance of treatment. Isometamidium chloride at increased dose rates of 12.5–35 mg/kg i.m. or a combination of quinapyramine (7.5 mg/kg s.c.) and diminazene aceturate (5 mg/kg i.m.) can be used. A suramin–quinapyramine complex (4 mL per 5 kg) has shown some success in prophylaxis in young piglets for a period of 3 months, and in adults for 5 months.

Trypanosoma suis

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Pycnomonas*

Description: Tryptomastigotes are monomorphic, stout, 14–19 µm long with a small marginal kinetoplast and a short free flagellum.

Host: Pig

Geographical distribution: Central Africa

Treatment: As for *T. simiae*.

Babesiosis

Two species of *Babesia* are found in pigs: *Babesia perroncitoi* is a small babesia; *B. trautmanni* is a large babesia. Infection is transmitted to pigs via tick vectors.

Pathogenesis: The rapidly dividing parasites in the red cells produce destruction of the erythrocytes with accompanying haemoglobinuria, haemoglobinuria and fever.

Diagnosis: The history and clinical signs of fever, anaemia, jaundice and haemoglobinuria in pigs located in enzootic areas where ticks occur are usually sufficient to justify a diagnosis of babesiosis. For confirmation, the examination of blood films, stained with Giemsa, will reveal the parasites in the red cells.

Pathology: The spleen is enlarged and there is pulmonary, renal and gastrointestinal hyperaemia and oedema. Subepicardial and subendocardial haemorrhages are present with petechiation present on the serous membranes.

Treatment: Diminazene aceturate at 3.5 mg/kg i.m. is effective.

Control: Tick control measures can be considered for controlling disease. Topical application of acaricides may provide some level of protection but may be difficult in pigs, be expensive and may have a negative cost–benefit. Under certain conditions, it may be more beneficial to attain endemic stability by allowing early infection and development of immunity.

Babesia perroncitoi

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: A small babesia that occurs most commonly as annular forms measuring 0.7–2 µm, although oval to pyriform forms, 1–3 by 1–2 µm in size, may also occur. Merozoites usually occur singly in erythrocytes, but sometimes two or more may be present.

Host: Pig

Geographical distribution: Southern Europe, West and Central Africa, Vietnam

Clinical signs: Clinical signs include fever, anaemia, haemoglobinuria, jaundice, oedema and incoordination. Abortion may occur in pregnant sows.

Epidemiology: Wild pigs may act as reservoirs of infection and the tick vectors include *Rhipicephalus* (*R. appendiculatus*, *R. sanguineus*) and *Dermacentor* (*D. reticulatus*).

Babesia trautmanni

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: A large babesia that occurs as oval, pyriform and less commonly round forms. Merozoites measure 2.5–4 by 1.5–2 µm, and usually occur in pairs within erythrocytes, but sometimes four or more may be present.

Host: Pig

Life cycle: As for *B. perroncitoi*.

Geographical distribution: Southern Europe, Africa and parts of Asia

Clinical signs: Clinical signs include fever, anaemia, haemoglobinuria, jaundice, oedema and incoordination. Abortion may occur in pregnant sows. Mortality may reach 50% and pigs of all ages are affected.

Epidemiology: Infection and disease is seasonal according to the activity of the tick vector. Wild boar and warthogs may act as reservoirs of infection and the tick vectors include *Rhipicephalus* (*R. appendiculatus*, *R. sanguineus*), *Dermacentor* (*D. reticulatus*) and *Rhipicephalus* (*Boophilus*) *decoloratus*. Transovarian transmission has been reported in *R. sanguineus*.

Eperythrozoon suis

Synonym: *Mycoplasma suis*

Predilection site: Blood

Kingdom: Bacteria

Phylum: Firmicutes

Order: Mycoplasmatales

Family: Mycoplasmataceae

Description: Pleomorphic coccobacilli usually occurring as eperythrocytic organisms in depressions on the cell surface. Cocci appear light blue with Giemsa or Romanowsky's stains.

Host: Pig

Life cycle: Organisms are transmitted by biting insects and possibly lice. Replication takes place by binary fission or budding.

Geographical distribution: Worldwide

Pathogenesis: Of the *Eperythrozoon* species, *E. suis* is the most pathogenic, and infection may be very severe and fatal. Pigs are first depressed and inappetent, have high fever and go on to develop anaemia, becoming weaker and constipated, then jaundiced. Infection in sows produces both acute and chronic syndromes. Acute infections often occur postpartum and affected animals are pyrexia and anorexic and may show agalactia and mammary and vulvular oedema. Chronic infections are usually subclinical and often difficult to diagnose. Affected animals are generally in poor condition, pale and jaundiced.

Clinical signs: Jaundice and anaemia in very young pigs.

Diagnosis: Identification from staining artefacts requires good blood films and filtered Giemsa stain. The organisms appear as cocci or short rods on the surface of the erythrocytes, often completely surrounding the margin of the red cell. However, *Eperythrozoon* organisms are relatively loosely attached to the red cell surface and are often found free in the plasma.

Pathology: The main pathological changes occur in the liver and spleen. In the liver there is fatty degeneration and atrophy and necrosis of central hepatic cells with widespread lymphatic infiltration. Reticuloendothelial cells in liver, spleen and lymph nodes are hypertrophied and filled with haemosiderin deposits.

Epidemiology: Transmission is seasonal, being more common in summer and autumn when biting flies are active. The pig louse (*Haemotopinus suis*) has also been incriminated in transmission.

Treatment and control: Tetracyclines and the arsenical roxarsone are reported to be effective. Control of ectoparasite infections and possibly addition of arsenicals or tetracyclines to the diet have been advocated in countries where the disease is endemic.

Notes: The taxonomy of this species is subject to much debate and it is now considered to be in the bacterial genus *Mycoplasma* (class Mollicutes) based on 16S rRNA gene sequences and phylogenetic analysis.

Parasites of the nervous system

Toxoplasma gondii

For more details see Parasites of the locomotory system.

Parasites of the reproductive/urogenital system

Stephanurus dentatus

Common name: Pig kidney worm

Predilection site: Kidney, perirenal fat and occasionally the axial musculature and the spinal canal

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: A large stout worm up to 4.5 cm long, and 2 mm wide with a prominent buccal capsule and transparent cuticle through which the internal organs may be seen. The gut is convoluted. Males are 2–3 cm and females 3–4.5 cm long. The colour is usually pinkish. The size and site are diagnostic.

Description, microscopic: The buccal capsule is cup-shaped with small leaf crowns and six external cuticular thickenings (epaulettes) of which the ventral and dorsal are most prominent, and six cusped teeth at the base. The male bursa is short and the two spicules are of either equal or unequal length. The medium-sized eggs are a broad ellipse with a thin transparent shell and appear only in the urine. They measure about 90–120 by 53–70 µm and contain numerous blastomeres (32–64).

Hosts: Pig, wild boar, rarely cattle

Geographical distribution: Mainly warm to tropical regions of all continents. It does not occur in western Europe.

Pathogenesis: Though the favoured site is in the perirenal fat, some worms occur in the kidney itself, in the calyces and pelvis (Fig. 11.17). Erratic migration is common in *Stephanurus* infection, and larvae have been found in most organs, including the lungs, spleen, spinal cord, and in muscle. In these sites they are trapped by encapsulation and never reach the perirenal area. Prenatal infection has been reported.

The main pathogenic effect is due to the larvae, which by the late L₄ stage have heavily sclerotised buccal capsules capable of tearing tissue and they cause much damage to the liver and occasionally other organs in their wanderings. In heavy infections there may be severe cirrhosis, thrombosis of hepatic vessels and ascites and, in rare cases, liver failure and death. In most infections, however, the effects are seen only after slaughter as patchy cirrhosis, and the main importance of the worm is economic, from liver condemnation. In general the adult worms are not pathogenic. Usually the adult worms, soon after arrival at the perirenal site, are

Fig. 11.17 *Stephanurus dentatus* worms in a kidney.

encapsulated in cysts, which may contain greenish pus. In rare cases the ureters may be thickened and stenosed, with consequent hydronephrosis.

Clinical signs: In most infections the only sign is failure to gain weight or, in more severe cases, weight loss. Where there is more extensive liver damage there may be ascites, but it is only when there is massive invasion, comparable to acute fasciolosis in sheep, that death occurs.

Diagnosis: The clinical signs are likely to be few, and since most of the damage occurs during the prepatent phase, eggs may not be found in the urine. However, in endemic areas, where pigs are failing to thrive and where local abattoirs record appreciable numbers of cirrhotic livers, a presumptive diagnosis can be made. Worms can be identified at necropsy.

Pathology: Percutaneous infection leads to the formation of nodules in the skin, with oedema and enlargement of the superficial lymph nodes. Migrating larvae produce acute inflammatory lesions especially in the liver. Inflammation may lead to abscess formation and extensive liver cirrhosis. The adult parasite is not markedly pathogenic and is found in cysts 0.5–4 cm in diameter, each cyst containing a pair of worms. Cysts in the kidney may cause thickening of the ureter, which in chronic cases may be almost occluded.

Epidemiology: Though the adult worms are never numerous, they are very fecund, and an infected pig may pass a million eggs per day. The L₃ is susceptible to desiccation, so that stephanurosis is mainly associated with damp ground. Since it infects readily by skin penetration, the pigs' habit of lying around the feeding area when kept outside presents a risk, as does damp unhygienic accommodation for housed animals. Such conditions, coupled with prenatal infection and the longevity of the worm, ensure continuity of infection through many generations of pigs. All ages of pigs are susceptible to infection. Piglets can be infected *in utero*.

Treatment: Levamisole, the modern benzimidazoles and ivermectin are effective.

Control: One approach to control is based on the susceptibility of the L₃ to desiccation and on the fact that a major route of infection is percutaneous. It follows that the provision of impervious surfaces around the feeding areas for outdoor reared pigs, and simple hygiene, ensuring clean dry flooring in pig houses, will help to limit infection. This approach may be supplemented by segregating young pigs from those of more than 9 months of age, which will be excreting eggs.

The 'gilt only' scheme, which was advocated by workers in the USA, consists essentially of using only gilts for breeding. The gilts are reared on land which is dry and exposed to the sun. A single litter is taken from them, and as soon as the piglets can be weaned the gilts are marketed. The scheme takes advantage of the extremely long prepatent period, which allows a single breeding cycle by the gilts to be completed before egg laying begins and so progressively eliminates infection. The boars used in the scheme are housed on concrete.

Regimens incorporating anthelmintic control recommend treatment of sows and gilts 1–2 weeks before putting to the boar, and again 1–2 weeks before farrowing. It should be remembered in designing a control system that the earthworm transport hosts present a continuous reservoir of infection.

Parasites of the locomotory system

Taenia solium

Synonyms: *Cysticercus cellulosae*, *Cysticercus solium*

Common name: Human pork tapeworm

Predilection site: Small intestine (final host); muscle (intermediate host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: The adult tapeworm is 3–5 m long with a scolex that is typically taeniid, having a rostellum with four suckers and armed with two concentric rows of 22–32 hooks, while the uterus of the gravid segment has 7–13 lateral branches. Adults can survive in humans for many years.

Description, microscopic: Cysts are milky white and have a scolex bearing a rostellum and hooks similar to the adult. The small egg is slightly ellipsoidal with a smooth shell with a radially striated embryophore. They are yellowish-brown and measure about 35–40 by 30–35 µm and contain a hexacanth embryo. Eggs are released when the shed gravid proglottid disintegrates.

Final host: Human. Note that the human can act as an intermediate host as well as a definitive host.

Intermediate hosts: Pig, wild boar, rarely dog and human

Geographical distribution: This cestode is most prevalent in South and Central America, India, Africa and parts of the Far East, apart from areas where there are religious sanctions on the eating of pork. It is now uncommon in many developed countries.

Pathogenesis: Clinical signs are inapparent in pigs naturally infected with cysticerci and generally insignificant in humans with adult tapeworms. However, when humans are infected with cysticerci, various clinical signs may occur depending on the location of the cysts in the organs, muscles or subcutaneous tissue. Cysticerci may be found in every organ of the body in humans but are most common in the subcutaneous tissue, eye and brain. Larvae that reach the brain develop in the ventricles and frequently become racemose in character. Most seriously, cysticerci that develop in the CNS produce mental disturbances or clinical signs of epilepsy or increased intracranial pressure. They may also develop in the eye with consequent loss of vision. In Latin America alone it is estimated that almost 0.5 million people are affected, either by the nervous or ocular forms of cysticercosis.

Clinical signs: Infected pigs are usually asymptomatic. Infection is generally insignificant in humans, although adult tapeworms can occasionally cause abdominal discomfort and diarrhoea. However, when humans, acting as the intermediate host, are infected with cysticerci, various clinical signs may occur depending on the location and number of cysts in the organs, muscles or subcutaneous tissue. CNS signs include mental disturbances or clinical signs of epilepsy and may be fatal. Loss of vision may occur when the eye is involved.

Diagnosis: For all practical purposes, diagnosis in pigs depends on meat inspection procedures but this lacks sensitivity for low

infection levels. Individual countries have different regulations regarding the inspection of carcasses, but invariably the masseter muscle, tongue and heart are incised and examined and the intercostal muscles and diaphragm inspected. Proglottids can sometimes be seen in faeces. Cysticerci of *T. solium* are larger and more numerous than those of *T. saginata* (see Chapter 8). In humans, the diagnosis of cerebral cysticercosis depends primarily on the detection of cysticerci by computed tomography (CT) and on the finding of antibodies to cysticerci in the cerebrospinal fluid.

Pathology: Cysticerci, comprising a single large cyst and inverted scolex, measure 1–2 cm and are easily visible between muscle fibres. The cysticerci are rapidly ensheathed in connective tissue and create a crescentic zone of degenerative lysis around them, thereby allowing room to grow. Pigs are usually slaughtered at an age when all cysticerci are generally still viable.

Epidemiology: In developing countries this depends primarily on the close association of rural pigs with humans, and in particular their often unrestricted access to human faeces. Indifferent standards of meat inspection and illicit trading in uninspected pork are also major factors in the spread of the infection. Pigs may acquire massive infections because the gravid segments are not active and may remain in faeces. Humans normally become infected when they consume raw or undercooked pork. As noted above, humans may become infected with cysticerci and this may occur from the ingestion of eggs on vegetables or other foodstuffs contaminated with human faeces or handled by an infected person.

Treatment: No effective drugs are available to kill cysticerci in the pig, although in humans praziquantel and albendazole are considered to be of some value as possible alternatives to surgery.

Control: This depends ultimately on the enforcement of meat inspection regulations and deep-freezing procedures. Freezing pork at –10 to –8°C continuously for 4 days kills the cysticerci, but chilling the meat at 0°C is not sufficient and cysts may remain viable in chilled meat for 70 days. The exclusion of pigs from contact with human faeces, the thorough cooking of pork and proper standards of personal hygiene will reduce the prevalence of infection.

Notes: A third form of *Taenia* ('Asian *Taenia*') has been reported throughout eastern Asia and also from parts of East Africa and Poland. The 'Asian *Taenia*' appears to be closely related to *T. saginata* but its molecular profile indicates that it is genetically different. The cysticerci of this tapeworm are located in the liver of the pig and wild boar and occasionally in cattle, goats and monkeys. The 'Asian *Taenia*' is considered not to be an important cause of human cysticercosis.

Trichinella spiralis

For more details see section Small intestine.

Toxoplasma gondii

Predilection site: Muscle, lung, liver, reproductive system, CNS

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: Tachyzoites are found developing in vacuoles in many cell types, for example fibroblasts, hepatocytes, reticular cells and myocardial cells. In any one cell there may be 8–16 organisms, each measuring 6.0–8.0 µm. Tissue cysts, measuring up to 100 µm in diameter, are found mainly in the muscle, liver, lung and brain and may contain several thousand lancet-shaped bradyzoites.

Final hosts: Cat, other felids

Intermediate hosts: Any mammal, including human, or birds. Note that the final host, the cat, may also be an intermediate host and harbour extra-intestinal stages.

Geographical distribution: Worldwide

Pathogenesis: Most *Toxoplasma* infections in animals are light and consequently asymptomatic. Toxoplasmosis has been occasionally reported in young pigs and may cause severe fetal losses in pregnant sows, but more usually is mild and unnoticed.

Diagnosis: Tachyzoites of *T. gondii* are often difficult to find in tissue sections, but are more likely to be present in sections of brain and placenta. Identification can be confirmed by immunohistochemistry, while the polymerase chain reaction may be used to identify parasite DNA in tissues. A number of serological tests have been developed, of which the dye test is the longest established serological method, and in many ways represents the gold standard. Its reliability for use in pigs is not known.

Pathology: In heavy infections, the multiplying tachyzoites may produce areas of necrosis in vital organs such as the myocardium, lungs, liver and brain. Examination of the brain may reveal focal microgliosis. The lesions often have a small central focus of necrosis that might be mineralised. Focal leucomalacia in cerebral white matter, due to anoxia arising from placental pathology, is often present.

Epidemiology: The cat plays a central role in the epidemiology of toxoplasmosis, and infection in pigs may occur through ingestion of feed contaminated with cat faeces or through ingestion of bradyzoites and tachyzoites in the flesh of another intermediate host, such as rats.

Treatment: Not indicated

Control: On farms, control is difficult, but where possible animal feedstuffs should be covered to exclude access by cats and insects. Control of rats and regulation of feeding of swill to pigs are also measures that will limit exposure to infection.

Sarcocystiosis

Sarcocystis is one of the most prevalent parasites of livestock and three species are reported in pigs (Table 11.3). Most cases of *Sarcocystis* infection are only revealed at meat inspection when the grossly visible sarcocysts in the muscle are discovered. Little is

known of the epidemiology, but from the high prevalence of symptomless infections observed in abattoirs it is clear that where dogs and cats are kept in close association with farm animals or their feed, then transmission is likely.

The only control measures possible are those of simple hygiene. Farm dogs and cats should not be housed in, or allowed access to, fodder stores nor should they be allowed to defecate in pens where livestock are housed. It is also important that they are not fed uncooked meat.

Sarcocystis suicanis

Synonyms: *Sarcocystis porcicanis*, *Sarcocystis miescheriana*

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: Tissue cysts are compartmented, up to 0.5–1.5 mm long by 15–100 µm. The cyst wall has numerous palisade-like processes with randomly arranged filaments seen on electron microscopy.

Final host: Dog

Intermediate host: Pig

Geographical distribution: Worldwide

Pathogenesis: *Sarcocystis suicanis* is pathogenic to the pig and is known to produce signs of enteritis, myositis and lameness. More generally clinical signs are rarely observed and the most significant effect is the presence of cysts in the muscles of food animals, resulting in downgrading or condemnation of carcasses.

Clinical signs: In heavy infections of the intermediate hosts there may be anorexia, fever, anaemia, loss of weight, a disinclination to move and sometimes recumbency.

Pathology: In pigs, meronts present in endothelial cells of capillaries in various organs lead to endothelial cell destruction. As the organisms enter muscle, a wide range of change may be encountered. Microscopic inspection of *Sarcocystis*-infected muscle often reveals occasional degenerate parasitic cysts surrounded by variable numbers of inflammatory cells (very few of which are eosinophils) or, at a later stage, macrophages and granulation tissue. Usually there is no muscle fibre degeneration, but there may be thin linear collections of lymphocytes between fibres in the region. The extent of muscle change bears little relationship to the numbers of developing cysts, but generally very low numbers of *Sarcocystis* produce no reaction. As cysts mature, the cyst capsule within the enlarged muscle fibre becomes thicker and more clearly differentiated from the muscle sarcoplasm.

Table 11.3 *Sarcocystis* species found in the muscles of pigs.

| Species | Synonym | Definite host | Pathogenicity Pig | Final host |
|-------------------------------|--|----------------|-------------------|------------|
| <i>Sarcocystis suicanis</i> | <i>Sarcocystis porcicanis</i> <i>Sarcocystis miescheriana</i> | Dog, wolf, fox | +++ | 0 |
| <i>Sarcocystis porcifelis</i> | <i>Sarcocystis suifelis</i> | Cat | 0 | 0 |
| <i>Sarcocystis suihominis</i> | <i>Isoospora hominis</i> | Human | +++ | +++ |

0, non-pathogenic; +, mildly pathogenic; +++, severe pathogenicity.

Sarcocystis porcifelis

Synonym: *Sarcocystis suisfelis*

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Final host: Cat

Intermediate host: Pig

Description: The sporulated sporocysts are ellipsoidal and measure 13.2–13.5 by 7.2–8 µm, without a Stieda body, but with a residuum.

Geographical distribution: Unknown

Pathogenesis: Non-pathogenic

Clinical signs: Infection is usually asymptomatic.

Pathology: Cysts are found in oesophageal muscles but their detailed pathology has not been described.

Sarcocystis suihominis

Synonym: *Isospora hominis*

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: In the pig, the mature sarcocysts are thin-walled, compartmented, up to 1.5 mm long, and have protrusions up to 13 µm long, folded closely on the surface.

Final hosts: Human, primates

Intermediate host: Pig

Geographical distribution: Unknown

Pathogenesis: Infection is not pathogenic for non-human primates but is extremely pathogenic for humans and the pig intermediate host. In the pig, the principal pathogenic effect is attributable to the merogony stages in the vascular endothelium of the liver.

Clinical signs: Acute sarcocystiosis in pigs shows a biphasic fever between 5–9 and 11–15 days post infection. During the second phase, there is apathy, dyspnoea, anaemia and cyanosis of the skin, muscle spasms and hyperexcitability and prostration. Abortion may occur in pregnant sows.

Control: The contamination of animal feed and grazing land with human faeces should be avoided. Human infection can be prevented through adequate cooking or freezing of meat.

Notes: In humans, the ingestion of infected pork containing *S. suihominis* produces clinical signs of bloat, nausea, loss of appetite, stomach ache, vomiting, diarrhoea, difficulty breathing and rapid pulse within 6–42 hours. *Sarcocystis* may be responsible for several idiopathic diseases in humans, including cardiac diseases such as cardiomyopathy and myocarditis and rheumatic

diseases. It has also been suggested that *Sarcocystis* may be associated with muscle aches and fatigue as part of chronic fatigue syndrome.

Parasites of the integument***Suifilaria suis***

Predilection site: Subcutaneous and connective tissue

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: The adult filarioid worms are about 2–4 cm long. Males are 17–25 mm and females 32–40 mm.

Description, microscopic: The hind end of the male is spirally coiled and the spicules unequal with the left shorter than the right. The tail of the female bears a number of small tubercles on its tip, which ends abruptly. Small embryonated eggs, 51–61 by 28–32 µm, have a thin flexible shell and are laid on the skin surface where they hatch to release the microfilariae or L₁, which are about 200 µm in length.

Final host: Pig

Intermediate hosts: Not known

Geographical distribution: Southern Africa

Pathogenesis: The worms induce small, hard, whitish nodules in the subcutaneous and intermuscular connective tissues. Infection is generally considered to be non-pathogenic, although erupted skin vesicles may become secondarily infected, forming abscesses.

Clinical signs: Infection is usually asymptomatic causing no effect on productivity.

Diagnosis: This is normally based on clinical signs of small whitish nodules, which eventually burst. Vesicular eruptions contain the eggs.

Pathology: Vesicular nodules may form in the cutaneous and intermuscular connective tissue.

Epidemiology: The epidemiology is unknown.

Treatment: Treatment is seldom required as infection is of little veterinary relevance.

Control: As the intermediate host is unknown control is not feasible or usually required.

ECTOPARASITES**LICE*****Haematopinus suis***

Common name: Hog louse

Predilection site: Skin; most often present on skin folds of the neck and jowl, the flanks and the insides of the legs on thin-coated animals

Fig. 11.18 *Haematopinus suis*.

Class: Insecta

Order: Phthiraptera

Suborder: Anoplura

Family: Haematopinidae

Description: *Haematopinus suis* is a large greyish-brown louse with brown and black markings, measuring 5–6 mm in length (Fig. 11.18). It is the largest blood-sucking louse found on domestic animals. It has a long narrow head and long mouthparts adapted for sucking blood. It has prominent angular processes, known as ocular points or temporal angles, located behind the antennae. Eyes are absent. The thoracic sternal plate is dark and well developed. The legs are of similar sizes, each terminating in a single large claw that opposes the tibial spur. Distinct sclerotised paratergal plates are visible on abdominal segments 2 or 3 to 8.

Host: Pig

Geographical distribution: Worldwide

Pathogenesis: Infested animals show a reduction in weight gain and are more susceptible to other diseases. In severe infestations piglets may die of anaemia. *Haematopinus suis* is believed to be a vector of African swine fever, *Eperythrozoon suis* and the virus of swine pox.

Clinical signs: This louse is very common, and at low intensities is usually tolerated without any signs apart from occasional mild irritation. It usually occurs in the folds of the neck and jowl, around the ears and on the flanks and backs (Fig. 11.19). The majority of nymphs occur on the head region. However, irritation is caused by the small but frequent blood meals, each of which is taken via a different puncture wound. In heavy infestations, pigs are restless and fail to thrive. Economically, the most important feature of pediculosis in pigs is probably skin damage from scratching, with reduction in hide value. In the most severe cases, pigs may rub most of the hair off their bodies and, if acquired by piglets, *H. suis*

Fig. 11.19 Louse infestation.

infestation may retard growth. Transfer is usually by contact but *H. suis* may survive for up to 3 days off its host. Hence, transfer can also occur when animals are put into recently vacated dirty accommodation.

Diagnosis: *Haematopinus suis* is the only louse found on pigs. Adults are easily seen on the skin and can be removed and identified under a light microscope.

Pathology: Both epidermis and corium may be affected by inflammatory lesions at the bite puncture sites. Initially neutrophil infiltration with necrosis of epithelial cells prevails. This is followed by capillary proliferation with angioblast and fibroblast multiplication and straggled lymphoid infiltration.

Epidemiology: Infection is primarily by physical contact between pigs, particularly in closely confined fattening animals and in suckling sows penned with their piglets. However, lice may also be acquired when animals are put into recently vacated dirty accommodation.

Treatment: Avermectins given parenterally or the organophosphate phosmet administered as a pour-on have both proved highly effective as a single treatment. Amitraz and deltamethrin are also effective. Once lice have been diagnosed it is essential to treat the entire herd.

Control: Generally, control is based on the application of insecticides or use of a macrocyclic lactone. For herd prophylaxis, gilts and sows should be treated before farrowing to prevent spread of infection to their piglets, and boars treated twice annually.

MITES

Sarcoptes scabiei

Common name: Scabies

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Sarcoptidae

Description, adults: The adult of this species has a round, ventrally flattened, dorsally convex body (see Fig. 3.89). Adult females are 0.3–0.6 mm long and 0.25–0.4 mm wide, while males are smaller, typically up to 0.3 mm long and 0.1–0.2 mm wide. The posterior two pairs of limbs do not extend beyond the body margin. In both sexes, the pretarsi of the first two pairs of legs bear empodial claws and a sucker-like pulvillus, borne on a long stalk-like pretarsus. The sucker-like pulvilli help the mite grip the substrate as it moves. The third and fourth pairs of legs in the female and the third pair of legs in the male end in long setae and lack stalked pulvilli. The mouthparts have a rounded appearance. These mites have no eyes or stigmata. The dorsal surface of the body of *S. scabiei* is covered with transverse ridges, but also bears a central patch of triangular scales. The dorsal setae are strong and spine-like. The anus is terminal and only slightly dorsal. There are several host-adapted varieties of *S. scabiei* that differ subtly in their morphology.

Description, larvae and nymphs: The hexapod larvae and the octopod nymphs resemble the adults in general form.

Hosts: All domestic mammals and humans

Geographical distribution: Worldwide

Pathogenesis: Host reactions occur primarily in response to the feeding and burrowing activity of the mites and their faecal deposits. This commonly occurs progressively 3 weeks into the initial infection. Lesions can occur anywhere on the body, but are usually found on the head where the hair is relatively thin. The infestation spreads quickly from the initial lesions to cause more generalised mange.

In pigs, the ears are the most common site of infestation, and are usually the primary focus from which the mite population spreads to other areas of the body, especially the back, flanks and abdomen. Many pigs harbour unapparent infections throughout their lives, and the main mode of transmission appears to be between carrier sows and their piglets during suckling. Signs may appear on the face and ears within 3 weeks of birth, later extending to other areas. Transmission may also occur during service, especially from an infected boar to gilts.

Clinical signs: Affected pigs scratch continuously and may lose condition. Common signs are papular eruptions with erythema, pruritus and hair loss. As the infestation progresses the skin becomes thickened, crusted with exudates and secondarily infected due to damage caused by the host scratching (Fig. 11.20). Scaly areas around the

Fig. 11.20 Sarcoptic mange in a pig.

edge of lesions indicate the spread of mites. Severe cases exhibit loss of appetite and weight, impaired hearing, blindness and exhaustion.

Diagnosis: Useful diagnostic features of porcine sarcoptic mange include the following.

- The edges of the ears are often first affected, and on rubbing a scratch reflex is readily elicited.
- There is always intense itching, so in cases of dermatitis where there is no itch, sarcoptic mange can be eliminated as a possibility.
- It is a highly contagious condition, and single cases are rarely seen in groups of animals kept in close contact.

Confirmatory diagnosis is by examination of skin scrapings for the presence of mites. However, since these are sometimes difficult to demonstrate, a negative finding should not preclude a tentative diagnosis of mange and initiation of treatment. For confirmatory diagnosis in pigs, a reliable source of material for examination is wax from the ear.

Pathology: The first lesions appear as small red papules or weals and general erythema about the eyes, around the snout, on the concave surface of the external ears, in the axillae and on the front of the hocks where the skin is thin. Scratching results in excoriation of these affected areas and the formation of brownish scabs on the damaged skin. Subsequently, the skin becomes wrinkled, covered with crusty lesions and thickened.

Epidemiology: New hosts are infected by contact with infected individuals, presumably by the transfer of larvae, which are commonly present more superficially on the skin surface. Transmission occurs between mature animals and also from mother to offspring at birth. Transfer of different host-adapted populations of *S. scabiei* between different host species often results in only temporary infestations. Infestation may also occur by indirect transfer, since the mites have been shown to be capable of surviving off the host for short periods. The length of time that *S. scabiei* can survive off the host depends on environmental conditions but may be between 2 and 3 weeks. Consequently, animal bedding may become contaminated and is a possible source of infestation.

Treatment: In pigs, effective preparations that have been used include amitraz, trichlorphon and bromocyclen. Newer and more convenient products with a better residual effect include the systemic organophosphate pour-on phosmet and the macrocyclic lactones.

Control: In pigs, a common control approach is to treat the sow (the main reservoir of infection) before she goes into the farrowing crate or pen. This procedure will be more successful than having to treat partly grown pigs. The offspring of treated sows show better growth rates and shorter finishing periods than those of untreated sows. It is most important that boars are routinely treated at 6-monthly intervals, and any newly introduced boar is treated and quarantined as they can readily infect sows at service. In the treatment of affected pigs, acaricide may be applied weekly, by wash or by spray, until the signs have regressed. It is recommended that phosmet is applied to the back of the sow 3–7 days before farrowing, pouring a small part of the dose into the ears. As an alternative, systemic macrocyclic lactones may be given.

Demodex phylloides

Predilection site: Hair follicles and sebaceous glands, particularly the eyelids

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Demodicidae

Description: Species of *Demodex* have an elongate tapering body, up to 0.1–0.4 mm in length, with four pairs of stumpy legs ending in small blunt claws in the adult (see Fig. 3.100). Setae are absent from the legs and body. The legs are located at the front of the body, and as such the striated opisthosoma forms at least half the body length.

Host: Pig

Geographical distribution: Worldwide

Pathogenesis: Infestation is usually confined to the head, where there is erythema, papules and thickened skin. If there is secondary bacterial infection or follicular rupture, pustules and nodules may be observed.

Clinical signs: Erythema, papules and thickened skin on the head.

Diagnosis: For confirmatory diagnosis, deep scrapings are necessary to reach the mites deep in the follicles and glands. This is best achieved by taking a fold of skin, applying a drop of liquid paraffin, and scraping until capillary blood appears.

Pathology: Lesions typically involve the ventral abdomen, ventral neck, eyelids and snout. They commence as small red macules, developing into cutaneous nodules, covered by surface scale. Excision of the nodules releases thick white caseous debris.

Epidemiology: Probably because of its location deep in the dermis, it is difficult to transmit *Demodex* between animals unless there is prolonged contact. Such contact occurs most commonly at suckling. This mange is rare in pigs, although sporadic incidences of up to 5% have been noted in eastern European countries.

Treatment: In many cases demodicosis spontaneously resolves and treatment is unnecessary. The organophosphates (e.g. malathion, coumaphos, diazinon, fenchlorvos, chlorfenvinphos, phosmet or trichlorophon) and systemic macrocyclic lactones may be effective.

Control: Control is rarely applied.

Notes: Species of the genus *Demodex* are highly specialised mites that live in the hair follicles and sebaceous glands of a wide range of wild and domestic animals, including humans. They are believed to form a group of closely related sibling species that are highly specific to particular hosts: *Demodex phylloides* (pig), *Demodex canis* (dog), *Demodex bovis* (cattle), *Demodex equi* (horse), *Demodex musculi* (mouse), *Demodex ratti* (rat), *Demodex caviae* (guinea pig), *Demodex cati* (cat) and *Demodex folliculorum* and *Demodex brevis* on humans. Various morphological variations may be seen on a host; these are sometimes, probably incorrectly, ascribed separate species status.

A number of non-host-specific ectoparasites are found on pigs and are listed in the host–parasite checklist at the end of this chapter. More detailed descriptions of these parasites can be found in Chapter 17.

HOST-PARASITE CHECKLISTS

In the following checklists, the codes listed below apply:

Helminths

N, nematode; T, trematode; C, cestode; A, acanthocephalan.

Arthropods

F, fly; L, louse; S, flea; M, mite; Mx, maxillopod; Ti, tick.

Protozoa

Co, coccidia; Bs, blood sporozoa; Am, amoeba; Fl, flagellate; Ci, ciliate.

Miscellaneous 'protozoal organisms'

B, blastocyst; Mi, microsporidian; My, *Mycoplasma*; P, Pneumocystidomycete; R, *Rickettsia*.

Parasites of dogs and cats

ENDOPARASITES

Parasites of the digestive system

MOUTH

Tetratrichomonas canistomae

Synonym: *Trichomonas canistomae*

Predilection site: Mouth

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is pyriform, 7–12 by 3–4 μm . The four anterior flagella are about as long as the body and arise in pairs from a large blepharoplast (see Fig. 2.14). The undulating membrane extends almost the length of the body, and terminates in a free posterior flagellum, which is about half the length of the body. The axostyle is thread-like, stains black with haematoxylin and extends a considerable length beyond the body. The costa is slender and there are no subcostal granules.

Host: Dog

Geographical distribution: Unknown

Pathogenesis: Considered non-pathogenic

Diagnosis: Morphological identification of the organisms from fresh and stained mouth swab preparations. The organisms can also be cultured in a range of media used for trichomonads.

Epidemiology: Transmission presumably occurs by ingestion of trophozoites from saliva during licking and grooming.

Treatment and control: Not required

Tetratrichomonas felistomae

Predilection site: Mouth

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is pyriform, 6–11 by 3–4 μm (mean $8 \times 3 \mu\text{m}$). There are four anterior flagella, which are longer than the body. The undulating membrane extends most of the body length and terminates in a free posterior flagellum and the axostyle extends a considerable distance beyond the body.

Host: Cat

Notes: The two species may be synonymous. All other details are as for *T. canistomae*.

OESOPHAGUS

Spirocerca lupi

Synonym: *Spirocerca sanguinolenta*

Predilection site: Oesophagus, stomach, aorta

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Adult worms are spirally coiled and have a blood-red colour; males are around 30–55 mm and females 55–80 mm.

Description, microscopic: The lips are trilobed and the pharynx is short. The male tail bears lateral alae, four pairs and one unpaired median pre-cloacal papillae and two pairs of post-cloacal papillae, with a group of minute papillae near the tail tip. The very small eggs have smooth thick shells and are elongate with parallel side walls. They measure about 30–37 by 11–15 μm and are larvated when passed in faeces.

Final hosts: Dog, fox, wild canids and occasionally cat and wild felids

Intermediate hosts: Coprophagous beetles: *Scarabeus sacer*, *Akis*, *Atenachus*, *Gymnopleurus*, *Cauthon* spp. Many vertebrates such as rodents, birds, chickens, insectivores and reptiles can act as paratenic hosts.

Geographical distribution: Tropical and subtropical areas

Pathogenesis: The migrating larvae produce haemorrhages, scarring and/or the formation of fibrotic nodules on the internal wall of the aorta which, if particularly severe, may cause stenosis or even rupture. The oesophageal granulomas, up to 4.0 cm in size, associated

with the adult worms may be responsible for a variety of clinical signs including dysphagia and vomiting arising from oesophageal obstruction and inflammation.

Two further complications are, first, the development of oesophageal osteosarcoma in a small proportion of infected dogs. These may be highly invasive and produce metastases in the lung and other tissues. Secondly, also relatively rare, is the occurrence of spondylosis of the thoracic vertebrae or of hypertrophic pulmonary osteoarthropathy of the long bones. The aetiology of these lesions is unknown. Occasionally *S. lupi* infection can induce a pyaemic nephritis.

Clinical signs: Despite the potential pathogenicity of this parasite, many infected dogs do not exhibit clinical signs even when extensive aortic lesions and large, often purulent, oesophageal granulomas are present. In some dogs infection will induce persistent vomiting with worms passed in the vomit. In less serious cases there may be difficulty in swallowing or interference with the action of the stomach. Aortic infection is not usually observed until sudden death is caused by rupture.

Diagnosis: The location and appearance of the granulomatous lesions, up to golf-ball size, is usually sufficient for identification. Numerous pink-reddish, stout, spirally coiled worms may be seen on section of the granulomas, but these are difficult to extricate intact since they are coiled and up to 8.0 cm long. Eggs may be found in the faeces or vomit if there are fistulae in the oesophageal granulomas. However, the eggs are similar in appearance to those of other spirurids. Otherwise diagnosis may depend on endoscopy or radiography.

Pathology: The migrating larvae produce characteristic lesions in the wall of the aorta (Fig. 12.1) while the adults are found embedded in granulomatous lesions in the wall of the oesophagus and occasionally the stomach. Aortic lesions include haemorrhage and necrosis with eosinophilic inflammation, intimal roughening with thrombosis, aneurysm with rare aortic rupture, and subintimal and medial mineralisation and heterotopic bone deposition. Spondylosis of the ventral aspects of thoracic vertebrae occurs in some cases with exostoses of the vertebral bodies. Granulomas in the oesophagus contain pleomorphic fibroblasts. In some animals mesenchymal neoplasms develop in the wall of the oesophageal granuloma with lesions showing cytological characteristics typical of fibrosarcoma and osteosarcoma, with local tissue invasion and, in many cases, pulmonary metastasis.

Fig. 12.1 Fibrotic nodules on the internal wall of the aorta from a dog infected with *Spirocerca lupi*.

Epidemiology: In endemic areas the incidence of infection in dogs is often extremely high, sometimes approaching 100%. Probably this is associated with the many opportunities of acquiring infection from the variety of paratenic hosts.

Treatment: Treatment is rarely practical, but levamisole and albendazole have been reported to be of value. Levamisole is given at 5–10 mg/kg as a single dose. Doramectin, administered at intervals over 4–6 weeks, followed by monthly treatment has been successful at resolving the lesions in the oesophagus. Diethylcarbamazine at oral doses of 10 mg/kg twice daily for 10 days may kill adult worms but not larvae.

Control: This is difficult because of the ubiquity of the intermediate and paratenic hosts. Dogs should not be fed uncooked viscera from wild birds or from free-range domestic chickens.

STOMACH

Ollulanus tricuspis

Predilection site: Stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: This is a very small trichostrongyle. Males are 0.7–0.8 mm, and females 0.8–1 mm long.

Description, microscopic: The worm is identified microscopically by the spiral coil of the head. The male bursa is well developed and the spicules are stout and each is split into two for a considerable distance. The female has a tail with three or four short cusps. The vulva is in the posterior part of the body and there is only one uterus and ovary.

Hosts: Cats, wild felids; occasionally found in pigs, foxes and domestic dogs

Geographical distribution: Mainly occurs in Europe, North and South America, Australasia and the Middle East

Pathogenesis: The parasite is considered non-pathogenic in cats. Heavy infections may induce a severe catarrhal gastritis and vomiting. Untreated cats may become emaciated. Little is known of its pathogenicity in other hosts, although a chronic gastritis has been reported in the pig.

Clinical signs: Occasional vomiting and emaciation

Diagnosis: Diagnosis of ollulanosis is seldom made because of their small size and lack of eggs and larvae in the faeces. Examination of vomit, following an emetic, for the presence of worms is a useful approach. At necropsy, recovery and identification of the very small worms from the gastric mucosa should lead to a diagnosis.

Pathology: The worms lie beneath the mucus on the surface of the stomach, or partly in the gastric glands, and their presence may lead to mucosal lymphoid hyperplasia and elevated numbers of globule leucocytes in the gastric epithelium. Heavy infections cause hyperplasia of the gastric glands causing the stomach mucosa to become convoluted and thrown into folds.

Epidemiology: The parasite is common in some parts of the world, particularly in cat colonies and cats that roam. The parasite can

replicate in the stomach without any need for external egg or larval phases and can spread via vomit. The disease spreads mainly among starving stray cats and sometimes stray dogs.

Treatment: Levamisole, ivermectin or repeated doses of oxfendazole 10 mg/kg twice daily for 5 days are effective.

Control: This is mainly achieved through the implementation of good hygiene procedures.

Spirocerca lupi

See section Oesophagus.

Gnathostoma spinigerum

Predilection site: Stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Thick-bodied worms, reddish at the front and greyish posteriorly. The males are 1–2.5 cm and the females up to 3.0 cm long. The presence of the worms in gastric nodules is sufficient for generic diagnosis.

Description, microscopic: Confirmation is easily made with a hand lens when the swollen anterior head bulb covered with transverse rows of 6–11 small hooks will be seen. The head contains four sub-median cavities that each communicate with a cervical sac. The anterior of the body is covered with flat cuticular spines and the ventral caudal region of the male bears small spines and four pairs of large pedunculate papillae as well as several smaller sessile ones. The left spicule is longer than the right. The medium-sized eggs are oval, with a greenish shell which possesses fine granulations and they have a thin cap at one pole. Eggs measure 69 by 37 µm and contain one cell or a morula when passed in faeces.

Final hosts: Cat, dog, human, mink, polecat and several wild carnivores

Intermediate hosts: Host 1: many species of freshwater crustaceans, copepods. Host 2: small vertebrates including mammals, birds, reptiles, fish and amphibians

Geographical distribution: Thailand, Japan, Southeast Asia, China, Mexico

Pathogenesis: *Gnathostoma spinigerum* is the most pathogenic *Gnathostoma* species, which in cats may cause fatal gastric perforation and peritonitis. In some cases a number of larvae will migrate from the stomach to other organs, most commonly the liver, in which they burrow, leaving necrotic tracks in the parenchyma.

Clinical signs: *Gnathostoma* infection in the cat may cause acute abdominal signs.

Diagnosis: The infection in the living animal can only be diagnosed by the finding of the greenish oval eggs, which have a thin cap at one pole, in the faeces. Often, however, eggs are not present in faeces.

Pathology: As in many spiruroid infections, the most obvious effect of gnathostomosis is the presence of fibrous growths on the stomach wall. These growths are of variable size, the largest being 3–4 cm in diameter, and are cavitated, amounting to thick-walled cysts containing worms and fluid. Ulceration and necrosis of the stomach wall are often present.

Epidemiology: Dogs, cats and several species of wild mammals are reservoirs of the parasite. These final hosts become infected primarily through eating infected fish or other animals that serve as paratenic hosts. In humans, the ingestion of raw or inadequately cooked fish is the major source of infection. Human infections are also reported from eating raw or poorly cooked catfish, eels, frogs, chickens, ducks and snakes.

Treatment: Treatment has not been fully investigated.

Control: With the ubiquity of the first and second intermediate hosts complete control cannot be achieved. Ensuring only well-cooked fish, eels or other intermediate hosts, such as snakes, frogs and poultry, are eaten can prevent infections. Potentially copepod-infested water should be boiled or treated.

Notes: Like most spiruroids, *Gnathostoma* inhabits the upper alimentary tract, occurring in nodules in the stomach wall of omnivores and carnivores. It is exceptional in requiring two intermediate hosts in most species.

When visceral larva migrans due to *Gnathostoma* occurs in humans, *G. spinigerum* is the species usually involved, and the commonest source of infection is inadequately cooked domestic poultry and fish acting as second intermediate hosts. Infection is particularly common in Southeast Asia, Japan and China but occurs in many other countries. The worms never become fully adult, and the immature forms are most commonly found in subcutaneous tissues and other organs in nodules that appear and disappear irregularly as the parasites wander in various parts of the body. In humans, cutaneous gnathostomosis can result in pruritic swellings and eosinophilia with occasional abscess formation. Ocular gnathostomosis is characterised by haemorrhage, uveitis and perforation of the iris. A severe form of infection is central nervous system (CNS) gnathostomosis, leading to haemorrhage and intracranial necrotic tracks that can be fatal.

Physaloptera praeputialis

Predilection site: Stomach and occasionally anterior duodenum by the gastric valve

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Adult worms are white or pinkish in colour and larger than most spiruroids, being stout and resembling ascarids. Males measure 1–45 mm and females 2–60 mm.

Description, microscopic: The cuticle in both sexes extends posteriorly as a sheath (pseudolabia) beyond the end of the body and the mouth is surrounded by a cuticular collar. The lips are simple and bear a set of three flattened internal teeth and a single conical external tooth. The male bears lateral alae, joined anteriorly across the ventral surface. In the female the vulva is slightly anterior to the

mid-body. The larvated eggs have a thick clear shell and measure 45–58 by 30–36 µm (Fig. 12.2).

Final hosts: Cat and wild felids; occasionally the dog

Intermediate hosts: Beetles, cockroaches, crickets and paratenic hosts

Geographical distribution: China, Africa, North and South America

Pathogenesis: The adult worms have small teeth on their large triangular lips, and attach strongly to the gastric mucosa, leaving small ulcers when they move to fresh sites. These feeding sites may continue to bleed. They may cause catarrhal gastritis, with emesis, and in heavy infections blood may appear in the faeces.

Clinical signs: In heavy infections there may be vomiting and some degree of anorexia. The faeces may appear dark in colour. Severely affected animals may lose weight.

Diagnosis: Diagnosis is based on clinical signs and by the finding of the elongate eggs, thickened at either pole, in the faeces or vomit.

Pathology: Presence of the adult worms may cause gastric ulceration and haemorrhage.

Epidemiology: The epidemiology depends on the presence and abundance of the intermediate beetle hosts. Infection is more prevalent in outdoor cats that have access to intermediate hosts or paratenic hosts.

Treatment: Treatment with benzimidazoles over a 5-day period has been reported to be effective. Pyrantel, praziquantel and febantel are also effective but elevated or repeated doses may be required.

Control: The ubiquity of the insect intermediate hosts means that control is not usually feasible.

Physaloptera rara

Predilection site: Stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Fig. 12.2 *Physaloptera* egg.

Hosts: Cat, dog

Description, gross: Adult male worms are 2.5–3 cm long and females 3–6 cm.

Description, microscopic: This species differs from *P. praeputialis* in that there is no sheath over the posterior portion of the body in both sexes. The female vulva is anterior to the middle of the body. Eggs are thick-shelled and ellipsoid, 42–53 by 29–35 µm.

Geographical distribution: North America

Details of the life cycle, pathogenesis, treatment and control are essentially similar to those of *P. praeputialis*.

Spirura ritypleurites

Predilection site: Stomach, occasionally oesophagus

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Thick, short, white worms with the posterior region thicker than the anterior of the worm and twisted in a spiral.

Description, microscopic: The eggs have a thick shell and are embryonated when passed and measure up to 52 by 36 µm.

Final hosts: Cat, rarely dog, fox

Intermediate hosts: Coprophagous beetles

Geographical distribution: This worm is endemic in parts of southern Europe, Africa and Asia.

Pathogenesis: *Spirura ritypleurites* is usually presumed to be non-pathogenic.

Clinical signs: Symptoms of nausea, vomiting and digestive upsets have been reported.

Diagnosis: As for *Physaloptera* spp.

Pathology: No associated pathology reported

Epidemiology: The epidemiology depends on the presence and abundance of the intermediate beetle hosts. Infection is more prevalent in outdoor cats that have access to intermediate hosts or paratenic hosts.

Treatment: Not usually indicated. Treatment with a benzimidazole over an extended period is likely to be effective.

Control: Prevention is difficult because of the large number of intermediate hosts and paratenic hosts.

Capillaria putorii

Synonym: *Aonchotheca putorii*

Predilection site: Stomach, small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: These are thin filamentous worms, about 1 cm long; males are 5–8 mm and females 9–15 mm.

Description, microscopic: The medium-sized, oval, elongate eggs have broad flat poles with two protruding semi-transparent polar plugs. They measure around 60 by 30 μm and contain granular unsegmented contents.

Hosts: Cat, dog, mustelids, hedgehog, bear, raccoon, bobcat

Geographical distribution: Europe, New Zealand and Russia.

Pathogenesis and clinical signs: There are few reports on the clinical signs of infection in cats. Infected cats have reported anorexia and intermittent bloody vomitus.

Diagnosis: Identification of the characteristic eggs in faeces.

Pathology: There is reported chronic hyperplastic pyloric gastritis and ulceration around the pylorus associated with the presence of worms, with eggs present in the pyloric mucus and in the lumen of the pyloric glands.

Epidemiology: Cats are thought to become infected by eating infective eggs from soil contaminated by hedgehog faeces.

Treatment and control: Levamisole, given as two doses of 7.5 mg/kg at 2-week intervals, and ivermectin 300 $\mu\text{g}/\text{kg}$ have been reported to be effective.

SMALL INTESTINE

Toxocara canis

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: *Toxocara canis* is a large white/cream-coloured worm. Males are around 10 cm, and females up to 18 cm in length (Fig. 12.3).

Description, microscopic: The adult head is elliptical due to the presence of large cervical alae. The mouth is surrounded by three large lips. There is no buccal capsule and the oesophagus lacks a bulb. The tail of the male has a terminal narrow appendage and caudal alae. Female genital organs extend anteriorly and posteriorly to the vulval region. The medium-sized egg is dark brown and subglobular, with a thick rough pitted shell. The granular unsegmented contents are very dark and normally fill the whole volume of the shell. Eggs measure 90 by 75 μm . The egg is very similar to that of *Parascaris*.

Hosts: Dog, fox

Geographical distribution: Worldwide

Pathogenesis: In moderate infections, the larval migratory phase is accomplished without any apparent damage to the tissues, and the adult worms provoke little reaction in the intestine. In heavy infections the pulmonary phase of larval migration is associated with pneumonia, which is sometimes accompanied by pulmonary oedema; the adult worms cause mucoid enteritis, there may be partial or complete occlusion of the gut and, in rare cases, perforation

with peritonitis or in some instances blockage of the bile ducts of the liver.

Clinical signs: In mild to moderate infections, there are no clinical signs during the pulmonary phase of larval migration. The adults in the intestine may cause tucked-up abdomen or potbelly, with failure to thrive, and occasional vomiting and diarrhoea. Entire worms are sometimes vomited or passed in the faeces. The signs in heavy infections during larval migration result from pulmonary damage and include coughing, increased respiratory rate and a frothy nasal discharge. Most fatalities from *T. canis* infection occur during the pulmonary phase, and pups which have been heavily infected transplacentally may die within a few days of birth. Nervous convulsions have been attributed by some clinicians to toxocarosis, but there is still some disagreement on whether the parasite can be implicated as a cause of these signs.

Diagnosis: Only a tentative diagnosis is possible during the pulmonary phase of heavy infections when the larvae are migrating, and is based on the simultaneous appearance of pneumonic signs in a litter, often within 2 weeks of birth. The eggs in faeces, subglobular and brown with thick pitted shells, are species-diagnostic. The egg production of the worms is so high that there is no need to use flotation methods, and they are readily found in simple faecal smears to which a drop of water has been added.

Toxocara canis in the dog can be confused only with *Toxascaris leonina*, which is slightly smaller. Differentiation of these two species is difficult, as the only useful character, visible with a hand lens, is the presence of a small finger-like process on the tail of the male *T. canis*.

Pathology: On postmortem, the animal appears poorly grown, potbellied and cachectic. Large numbers of maturing worms are present in the intestines and sometimes the stomach. Focal haemorrhages may be found in the lungs of puppies with migrating *T. canis* larvae. Inflammatory foci are often observed in the kidneys as white elevated spots 1–2 mm in diameter in the cortex beneath the capsule. In

Fig. 12.3 Heavy *Toxocara canis* infection in the small intestine of a pup.

section, they are composed of a small focus of macrophages, lymphocytes, plasma cells and a few eosinophils, possibly containing larvae. Occasionally, granulomas may be found in the eye.

Epidemiology: Surveys of *T. canis* prevalence in dogs have been carried out in most countries and have shown a wide range of infection rates, from 5% to over 80%. The highest rates of prevalence have been recorded in dogs of less than 6 months of age, with the fewest worms in adult animals. Infection induces immunity that results in loss of adult worms.

The widespread distribution and high intensity of infection with *T. canis* depend essentially on three factors. First, the females are extremely fecund, one worm being able to contribute about 700 eggs per gram of faeces (epg) per day, and egg counts of 15,000 epg are not uncommon in pups. Second, the eggs are highly resistant to climatic extremes, and can survive for years on the ground. Third, there is a constant reservoir of infection in the somatic tissues of the bitch, and larvae in these sites are not susceptible to most anthelmintics.

Treatment: The adult worms are easily removed by anthelmintic treatment. The most popular drug used has been piperazine, although this is being superseded by the benzimidazoles (fenbendazole and mebendazole) and by nitroscanate. Pyrantel and the avermectin selamectin are also effective. Although several anthelmintics have activity against larval stages and juvenile worms, none are fully effective at their removal.

A simple and frequently recommended regimen for control of toxocarosis in young dogs is as follows. All pups should be dosed at 2 weeks of age, and again 2–3 weeks later, to eliminate prenatally acquired infection. It is also recommended that the bitch should be treated at the same time as the pups. A further dose should be given to the pups at 2 months old to eliminate any infection acquired from the milk of the dam or from any increase in faecal egg output by the dam in the weeks following whelping. Newly purchased pups should be dosed twice at an interval of 14 days.

Since there are likely to be a few worms present, even in adult dogs and despite the diversion of the majority of larvae to the somatic tissues, it is recommended that adult dogs should be treated every 3–6 months throughout their lives.

It has been shown that daily administration of high doses of fenbendazole to the bitch from 3 weeks prepartum to 2 days postpartum has largely eliminated transmammmary and prenatal infection of the pups, although residual infection in the tissues of the bitch may persist. This regimen may be useful in breeding kennels.

Control: The main aim is to prevent transmammmary and intrauterine transmission of infection using the anthelmintic treatment regimens described. Hygienic disposal of dog faeces should be encouraged. Where practical, access of rodents to kennels should be prevented.

Notes: Apart from its veterinary importance, this species is responsible for the most widely recognised form of visceral larva migrans in humans. Though this term was originally applied to invasion of the visceral tissues of an animal by parasites whose natural hosts were other animals, it has now, in common usage, come to represent this type of invasion in humans alone and, in particular, by the larvae of *T. canis*, although the larval stages of *T. mystax*, *T. leonina* and *T. vitulorum* (see Chapter 8, Small intestine) can be implicated. Its complementary term is cutaneous larva migrans (CLM) for infections by 'foreign' larvae that are limited to the skin.

The global condition occurs most commonly in children, often under 5 years of age, who have had close contact with household pets or who have frequented areas such as public parks where there is contamination of the ground by infective dog faeces. Surveys of such areas in many countries have almost invariably shown the presence of viable eggs of *T. canis* in around 10% of soil samples. Despite this high risk of exposure to infection, the reported incidence of clinical cases is small. For example, in 1979 a French survey of the world literature reported that only 430 cases of ocular and 350 cases of visceral larva migrans had been recorded. However, it has been suggested that 50–60 clinical cases occur in Britain each year, since many are not recorded.

In many cases, larval invasion is limited to the liver, and may give rise to hepatomegaly and eosinophilia, but on some occasions a larva escapes into the general circulation and arrives in another organ, the most frequently noted being the eye. Here, a granuloma forms around the larva on the retina, often resembling a retinoblastoma. Only in rare cases does the granuloma involve the optic disc, with total loss of vision, and most reports are of partial impairment of vision, with endophthalmitis or granulomatous retinitis. Such cases are currently treated using laser therapy. In a few cases of epilepsy, *T. canis* infection has been identified serologically, but the significance of the association has yet to be established. Control of visceral larva migrans is based on the anthelmintic regimen described previously, on the safe disposal of dog faeces in houses and gardens, and on the limitation of access by dogs to areas where children play such as public parks and recreation grounds.

Other hosts apart from humans, such as sheep and pigs, can also suffer from migration of *T. canis* and *T. mystax* larvae through their tissues. In pigs the larval migration can cause white-spot disease in the liver.

Toxocara mystax

Synonym: *Toxocara cati*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: Typical of the superfamily, *Toxocara mystax* is a large white/cream-coloured worm (up to 10 cm in length), often occurring as a mixed infection with the other ascarids of cats, such as *Toxascaris leonina*. Males are 3–6 cm and females 4–10 cm in length.

Description, microscopic: The tail of the male has a terminal narrow appendage. Differentiation is readily made between *Toxocara mystax* and *Toxascaris leonina* on gross examination or with a hand lens, when the cervical alae of the former are seen to have an arrowhead form, with the posterior margins almost at a right angle to the body, whereas those of *Toxascaris* taper gradually into the body (see Fig. 1.52a). The male, like that of *Toxocara canis*, has a small finger-like process at the tip of the tail. The egg is subglobular with a thick rough pitted shell. The granular unsegmented contents are dark brown to black in colour and usually occupy the whole volume of the shell. Eggs measure 65 by 75 µm and are characteristic in cat faeces.

Host: Cat

Geographical distribution: Worldwide

Pathogenesis: Because the majority of infections are acquired either in the milk of the dam or by ingestion of paratenic hosts, there is no migratory phase so any changes are usually confined to the intestine, showing as potbelly, diarrhoea, poor coat and failure to thrive.

Clinical signs: Unthriftiness, potbelly, diarrhoea

Diagnosis: The subglobular eggs, with thick pitted shells, are easily recognised in faeces.

Pathology: Larvae developing in the mucosa of the stomach may provoke a mild granulomatous reaction comprising lymphocytes and a few macrophages around the coiled larvae.

Epidemiology: The epidemiology of *T. mystax* depends largely on a reservoir of larvae in the tissues of the dam, which are mobilised late in pregnancy and excreted in the milk throughout lactation. The paratenic host is also of considerable significance because of the strong hunting instinct in cats. Exposure to the latter route of infection does not occur until kittens begin to hunt for themselves or to share the prey of their dams.

Treatment: Fenbendazole, mebendazole, piperazine and pyrantel are all effective against adult nematodes. The benzimidazole anthelmintics are more effective against larval ascarids.

Control: Since infection is first acquired during suckling, complete control would be based on removal of kittens from the dam and artificial rearing. Good hygiene is essential in catteries. Young kittens should be wormed regularly with an anthelmintic from 4–6 weeks of age at 3-week intervals until 4 months of age and thereafter at regular intervals.

Notes: *Toxocara mystax* has been reported as a rare cause of visceral larva migrans in humans.

Toxocara malayi

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: *Toxocara malayi* is a large white worm; males are 5.3–8.5 cm, females 1.1–1.4 cm, morphologically similar to *T. canis* in dogs.

Description, microscopic: There are three well-defined lips, each with a deep median notch lined with denticles, comprising a dorsal lip with two large outer papillae and two subventral lips each with one outer papilla. Cervical alae arise immediately behind the lips, gradually increasing in width to mid-length, then tapering gradually posteriorly.

Host: Cat

Geographical distribution: Malaysia

Diagnosis: The subglobular eggs, with thick pitted shells, are similar to those of *T. canis*.

Epidemiology: Not described

Treatment and control: Presumed similar to *T. mystax*.

Details of the pathogenesis, pathology and clinical signs have not been reported.

Toxascaris leonina

Synonym: *Toxascaris limbata*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: Males measure up to 7 cm and females up to 10 cm long.

Description, microscopic: Adults have an elliptical head due to the presence of cervical alae, which are slender and arrow-like, and taper posteriorly (see Fig. 1.52b). Three large lips surround the mouth, there is no buccal capsule and the oesophagus lacks a bulb. The tail of the male is simple. The female genital organs lie behind the level of the vulva. The egg is slightly ovoid, with a smooth thick almost colourless shell. The yellowish-brown granular unsegmented contents fill only part of the shell. Eggs measure about 75–85 by 60–70 µm and are characteristic in dog and cat faeces.

Hosts: Dog, cat, fox

Geographical distribution: Worldwide, particularly in the cooler regions

Pathogenesis: Infection with *Toxascaris* is unlikely to occur in isolation and is more usually accompanied by a *Toxocara* infection. In puppies and young dogs less than 2 months of age the infection is usually absent as there is no prenatal or lactogenic transmission. Damage is caused predominantly by the adult worms and is determined by the number of worms present in the intestine.

Clinical signs: Unthriftiness, potbelly, diarrhoea

Diagnosis: *Toxascaris* is almost indistinguishable grossly from *Toxocara canis*, the only point of difference being the presence of a finger-like process at the tip of the male tail of the latter. In the cat, differentiation from *Toxocara mystax* is based on the shape of the cervical alae, which are lanceolate in *Toxascaris* but arrowhead shaped in *Toxocara mystax*. The characteristic ovoid smooth-shelled eggs are easily recognised in the faeces.

Pathology: Pathological effects due to *Toxascaris leonina* are rarely seen. Heavy infections may cause occlusion of the intestinal lumen and are usually associated with the mixed presence of *Toxocara* spp.

Epidemiology: Infection normally occurs through the ingestion of the larvated eggs. Larvae of *Toxascaris leonina* may occur in mice with the encysted third-stage larvae distributed in many tissues. If a dog or cat ingests an infected mouse, the larvae are released and develop to maturity in the wall and lumen of the intestine of the final host.

Treatment: Fenbendazole, mebendazole, piperazine and pyrantel are all effective against adult nematodes. The benzimidazole anthelmintics are more effective against larval ascarids.

Control: Ascarid infections in the domestic carnivores invariably include *Toxocara*, such that the measures recommended for control

of the latter will also have an effect on *Toxascaris*. Since the two main reservoirs of infection are larvae in the prey or eggs on the ground, control has to be based on treatment of worm infection in the host animals, and on adequate hygiene to limit the possibility of acquisition of infection by ingestion of eggs.

Notes: This genus occurs in domestic carnivores, and though common is of less significance than *Toxocara* because its parasitic phase is non-migratory.

Ancylostoma caninum

Common name: Canine hookworm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ancylostomatoidea

Description, gross: The worms are reddish-grey in colour, depending on whether the worm has fed, and are readily recognised on the basis of size and by their characteristic hook-like posture (Fig. 12.4). Males are about 12 mm and females 15–20 mm in length, (much smaller than the common ascarid nematodes, which are also found in the small intestine).

Description, microscopic: The anterior end is bent dorsad and the oral aperture is directed anterodorsally. The buccal capsule is large with three pairs of sharp marginal teeth and a pair of ventrolateral teeth and possesses a dorsal gutter (see Fig. 1.47). The male bursa is well developed. Eggs are typically ‘strongylate’ with slightly dissimilar bluntly rounded poles, barrel-shaped side walls and a thin smooth shell (see Fig. 4.6). They measure about 56–75 by 34–47 µm and contain two to eight blastomeres when passed in faeces.

Hosts: Dog, fox and occasionally human

Geographical distribution: Worldwide in the tropics and warm temperate areas. In other countries it is sometimes seen in dogs imported from endemic regions.

Pathogenesis: This is essentially that of an acute or chronic haemorrhagic anaemia. The disease is most commonly seen in dogs under 1 year old and young pups, infected by the transmammmary

route, are particularly susceptible due to their low iron reserves. Transmammary infection is often responsible for severe anaemia in litters of young pups in their second or third week of life. Infection of the bitch on a single occasion has been shown to produce transmammmary infections in at least three consecutive litters.

Following infection, blood loss starts about the eighth day of infection when the immature adult has developed the toothed buccal capsule, which enables it to grasp plugs of mucosa containing arterioles. Each worm removes about 0.1 mL of blood daily and in heavy infections of several hundred worms pups quickly become profoundly anaemic. In lighter infections, common in older dogs, the anaemia is not so severe, as the marrow response is able to compensate for a variable period. The nutritional state of the individual will influence the progression of the anaemia. Ultimately, however, the dog may become iron deficient and develop a microcytic hypochromic anaemia. In previously sensitised dogs, skin reactions such as moist eczema and ulceration at the sites of percutaneous infection occur, especially affecting the interdigital skin.

It appears that dormant L₃ in the muscles of both bitches and dogs can recommence migration months or years later to mature in the host’s intestine. Stress, severe illness or repeated large doses of corticosteroids can all precipitate these apparently new infections in dogs, which may perhaps now be resident in a hookworm-free environment. Experimentally, L₃ of some strains of *A. caninum* exposed to chilling before oral administration have been shown to remain in arrested development in the intestinal mucosa for weeks or months. The significance of this observation is still unknown, but it is thought that such larvae may resume development if the adult hookworm population is removed by an anthelmintic or at times of stress, such as lactation.

Clinical signs: In acute infections, associated with the sudden exposure of susceptible animals to large numbers of infective larvae, there is anaemia and lassitude and occasionally respiratory embarrassment. In suckled pups the anaemia is often severe and is accompanied by diarrhoea, which may contain blood and mucus. Respiratory signs may be due to larval damage in the lungs or to the anoxic effects of anaemia. In more chronic infections, the animal is usually underweight, the coat is poor, and there is loss of appetite and perhaps pica. Inconsistently there are signs of respiratory embarrassment, skin lesions and lameness. The adverse effects of infection on the coat can have an economic impact where foxes are reared for their fur.

Diagnosis: This depends on the clinical signs and history supplemented by haematological and faecal examination. High faecal worm egg counts are valuable confirmation of diagnosis, but it should be noted that suckled pups may show severe clinical signs before eggs are detected in the faeces. The presence of a few hookworm eggs in the faeces, although giving confirmatory evidence of infection, do not necessarily indicate that an ailing dog is suffering from hookworm disease.

Pathology: Animals dying of ancylostomosis are extremely pale and there is often oedema of subcutaneous tissues and mesenteries, and serous effusion into the body cavities attributable to hypoproteinaemia. In chronic infections, cachexia may be evident. If recent exposure to heavy percutaneous infection has occurred, there may be dermatitis and numerous focal haemorrhages in the lung parenchyma. The liver is pale and the intestinal contents are mucoid and red in colour. Worms may be seen attached to the mucosa and pin-point haemorrhagic sites may be scattered over the intestinal surface.

Fig. 12.4 *Ancylostoma caninum* adult worms.

Epidemiology: In endemic areas the disease is most common in dogs under 1 year old. In older animals, the gradual development of age resistance makes clinical disease less likely, particularly in dogs reared in endemic areas, whose age resistance is reinforced by acquired immunity. The epidemiology is primarily associated with the two main sources of infection, transmammmary in suckled pups and percutaneous or oral from the environment. An important aspect of transmammmary infection is that disease may occur in suckled pups reared in a clean environment and nursed by a bitch which may have been recently treated with an anthelmintic and has a negative faecal egg count. Contamination of the environment is most likely when dogs are exercised on grass or earth runs that retain moisture and also protect larvae from sunlight. On such surfaces larvae may survive for some weeks. In contrast, dry impervious surfaces, particularly if exposed to sunlight, are lethal to larvae within a day or so. Housing is also important and failure to remove soiled bedding, especially if the kennels are damp or have porous or cracked floors, can lead to a massive build-up of infection.

Treatment: Affected dogs should be treated with an anthelmintic, such as mebendazole, fenbendazole, pyrantel or nitroscanate, all of which will kill both adult and developing intestinal stages; several of the macrocyclic lactones have similar activity. If the disease is severe, it is advisable to give parenteral iron and possibly vitamin B₁₂ and to ensure that the dog has a protein-rich diet. Young pups may require a blood transfusion. Arrested fourth-stage larvae are often refractory to anthelmintic treatment and further treatment may be required after these larvae mature.

Control: A system of regular anthelmintic therapy and hygiene should be adopted. Weaned pups and adult dogs should be treated every 3 months. Pregnant bitches should be dosed at least once during pregnancy with an anthelmintic that has high efficacy against somatic larvae, so as to reduce transmammmary infection, and the nursing litters dosed at least twice, at 1–2 weeks of age and again 2 weeks later, with a drug specifically recommended for use in pups. This will also help to control ascariid infections. The perinatal transfer of both *Ancylostoma* and *Toxocara* larvae may be reduced by the oral administration of fenbendazole daily from 3 weeks before to 2 days after whelping.

Kennel floors should be free of crevices and dry and the bedding should be disposed of daily. Runs should preferably be of tarmac or concrete and kept as clean and dry as possible; faeces should be removed with a shovel before hosing. Paved surfaces can be sprayed with a 1% solution of sodium hypochlorite after first being cleaned. If an outbreak has occurred, earth runs may be treated with sodium borate, which is lethal to hookworm larvae, but this also kills grass. A second possibility, which is often used in fox farms, is the provision of wire-mesh flooring in the runs.

Notes: *Ancylostoma caninum* is more pathogenic for dogs than either *A. braziliense* or *Uncinaria stenocephala* due to the greater level of blood loss. *Ancylostoma caninum* can occasionally use humans as a final host. Although infections do not reach full maturity, they may induce an eosinophilic enteritis.

Ancylostoma braziliense

Common name: Hookworm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ancylostomatoidea

Description, gross: As for *A. caninum* except it is smaller than either *A. caninum* or *A. tubaeforme*. In the dog, males measure around 7.5 mm and females 9–10 mm in length.

Description, microscopic: The buccal capsule is deep with two pairs of large dorsal and very small ventral teeth. Eggs are similar to those of *A. caninum*, measuring around 75–95 by 41–45 µm.

Hosts: Dog, fox and cat

Geographical distribution: Tropical and subtropical regions

Pathogenesis: While it may cause a degree of hypoalbuminaemia through intestinal leak of plasma, it is not a blood-sucker and consequently is of little pathogenic significance, causing only mild digestive upsets and occasional diarrhoea. The main importance of *A. braziliense* is that it is regarded as the primary cause of CLM or 'creeping eruption' in humans. CLM is characterised by tortuous erythematous inflammatory tracts within the dermis and by severe pruritus, and is caused by infective larvae penetrating the skin and wandering in the dermis. These larvae do not develop, but the skin lesions usually persist for weeks. The severity of the skin lesions relate to the degree of exposure to infective larvae.

Clinical signs: Mild digestive upset and diarrhoea in affected animals. In humans there may be skin erythema and pruritis.

Diagnosis: Worms that have been heat-fixed bend markedly at the position of the vulva. This differs from *A. ceylanicum*.

Pathology: Infected animals may show oedema of subcutaneous tissues and mesenteries, and serous effusion into the body cavities attributable to hypoproteinaemia. If recent exposure to heavy percutaneous infection has occurred there may be dermatitis.

Details of the epidemiology, treatment and control are as for *A. caninum*.

Notes: Humans exposed to *A. braziliense* larvae can develop an erythematous and intensely pruritic eruption of the skin associated with migration of larvae (human CLM).

Ancylostoma tubaeforme

Synonym: *Strongylus tubaeforme*

Common name: Feline hookworm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ancylostomatoidea

Description, gross: Almost identical to *A. caninum*, but slightly smaller, the males measuring around 10 mm and the females 12–15 mm.

Description, microscopic: The buccal capsule is deep, with the dorsal gutter ending in a deep notch on the dorsal margin of the buccal capsule, the ventral margin of which bears three teeth on

each side. The cuticle is thicker and the deep ‘oesophageal’ teeth slightly larger than in *A. caninum*. The male bursa is well developed and the spicules are about 50% longer than in *A. caninum*. Eggs are similar to those of *A. caninum* and measure about 56–75 by 34–47 µm.

Host: Cat

Geographical distribution: Worldwide

Pathogenesis: *Ancylostoma tubaeforme* is generally considered to be of low pathogenicity, although heavy infections may lead to a poor coat, anaemia and reduced growth. A strong immunity often develops to infection.

Ancylostoma ceylanicum

Common name: Hookworm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ancylostomatoidea

Description, gross: Almost identical to *A. braziliense*.

Description, microscopic: The cuticular striations are wider than in *A. braziliense*.

Hosts: Dog, cat, wild felids and human

Geographical distribution: Asia (Malaysia, Sri Lanka)

Pathogenesis: Infections are usually subclinical but heavy infections can induce anaemia and diarrhoea.

Diagnosis: The heat-fixed female worms are not bent as occurs with *A. braziliense*.

Notes: *Ancylostoma ceylanicum* can complete its life cycle in humans and may cause anaemia and abdominal pain and skin penetration by infective larvae may induce cutaneous lesions.

All other details of these two species are in most respects similar to *A. caninum*.

Uncinaria stenocephala

Common name: Northern hookworm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ancylostomatoidea

Description, gross: A small worm, up to about 1.0 cm long; males are 5–8.5 mm and females 7–12 mm.

Description, microscopic: The adult worms have a large funnel-shaped buccal capsule, which has a pair of chitinous plates, lacks dorsal teeth, but has a pair of subventral teeth at the base (see Fig. 1.48). The dorsal cone does not project into the buccal capsule. The male worm has a well-developed bursa with a short dorsal lobe and two large and separate lateral lobes and slender spicules. The

eggs resemble those of *Ancylostoma caninum* but are slightly longer and wider and have a thicker shell. They are ovoidal with dissimilar poles and the thin smooth side walls are almost parallel. Eggs measure 65–80 by 40–50 µm and contain large blastomeres.

Hosts: Dog, cat, fox, other canids and felids. Various mammals can act as paratenic hosts.

Geographical distribution: Temperate and sub-arctic areas, North America and northern Europe

Pathogenesis: The infection is not uncommon in groups of sporting and working dogs. The adult worms attach to the mucosa. They are not voracious blood-suckers like *A. caninum*, but hypoalbuminaemia and low-grade anaemia, accompanied by diarrhoea, anorexia and lethargy, have been recorded in heavily infected pups. Probably the most common lesion in dogs made hypersensitive by previous exposure is pedal dermatitis, affecting particularly the interdigital skin.

Clinical signs: Anaemia, diarrhoea, anorexia, lethargy, interdigital dermatitis

Diagnosis: In areas where *A. caninum* is absent, the clinical signs of the patent infection, together with the demonstration of strongyle eggs in the faeces, are indicative of uncinariosis. Where *Ancylostoma* is also endemic, differential diagnosis may require larval culture, although the treatment is similar.

Pathology: Severe hookworm infections cause villous fusion and atrophy in the small intestine and an inflammatory response in the lamina propria.

Epidemiology: Evidence suggests that in temperate climates like the UK, the seasonal pattern of infective larvae on paddocks used for greyhounds follows that described for gastrointestinal trichostrongyloids in ruminants, with a sharp rise in July and a peak in September, suggesting that development to the L₃ is heavily dependent on temperature.

Treatment: Fenbendazole, mebendazole, nitroscanate, piperazine, pyrantel and milbemycin oxime are all active against the northern hookworm.

Control: Regular anthelmintic treatment and good hygiene as outlined for *Ancylostoma* will control *Uncinaria* infection. The combination of ivermectin and pyrantel pamoate or a formulation of chewable ivermectin can give high efficacy. The pedal dermatitis responds poorly to symptomatic treatment, but regresses gradually in the absence of reinfection.

Strongyloides stercoralis

Synonyms: *Strongyloides canis*, *Strongyloides intestinalis*, *Anguillula stercoralis*

Common name: Threadworm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Rhabditoidea

Description, gross: Slender hair-like worms around 2 mm long. Only females are parasitic.

Description, microscopic: The long oesophagus may occupy up to one-third of the body length and the uterus is intertwined with the intestine, giving the appearance of twisted thread. Unlike other intestinal parasites of similar size the tail has a blunt point. *Strongyloides* eggs are oval, thin-shelled and small, 50–58 by 30–34 µm. The hatched L₁ is passed out in the faeces.

Hosts: Dog, fox, cat, human

Geographical distribution: Worldwide in warmer climates, Europe (Portugal, France, Poland, Ukraine, Romania, and Hungary)

Pathogenesis: Severe infections can occur in dogs, especially in puppies. Mature parasites are found in the duodenum and proximal jejunum and, if present in large numbers, may cause inflammation with oedema and erosion of the epithelium. This results in a catarrhal enteritis with impairment of digestion and absorption. Migrating larvae can cause bronchopneumonia.

Clinical signs: Bloody diarrhoea, dehydration, sometimes death

Diagnosis: The clinical signs in very young animals, usually within the first few weeks of life, together with the finding of large numbers of the characteristic eggs or larvae in the faeces are suggestive of strongyloidosis.

Pathology: Lesions consist of catarrhal inflammation of the small intestine while in severe infections there may be necrosis and sloughing of the mucosa. Adult worms establish in tunnels in the epithelium at the base of the villi in the small intestine. In young puppies, heavy invasion of the lungs by migrating larvae may result in petechial and ecchymotic haemorrhages.

Epidemiology: The dog may act as a natural host for this species. Transmission is either by the oral or percutaneous route or by autoinfection. The latter route can lead to cases of persistent strongyloidosis occurring without external reinfection. Unweaned puppies are infected orally via larvae adhering to the teats and larvae ingested with colostrum. Infection is most commonly seen in the summer when the weather is hot and humid and is frequently a kennel problem. A strain of *Strongyloides stercoralis* has become adapted to humans and usually occurs in warm climates.

Treatment: In dogs, oral fenbendazole 10–20 mg/kg daily for 3 days is effective. Ivermectin is effective against adult worms.

Control: Disinfection or replacement of kennels and bedding eliminates the sources of infection.

Three other species of *Strongyloides* are found in cats (Table 12.1). Details of the life cycle, diagnosis, treatment and control of these species are as for *S. stercoralis*.

Table 12.1 *Strongyloides* species reported in cats.

| Species | Description | Pathogenicity |
|--|--|---|
| <i>Strongyloides planiceps</i> | Parasitic females are 2.4–3.3 mm long (mean 2.8 mm). The tail of the parasitic female narrows abruptly to a blunt tip and the ovaries have a spiral appearance | Non-pathogenic |
| <i>Strongyloides felis</i> (syn. <i>Strongyloides cati</i>) | Similar to <i>S. planiceps</i> . Parasitic females of <i>S. felis</i> have a long tail narrowing slowly to the tip. Ovaries are straight | Non-pathogenic |
| <i>Strongyloides tumefaciens</i> | Parasitic female is about 5 mm long | Found in tumours in the mucosa of the large intestine |

Trichinella spiralis

For more details see Chapter 11.

Alaria alata

Common name: Intestinal carnivore fluke

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Diplostomatidae

Description, gross: Adult flukes are 2–6 mm in length and the flat, spoon-shaped, expanded anterior part is much longer than the posterior cylindrical hindbody which contains the reproductive organs.

Description, microscopic: At the anterior lateral corners of the anterior part there are two tentacle-like processes. The suckers are very small and the adhesive organ consists of two long folds with distinct lateral margins. The yellowish-brown eggs are large, 98–134 by 62–68 µm, operculate and unembryonated (Fig. 12.5).

Final hosts: Dog, cat, fox, mink, wild carnivores and rarely human

Intermediate hosts: Host 1: freshwater snails (*Planorbis* spp.). Host 2: frogs and toads

Geographical distribution: Eastern Europe

Pathogenesis: Adult fluke attach to the mucous membrane of the small intestine (Fig. 12.6) but cause little harm. However, the migratory mesocercariae may cause clinical symptoms. Heavy infections may cause a severe duodenitis and pulmonary damage in dogs and cats. A fatal case has been recorded in humans through eating inadequately cooked frogs' legs; the principal lesions were in the lungs.

Clinical signs: Infection is not usually associated with clinical signs.

Diagnosis: Diagnosis is by identifying the presence of eggs in the faeces.

Pathology: Effects are generally limited to the attachment of flukes to the intestinal mucosa and may include local irritation, erosion

Fig. 12.5 *Alaria* egg.

Fig. 12.6 *Alaria* spp. attached to the mucosa of the small intestine.

and ulceration and the production of excessive intestinal mucus and, rarely, haemorrhagic enteritis.

Epidemiology: Infection is maintained in endemic areas where intermediate hosts are abundant. Transmammary infection has been reported with some species in cats and rodents.

Treatment: Treatment with praziquantel or niclosamide is recommended.

Control: Dogs and cats should be prevented from catching or consuming paratenic hosts such as frogs, rodents and snakes.

Other species of *Alaria* found in canids and felids are given in Table 12.2.

Nanophyetus salmincola

Synonym: *Trogloremia salmincola*

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Nanophyetidae

Description, gross: The fluke is small, oval, white or cream in colour, and about 1–2.5 mm long by 0.3 mm wide.

Description, microscopic: The large testes are oval and situated side by side in the posterior third of the segment. The spherical ovary is situated behind the ventral sucker and to its right. The genital pore is just to the posterior of the ventral sucker and the cirrus sac is large. The vitellaria consist of large follicles. Eggs are yellowish-brown in colour, unembryonated and measure about 64–80 by 34–50 μm . They have an indistinct operculum and a small rounded abopercular knob at the opposite pole.

Final hosts: Dog, fox, coyote, cat, raccoon, mink, bear, lynx, other fish-eating mammals and rarely human

Intermediate hosts: Host 1: snails (*Oxytrema silicula*, *Goniobasis*, *Semisulcospira* spp.). Host 2: various salmonid fish

Geographical distribution: North America (northwest Pacific) and eastern Russia

Table 12.2 Intestinal flukes of dogs and cats.

| Species | Final hosts | Intermediate hosts | Distribution |
|--|--|------------------------------------|-------------------------------|
| Family Diplostomatidae | | | |
| <i>Alaria alata</i> | Dog, cat, fox, mink, wild carnivores, human | 1: Snails 2: Frogs and toads | Eastern Europe |
| <i>Alaria americana</i> | Dog, fox and other canids | 1: Snails 2: Frogs and toads | North America |
| <i>Alaria minnesotae</i> | Cat, skunk | 1: Snails 2: Frogs and toads | North America |
| <i>Alaria canis</i> | Dog, fox | 1: Snails 2: Frogs and toads | North America |
| <i>Alaria michiganensis</i> | Dog, fox | 1: Snails 2: Frogs and toads | North America |
| <i>Alaria marciana</i> | Cat | 1: Snails 2: Frogs and toads | North America |
| Family Troglotrematidae | | | |
| <i>Nanophyetus salmincola</i> | Dog, cat, raccoon, mink, bear, lynx, fish-eating mammals, rarely human | 1: Snails 2: Fish | North America, eastern Russia |
| Family Heterophyidae | | | |
| <i>Heterophyes heterophyes</i> | Dog | 1: Snails 2: Fish | Egypt, Asia |
| <i>Heterophyes nocens</i> | Dog | 1: Snails 2: Fish | Egypt, Asia |
| <i>Metagonimus yokagawai</i> | Dog | 1: Snails 2: Fish | Asia, Balkans |
| <i>Cryptocotyle lingua</i> | Gulls, fox | 1: Shellfish 2: Fish | Europe (Germany, Denmark, UK) |
| <i>Apophallus muhlingi</i> | Gulls | 1: Unknown 2: Fish | Europe |
| <i>Apophallus (Rossicotrema) donicum</i> | Cat, dog | 1: Unknown 2: Fish | Europe, North America |
| Family Echinostomatidae | | | |
| <i>Echinochasmus perfoliatus</i> | Dog | 1: Snails 2: Fish | Europe, Asia |
| <i>Euparyphium melis</i> | Cat | 1: Snail 2: Tadpole | Europe |
| <i>Euparyphium ilocanum</i> | Dog | 1: Snail 2: Freshwater molluscs | Europe |

Pathogenesis: The trematodes penetrate deeply into the mucosa of the duodenum or attach to the mucosa of other parts of the small or large intestine. In large numbers they produce a superficial enteritis which may lead to haemorrhagic enteritis. The real importance of *N. salmincola* is in its ability to transmit *Neorickettsia helminthoeca* the agent of 'salmon poisoning', which frequently produces severe and fatal infections in dogs, foxes and other animals.

Clinical signs: The presence of large numbers of flukes may cause diarrhoea. With complicated infections involving *Neorickettsia helminthoeca*, there is sudden onset of fever and complete loss of appetite. Within a few days there is purulent discharge from the eyes, vomiting and profuse diarrhoea, which may be haemorrhagic. Lymph nodes may be enlarged. Mortality varies from 50 to 90% of infected animals.

Diagnosis: Diagnosis is by identifying the presence of eggs in the faeces.

Pathology: In large numbers, superficial enteritis leading to haemorrhagic enteritis may occur.

Epidemiology: Infection is maintained in endemic areas where intermediate hosts are abundant.

Treatment: Since the rickettsial organisms cause the main pathogenic effects, tetracycline therapy is indicated. High doses of albendazole or fenbendazole over a prolonged period can be effective in treating the fluke infection. Praziquantel given intramuscularly or subcutaneously is also effective.

Control: Dogs and cats should not be fed raw fish and should be kept away from salmon rivers and streams.

Notes: *Nanophyetus* can occasionally infect humans, where it penetrates between the villi and causes inflammation and necrosis of the mucosa.

Several other trematodes parasitise the small intestine of dogs and cats and other definitive hosts, including birds and humans, but they are usually of minor veterinary significance and are briefly summarised in Table 12.2. More detailed descriptions are given in Chapter 1.

Diphyllobothrium latum

Synonym: *Dibothriocephalus latus*

Common name: Broad tapeworm

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Diphyllbothriidae

Description, gross: A very long ivory-coloured tapeworm, up to around 10–15 m in length, with several hundred proglottids. The scolex is unarmed with two muscular longitudinal slit-like grooves or bothria as organs of attachment.

Description, microscopic: The mature and gravid segments are rectangular-shaped with a central genital pore, being broader than they are long. The reproductive organs are located at the centres of the segments. Eggs are yellowish-light brown, ovoid with rounded poles, operculate and measure around 66–70 by 45–50 µm (Fig. 12.7). Note that eggs of *Spirometra* spp. are very similar but differ in having more pointed poles (see Fig. 12.9).

Fig. 12.7 *Diphyllobothrium latum* egg.

Final hosts: Human and fish-eating mammals, such as the dog, fox, cat, pig, mink, seal and bear

Intermediate hosts: Host 1: copepods of the genus *Diatomus*. Host 2: freshwater fish (pike, trout, perch, minnow)

Geographical distribution: Parts of Scandinavia, Russia, Japan and North America

Pathogenesis and clinical signs: In humans, infections are often asymptomatic but there can be fatigue, dyspepsia, vomiting and transient diarrhoea. Infection is usually asymptomatic in animals, although occasionally vitamin B₁₂ deficiency can occur.

Diagnosis: This depends on the detection of the characteristic eggs in the faeces.

Pathology: Does not induce damage to the intestine.

Epidemiology: *Diphyllobothrium latum* is essentially a parasite of humans since in other hosts the cestode produces few fertile eggs. The epidemiology is therefore largely centred around two factors, the access of human sewage to freshwater lakes and the ingestion of uncooked fish. Domestic animals, such as dogs or pigs, become infected by eating raw fish or fish offal.

Treatment: Praziquantel and niclosamide are effective against the adult tapeworm.

Control: In areas where infection is common, domestic animals should not be fed fish products unless these have been thoroughly cooked or deep-frozen.

Notes: *Diphyllobothrium latum* is an important cestode parasite of the small intestine of humans in northern climates; it may also infect other fish-eating mammals.

Dipylidium caninum

Common name: Double-pored or cucumber seed tapeworm

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Dilepididae

Description, gross: *Dipylidium* is a much shorter tapeworm than *Taenia*, the maximum length being about 50 cm.

Description, microscopic: The scolex has four suckers and a protrusible retractable rostellum, which is armed with four or five rows of small rose-thorn shaped hooks (see Fig. 1.99). The proglottid is easily recognised, being elongate, like a large rice grain or cucumber seed, and has two sets of genital organs, with a pore opening on each margin. Eggs are yellowish-brown in colour and almost spherical. They contain a hexacanth embryo and measure about 25–50 µm and are contained in an egg capsule (about 120–200 µm), which may hold up to 30 eggs (Fig. 12.8; see also Fig. 4.6).

Final hosts: Dog, fox and cat; rarely human

Intermediate hosts: Fleas (*Ctenocephalides* spp., *Pulex irritans*) and biting lice (*Trichodectes canis*)

Geographical distribution: Worldwide

Fig. 12.8 *Dipylidium caninum* egg packet.

Pathogenesis: The adult is non-pathogenic and several hundreds can be tolerated without clinical effect. They shed segments which, as they crawl actively from the anus, may cause some discomfort, and a useful sign of infection is excessive grooming of the perineum. It has been suggested that infected dogs form the habit of rubbing the anus along the floor, but impacted anal glands are a more common cause of this behaviour.

Clinical signs: Anal discomfort, itching

Diagnosis: Often the first indication of infection is the presence of a segment on the coat around the perineum. If the segment is freshly passed, preliminary identification may be made on the elongate shape, and the double genital organs, which may be seen with a hand lens. If it is dried and distorted it will be necessary to break it up with mounted needles in water, where the egg packets are easily seen under the microscope, thus differentiating the segment from that of *Taenia* spp., which contains only numerous single oncospheres.

Pathology: Adult tapeworms are of little pathogenic significance.

Epidemiology: *Dipylidium* infection is very common and, being dependent on the continuous presence of ectoparasites for its local endemicity, it is more prevalent in neglected animals, though infestations are also seen in well-kept dogs and cats.

Treatment and control: In *Dipylidium* infection, treatment and control must be instituted together, for it is clearly of no value to eliminate the adult tapeworm while leaving a reservoir in the animal's ectoparasites. Hence, administration of anthelmintics, such as nitroscanate and praziquantel, should be accompanied by the use of insecticides. It is also imperative that the animal's bedding and customary resting places should receive attention with insecticides to eliminate the immature stages of the flea, which are many times more numerous than the adult parasites feeding on the dog or cat.

Notes: This is the commonest tapeworm genus of the domestic dog and cat.

Echinococcus

The taxonomy of *Echinococcus* has suffered from uncertainty regarding the taxonomic status of described species and subspecies. This

has resulted in confusion regarding the nomenclature of intraspecific variants and impacted on the understanding of the epidemiology of echinococcosis, particularly the nature of transmission patterns. Recent application of molecular tools has led to the recognition of a series of largely host-adapted species that are maintained in distinct cycles of transmission.

Echinococcus granulosus possesses a high degree of genetic divergence and various strains (G1–G10) have been described which show differences in morphology, host range and pathogenicity and geographical distribution. Two former strains are now recognised as individual species: *E. equinus* (the former horse strain) and *E. orteleppi* (the former cattle strain). More strains or species of the *E. granulosus* complex undoubtedly exist.

Echinococcus multilocularis is primarily a parasite of foxes but is an important zoonosis also affecting dogs and cats. Two further species of *Echinococcus* occur in dogs: *E. oligarthrus* and *E. vogeli*. These are briefly summarised in the following sections. The metacystode stages can establish and develop in humans. Intermediate hosts include rodents such as the paca (*Cuniculus paca*), spiny rat (*Proechimys guyanensis*) and agouti (*Dasyprocta* spp.).

Echinococcus granulosus, *Echinococcus equinus* (G4), *Echinococcus orteleppi* (G5)

Common names: Dwarf dog tapeworm, hydatidosis

Predilection site: Anterior small intestine (final host); mainly liver and lungs (intermediate host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: All three species are similar in appearance. The entire cestode is only about 5.0–6.0 mm long, and is therefore difficult to find in the freshly opened intestine. It consists of a scolex and three or four segments, the terminal gravid one occupying about half the length of the complete tapeworm (see Fig. 1.94). 'Hydatid' cysts are large fluid-filled vesicles, 5–10 cm in diameter (see Fig. 9.44).

Description, microscopic: The scolex is typically taeniid and the rostellum has two rows of hooks, varying from 30 to 60 in numbers. Each segment has a single genital opening, with the penultimate segment sexually mature and the last segment gravid. The genital pores alternate irregularly. For more detailed morphology of hydatid cysts see description of *E. granulosus* in Chapter 9.

The small almost spherical eggs have a smooth thick shell and are typically 'taeniid'. They measure 32–36 by 25–30 μm and the lamellar embryophore is radially striated with a six-hooked oncosphere.

Final hosts: *Echinococcus granulosus*: dog and many wild canids such as coyote, dingo and wolf; *E. equinus*: dog and red fox; *E. orteleppi*: dog

Intermediate hosts: *Echinococcus granulosus*: domestic and wild ruminants, human and primates, pig and lagomorphs; horses and donkeys are resistant. *E. equinus*: horse, ass, mule and donkey; *E. orteleppi*: cattle

Geographical distribution: *Echinococcus granulosus*, worldwide; *E. equinus*, mainly Europe

Pathogenesis: The adult tapeworm is not pathogenic, and thousands may be present in the small intestine of a dog without clinical signs. In domestic animals the hydatid in the liver or lungs is usually tolerated without any clinical signs, and the majority of infections are only revealed at the abattoir. Where oncospheres have been carried in the circulation to other sites, such as the kidney, pancreas, CNS or marrow cavity of long bones, pressure by the growing cyst may cause a variety of clinical signs.

In contrast, when humans are involved as an intermediate host, the hydatid in its pulmonary or hepatic site is often of pathogenic significance. One or both lungs may be affected causing respiratory symptoms, and if several hydatids are present in the liver there may be gross abdominal distension. If a cyst should rupture there is a risk of death from anaphylaxis; alternatively if the person survives, released daughter cysts may resume development in other regions of the body.

Clinical signs: Asymptomatic in the dog and infection in cattle, sheep and horses is also generally not associated with clinical signs. Human infection can result in respiratory distress or abdominal enlargement depending on whether the lungs or liver are infected.

Diagnosis: Diagnosis of infection in dogs with adult tapeworms is difficult, because the segments are small and are only shed sparsely. When found, identification is based on their size (2.0–3.0 mm), ovoid shape and single genital pore.

In some countries control regimens have involved the administration of purgative anthelmintics, such as arecoline hydrochloride, so that the whole tapeworm is expelled in mucus and can be searched for in the faeces. If a necropsy is available the small intestine should be opened and immersed in shallow water, when the attached tapeworms will be seen as small slender papillae. Immunodiagnostic tests have been developed based on the detection of faecal antigen by the antibody sandwich enzyme-linked immunosorbent assay (ELISA) technique.

Pathology: No reported pathology in the final hosts.

Epidemiology:

- *Echinococcus granulosus*. Only a few countries, notably Iceland and Eire, are free from *E. granulosus*. It is customary to consider the epidemiology as being based on two cycles, pastoral and sylvatic. In the pastoral cycle the dog is always involved, being infected by the feeding of ruminant offal containing hydatid cysts. The domestic intermediate host will vary according to the local husbandry but the most important is the sheep, which appears to be the natural intermediate host, scolices from these animals being the most highly infective for dogs. In parts of the Middle East the camel is the main reservoir of hydatids, while in northern Europe and northern Russia it is the reindeer. The pastoral cycle is the primary source of hydatidosis in humans, infection being by accidental ingestion of oncospheres from the coats of dogs, or from vegetables and other foodstuffs contaminated by dog faeces. The sylvatic cycle occurs in wild canids and ruminants and is based on predation or carrion feeding. It is less important as a source of human infection, except in hunting communities where the infection may be introduced to domestic dogs by the feeding of viscera of wild ruminants.
- *Echinococcus equinus* (G4). Equine hydatidosis is commonest in Europe, and in other parts of the world most cases have been recorded in imported European horses. The strain is highly

specific for the horse and the eggs do not develop in the sheep. The domestic dog and the red fox are the final hosts, and the cycle in countries of high prevalence depends on access by dogs to infected equine viscera. On mainland Europe, the most likely source is offal from horse abattoirs and in Britain the viscera of hunting horses, which are fed to foxhounds. The horse strain does not appear to be infective to humans.

Treatment: *Echinococcus* tapeworms are more difficult to remove than *Taenia*, but several drugs, notably praziquantel, are now available which are highly effective. After treatment it is advisable to confine dogs for 48 hours to facilitate the collection and disposal of infected faeces. In humans, hydatid cysts may be excised surgically, although mebendazole, albendazole and praziquantel therapies have been reported to be effective.

Control: This is based on the regular treatment of dogs to eliminate the adult tapeworms and on the prevention of infection in dogs by exclusion from their diet of animal material containing hydatids. This is achieved by denying dogs access to abattoirs and, where possible, by proper disposal of sheep carcasses on farms. In some countries these measures have been supported by legislation, with penalties when they are disregarded. In countries where no specific measures for hydatid control exist, it has been found that an incidental benefit from the destruction of stray dogs for rabies control has been a great reduction in the incidence of hydatid infection in humans.

A recombinant DNA vaccine has been developed for *E. granulosus* but it requires further refinement for practical application and it is currently not available commercially.

Echinococcus multilocularis

Common names: Dwarf fox tapeworm, alveolar echinococcosis

Predilection site: Lower small intestine (final hosts); liver also lungs, brain, muscles, lymph nodes (intermediate hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: *Echinococcus multilocularis* is a very small tapeworm (2–4 mm) and is generally similar to *E. granulosus*, but usually with three to five segments, the terminal one measuring less than half the length of the whole worm.

Description, microscopic: The scolex has four suckers and possesses a double row of large and small hooks. The third segment of the adult tapeworm is sexually mature and the genital pores are in front of the middle of each segment. The uterus is sac-like with no lateral sacculations in the terminal proglottid. Gravid segments contain around 200–300 spherical eggs. Eggs that are shed have a diameter of about 30–40 µm and possess a smooth thick shell. The structure of the metacestode consists of a germinative gelatinous matrix that forms multiple compartments.

Final hosts: Wild canids (primarily foxes but in some areas coyote, wolf and raccoon dog may be involved), domestic dog and cat, although the cat is a less suitable host than canids.

Intermediate hosts: Mainly microtine rodents, such as voles, muskrats and lemmings, and insectivores; some of the larger mammals, including human, are also susceptible.

Geographical distribution: Northern hemisphere, including North America, Greenland, Scandinavia, central Europe, Russia, Middle East; also India, China and Japan

Pathogenesis: The larval metacestode stage develops primarily in the liver as the so-called multilocular or alveolar cyst, a diffuse growth with many compartments containing a gelatinous matrix into which the protoscolices are budded off. Growth of the intermediate stage is invasive, extending locally and capable of systemic metastases to other sites such as lungs, brain, muscles and lymph nodes. These hydatids are the causative agent of alveococcosis or alveolar echinococcosis.

Clinical signs: Usually asymptomatic in the definitive host. In the intermediate host, clinical signs are dependent on the level of infection and the location of the metacestode stages. Infection in humans often presents with few signs until the infection has markedly progressed. The slow infiltration of organs may cause symptoms resembling those of a slow-growing carcinoma.

Diagnosis: The sedimentation and counting technique at necropsy is the well-established method for the detection of intestinal *E. multilocularis* in the definitive host, although the intestinal scraping technique is also useful. More recent research techniques include the detection of copro-DNA by polymerase chain reaction (PCR) and the detection of *E. multilocularis* specific coproantigen in an ELISA-based assay. Serological and PCR-based tests are available for the early detection of infection in humans.

Pathology: The adult tapeworm causes little damage in the intestine of the definitive host. In the liver, invasion by the metacestode stage can result in atrophy of the parenchyma and cause cirrhosis. Expansion of alveolar *Echinococcus* in the liver produces aggregates of small gelatinous cysts that appear similar to malignant neoplasia.

Epidemiology: Though *E. multilocularis* has a wide distribution in the northern hemisphere, it is essentially a parasite of tundra regions with its greatest prevalence in the sub-arctic regions of Canada, Alaska and Russia. Its basic epidemiological cycle in these regions is in the arctic fox and wolf, and their prey, small rodents and insectivores. In North America, its range is extending south from Canada into the USA where the red fox and coyote act as final hosts. The cycle is therefore sylvatic, and most cases in humans occur in trappers and their families following contact with the contaminated fur of foxes and wolves. However, eating vegetables or fruit contaminated by infected foxes seeking garden voles may occasionally infect suburban humans.

Over the last decade the population of red foxes has expanded in Europe and foxes have also extended their distribution into urban and peri-urban areas. The demonstration of an urban wildlife cycle of *E. multilocularis* in foxes has implications for human health in areas where this parasite is endemic. In addition, the expansion of the synanthropic cycle, involving domestic dogs that prey on metacestode-infected rodents, may lead to an increase in the prevalence of human alveolar echinococcosis. *Echinococcus multilocularis* egg contamination has been predicted to be maximal where the urban and rural habitats overlap.

Treatment: Dogs and cats can be treated with praziquantel or epsiprantel. Treatment of domestic intermediate hosts is not advised. The invasive growth in humans simulates malignant neoplasia, and because of its infiltrative spread in tissues and its readiness to develop metastatically, surgery is not advisable; instead treatment with mebendazole or praziquantel is recommended.

Control: Because of the large sylvatic reservoir, control of *E. multilocularis* is unlikely ever to be achieved. Precautionary measures include:

- the wearing of protective rubber gloves when handling fresh skins/furs of foxes, wolves, etc.;
- thorough washing of forest fruits and berries prior to consumption in regions where infection is endemic; and
- treatment of dogs and cats with an effective cestocidal anthelmintic.

Echinococcus vogeli

Predilection site: Small intestine (final hosts); liver, lung and other visceral organs (intermediate hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: *Echinococcus vogeli* is a very small tapeworm (4–6 mm) and usually has three segments, the terminal gravid segment being very long in comparison to the rest of the tapeworm.

Description, microscopic: The uterus is sac-like, long and tubular in shape. The metacestode has a polycystic structure.

Final hosts: Bush dog (*Speothos venaticus*) and occasionally domestic dog. Humans can be an accidental host.

Geographical distribution: Central and South America

Notes: *Echinococcus shiquicus* is found in Tibet and cycles between a fox, *Vulpes ferrilata*, and the plateau pika.

Echinococcus oligarthrus

Predilection site: Small intestine (final hosts); viscera, musculature and skin (intermediate hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: *Echinococcus oligarthrus* is an extremely small tapeworm (2.5–3.0 mm) and usually has three segments.

Description, microscopic: The uterus is sac-like in the gravid proglottid. The metacestode is polycystic in form.

Final hosts: Cougar, jaguar, ocelot and other felids; humans can be an accidental host.

Geographical distribution: Central and South America

Other details for these species are similar to those for *E. multilocularis*.

Spirometra mansoni

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Diphyllbothriidae

Description, gross: The adult tapeworms are very similar to *Diphyllbothrium*, the scolex being unarmed and possessing two muscular longitudinal slit-like grooves as organs of attachment. The plerocercoids, also called spargana, are white, ribbon-like, crinkled and can measure around 300–400 mm.

Description, microscopic: The tapeworm possesses both a uterine and a vaginal pore and the uterus is spiral in shape. The operculate eggs have pointed ends and measure on average 65 by 45 µm (Fig. 12.9).

Final hosts: Dog, cat, wild carnivores and occasionally human

Intermediate hosts: Host 1: copepods. Host 2: amphibia, reptiles, birds and mammals

Geographical distribution: South America and Asia

Pathogenesis and pathology: The tapeworm usually causes little effect in the intestine of dogs and cats.

Clinical signs: Usually asymptomatic in animals.

Notes: Other details are similar in most respects to *D. latum*. Occasionally, humans may become infected with plerocercoids, either through drinking water containing proceroid-infected crustacea or from eating a plerocercoid-infected host such as a pig. This zoonosis, known as sparganosis (*Sparganum* was the old name for these plerocercoids), is characterised by the presence of larvae up to 35 mm long in the muscles and subcutaneous

Fig. 12.9 *Spirometra* egg.

tissues, particularly the periorbital area, causing oedema and inflammation. Occasionally, the spargana disintegrate into several pieces (proliferating disease), which develop separately, and this can be fatal.

Other species of *Spirometra* found in dogs and cats are detailed in Table 12.3. Descriptive details of taeniid tapeworms of dogs are listed in Table 12.4.

Table 12.3 Tapeworms of dogs and cats.

| Genus | Species | Hosts | Intermediate hosts | Metacestode stages Name | Site |
|--|-----------------------|--|--|--|---------------------------------------|
| <i>Echinococcus</i> | <i>granulosus</i> | Dog (wolf, fox, jackal, dingo, hyena) | Livestock, human | Hydatidosis, hydatid cyst | Liver, lungs, etc. |

* Values in parentheses indicate ranges.

Taenia hydatigena

Synonyms: *Taenia marginata*, *Cysticercus tenuicollis*

Common name: Thin-necked bladder worm

Predilection site: Small intestine (final hosts); abdominal cavity, liver (intermediate hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: *Taenia hydatigena* is a large tapeworm measuring up to 5 m in length. The scolex is large and has two rows of 26 and 46 rostellar hooks. Four suckers are present. Gravid proglottids are 12 by 6 mm and the uterus has five to ten lateral branches.

Description, microscopic: Eggs are subspherical or slightly elliptical and measure 36–39 by 31–35 µm. They have a smooth thick shell with a radially striated embryophore and contain a hexacanth embryo.

Final hosts: Dog, fox, weasel, stoat, polecat, wolf, hyena

Intermediate hosts: Sheep, goat, cattle, deer, pig, horse

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Adult tapeworms in dogs are usually asymptomatic. However, in heavy infections there may be gastrointestinal disturbances such as diarrhoea, abdominal pain and anal pruritis that result from the migration of proglottids from the perianal area.

Diagnosis: Often the first sign of tapeworm infection in dogs is the presence of proglottids in the faeces or more frequently the perianal area as a result of the active migration of the segments. These segments may cause itching and grooming of the perianal area.

Pathology: Usually causes little damage to the intestine although there have been occasional reports of obstruction when several worms are present.

Epidemiology: If untreated, the final host can harbour tapeworms from several months to a year or more.

Treatment: Tapeworms can be removed from dogs through the administration of an effective cestocidal anthelmintic, such as niclosamide, praziquantel, nitroscanate or multiple doses of mebendazole or fenbendazole (Table 12.5). No practical treatment is available for the intermediate host.

Table 12.5 Tapeworm treatments for dogs and cats.

| Anthelmintic | Dose rate (mg/kg) | <i>Taenia</i> spp. | <i>Echinococcus</i> spp. | <i>Dipylidium</i> | Comments |
|--------------|---|--------------------|--------------------------|-------------------|---|
| Praziquantel | 5 (oral) | + | + | + | Good activity against <i>E. multilocularis</i> |
| | 8 (spot-on) | + | + | + | |
| | 3.5–7.5 (injection) | + | + | + | |
| Dichlorophen | 200 | + | | + | |
| Nitroscanate | 50 | + | (+) | + | Active against <i>E. granulosus</i> . Use in dogs only |
| Niclosamide | 125 | + | | (+) | |
| Fenbendazole | 100 single dose 50 for 3 days | + | | | |
| Mebendazole | Variable (3.5–50) Given for 2–5 days | (+) | (+) | | Activity against tapeworms variable. Some activity against <i>E. granulosus</i> |
| Episprantel | 5.5 | + | | + | Combined with pyrantel pamoate |
| Bunamidine | 50 | + | + | + | No longer available in many countries |

+, active; (+), variable activity.

Control: This is similar to that of other taeniids and involves control of infection in the final host and through burial or disposal of ruminant carcasses and offal.

Notes: The correct nomenclature for the intermediate host stage is 'metacystode stage of *Taenia hydatigena*' rather than '*Cysticercus tenuicollis*'.

Taenia ovis

Synonyms: *Taenia cervi*, *Taenia krabbei*, *Taenia hyaenae*, *Cysticercus ovis*, *Cysticercus cervi*, *Cysticercus tarandi*, *Cysticercus dromedarii*, *Cysticercus cameli*

Common names: Cysticercosis, 'sheep measles', sheep bladder worm

Predilection site: Small intestine (final host); muscle, liver and other organs (intermediate host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: The adult tapeworms measure 0.5–1.5 m in length.

Microscopic: The rostellum bears 24–36 hooks and four suckers are present. The strobila has a scalloped edge and is often coiled into a spiral. The mature proglottids have a vaginal sphincter and the ovary and vagina cross each other. The uterus of the gravid proglottids has 20–25 lateral branches on either side. The oval egg measures 34 by 24–28 µm.

Final hosts: Dog, fox, wild carnivores

Intermediate hosts: Sheep, goat (*Cysticercus ovis*); deer (*Cysticercus cervi*); reindeer (*Cysticercus tarandi*); camel (*Cysticercus dromedarii*, *Cysticercus cameli*)

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Heavy infections in young dogs can sometimes cause diarrhoea and ill-thrift.

Diagnosis: Tapeworm infection in dogs is often recognised through the presence of shed proglottids and/or tapeworm segments in fresh faeces.

Epidemiology: Adult tapeworms shed three segments each containing 78,000–95,000 eggs. Dogs can be infected by more than one adult tapeworm. The thick-shelled eggs can survive 90–150 days at 16°C but survive for shorter periods at higher temperatures. Ruminants are infected by grazing pasture and forages contaminated with dog or fox faeces harbouring eggs of *T. ovis*.

Treatment: As for other taeniid species.

Control: Regular treatment of dogs with an effective anthelmintic will reduce contamination of the environment. Dogs should be denied access to raw sheep and goat meat and carcasses. A highly protective recombinant vaccine is available in some countries.

Notes: The correct nomenclature for the intermediate host stage is 'metacystode stage of *Taenia ovis*' rather than '*Cysticercus ovis*', etc.

Taenia multiceps

Synonyms: *Multiceps multiceps*, *Coenurus cerebralis*, *Taenia skrjabini*, *Coenurus skrjabini*, *Taenia (Multiceps) gaigeri*, *Coenurus gaigeri*

Common names: Gid, sturdy, staggers

Predilection site: Small intestine (definitive hosts); brain and spinal cord (intermediate hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: Adult tapeworms are 40–100 cm in length (Fig. 12.10).

Description, microscopic: Adults have a small head about 0.8 mm in diameter with four suckers. There is a double ring of 22–32 rostellar hooks. The gravid segments measure 8–12 by 3–4 mm and the uterus has 18–26 lateral branches which contain taeniid eggs. Eggs are approximately 29–37 µm in diameter and have thick smooth shells with a radially striated embryophore. They contain a hexacanth embryo.

Final hosts: Dog, fox, coyote, jackal and wolf

Intermediate hosts: Sheep, goat, cattle, deer, pig, horse, human

Geographical distribution: Worldwide, but absent from the USA and New Zealand

Pathogenesis and clinical signs: Infection in the intermediate hosts is usually asymptomatic.

Diagnosis: As for *T. hydatigena*.

Pathology: There is no associated pathology.

Epidemiology: This is largely influenced by whether sheepdogs and stray dogs have access to the heads or spinal cords of infected intermediate hosts. Foxes are in general less efficient than dogs in contaminating pastures.

Treatment: As for other taeniid species.

Control: This can be achieved through ensuring that dogs, in particular sheepdogs, do not have access to the heads of slaughtered or dead sheep or goats. It is essential that all sheep carcasses are buried as soon as possible. In areas where coenurosis is endemic, the

Fig. 12.10 Mature tapeworm, *Taenia multiceps*.

regular deworming of dogs with an effective anthelmintic every 6–8 weeks will reduce the contamination into the environment and, by breaking the sheep–dog cycle, may lead to eradication of the disease. Foxes are not thought to be an important final host for *T. multiceps*.

Taenia pisiformis

Synonym: *Cysticercus pisiformis*

Predilection site: Small intestine (final host); peritoneum, liver (intermediate host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: The adult tapeworm can measure up to 2 m in length.

Description, microscopic: The adult tapeworm has a large scolex with narrow strobila and the rostellum has 34–48 hooks (see Fig. 1.90). Gravid segments have a uterus with 8–14 lateral branches on either side. *Cysticercus pisiformis* is a small pea-like transparent cyst. Eggs are oval or elliptical, approximately 48 by 46 µm in size and have thick smooth shells with a radially striated embryophore. They contain a hexacanth embryo.

Final hosts: Dog, fox

Intermediate hosts: Rabbit, hare

Geographical distribution: Worldwide

Pathogenesis: Infection is usually asymptomatic in both the final and the intermediate host. However, in heavy infections liver damage can occur in the intermediate host as a result of migration of juvenile worms through the liver parenchyma. This can lead to hepatitis and cirrhosis.

Clinical signs: Infection is usually asymptomatic. In heavy infections the intermediate hosts may show emaciation and jaundice.

Diagnosis: Infection of the intermediate host is detected through the presence of a single cyst or a cluster of several cysts in the abdominal cavity.

Pathology: Pea-like cysts present on the peritoneum, wall of the mesentery and omentum.

Epidemiology: There is a high prevalence in hunting dogs.

Treatment: As for other taeniid species.

Control: Hunting dogs should be wormed regularly with an effective anthelmintic and should not be fed raw carcasses or offal from rabbits and hares.

Notes: The correct nomenclature for the intermediate host stage is ‘metacestode stage of *Taenia pisiformis*’ rather than ‘*Cysticercus pisiformis*’.

Taenia serialis

Synonyms: *Multiceps serialis*, *Coenurus serialis*

Predilection site: Small intestine (definitive host); intramuscular and subcutaneous connective tissue (intermediate host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: The adult tapeworm is of medium length, around 0.5–0.7 m, and bears two rows of hooks (see Fig. 1.92). The metacestode cysts may be 4–6 cm in size.

Description, microscopic: The numerous scolices in the coenurus are arranged in lines or strands as the name ‘*serialis*’ implies. The gravid uterus has 10–18 lateral branches and the vaginal sphincter is well developed. The slightly elliptical eggs measure 31–34 by 29–30 µm and have thick smooth shells with a radially striated embryophore. They contain a hexacanth embryo.

Final hosts: Dog, fox and other canids

Intermediate hosts: Rabbit, hare and rarely rodents and human

Geographical distribution: Worldwide

Pathogenesis: Infection is usually asymptomatic in both the definitive and the intermediate host.

Clinical signs: No clinical signs reported.

Diagnosis: Infection of the intermediate host is detected through the presence of cysts in subcutaneous or intramuscular connective tissue.

Pathology: Pea-like cysts are present in subcutaneous or intramuscular connective tissue.

Epidemiology: There is a high prevalence in hunting dogs.

Treatment: As for other taeniid species.

Control: Hunting dogs should be wormed regularly with an effective anthelmintic and should not be fed raw carcasses or offal from rabbits and hares.

Notes: The correct nomenclature for the intermediate host stage is ‘metacestode stage of *Taenia serialis*’ rather than ‘*Coenurus serialis*’. Another species, *Taenia brauni*, is very similar to *T. serialis* and is found in parts of Africa. The adult tapeworm occurs in the dog and other wild canids and the metacestode in rodents.

Taenia taeniaeformis

Synonyms: *Hydatigera taeniaeformis*, *Taenia crassicollis*, *Cysticercus fasciolaris*, *Strobilocercus fasciolaris*

Predilection site: Small intestine (final host); liver (intermediate host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: The adult tapeworm is of medium size, up to 70 cm in length.

Description, microscopic: The scolex is large and there is absence of a neck region. The uterus has five to nine lateral branches and

the posterior proglottids are bell-shaped. The metacestode stage is a strobilocercus (*Strobilocercus fasciolaris*), which is a small cyst connected with an evaginated scolex by a segmented juvenile strobila. The subspherical eggs measure on average about 31–37 µm and have thick smooth shells with a radially striated embryophore. They contain a hexacanth embryo.

Final hosts: Cat, lynx, stoat, fox

Intermediate hosts: Mouse, rat, rabbit, squirrel

Geographical distribution: Cosmopolitan

Pathogenesis: Adult tapeworms are of minor pathogenic significance and infections are usually subclinical.

Clinical signs: None reported

Diagnosis: Diagnosis depends on the demonstration of segments or individual taeniid eggs in the faeces. Specific identification of the adult tapeworm is a specialised task.

Epidemiology: Rodents are infected by grazing pasture and forages contaminated with cat faeces harbouring eggs of *T. taeniaeformis*. Two cycles can occur: an urban cycle that involves the domestic cat and house and field rodents; and a sylvatic cycle that in North America uses bobcats and wild rodents.

Treatment: Cats should be treated regularly with an effective cestocidal anthelmintic. For adult tapeworms a number of effective drugs are available, including praziquantel, mebendazole, fenbendazole and dichlorophen.

Control: Control depends on dietary methods that exclude access to the larval stage in the intermediate host. Where practical, cats should be prevented from eating rodents.

Mesocestoides lineatus

Synonyms: *Dithrydium variable*, *Tetrathyridium bailetti*, *Tetrathyridium elongatum*

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Mesocestoididae

Description, gross: The adult tapeworm can vary from 30 to 250 cm in length and up to 3 mm wide.

Description, microscopic: The scolex is large, unarmed, without a rostellum, and the four suckers are elongate and oval. The strobili are thin and narrow, up to 1.5 cm in length. Mature segments are longer than wide and each contains a single set of central reproductive organs, the central genital pore opening on the dorsal surface. The ovary and vitelline glands are bilobed and there are numerous testes. Oncospheres in gravid segments progress from the uterus into a paruterine organ. Eggs accumulate in the paruterine organ as the segments mature. The eggs are oval and measure 40–60 by 35–43 µm.

Final hosts: Dog, cat, fox, mink and wild carnivores

Intermediate hosts: Host 1: oribatid mites. Host 2: birds, amphibians, reptiles, small mammals

Geographical distribution: Europe, Asia, Africa

Pathogenesis: Adult tapeworms are of minor pathogenic significance and infections are usually subclinical.

Clinical signs: None reported

Notes: A related tapeworm, *M. corti*, reproduces asexually in the intestine of the dog.

Macracanthorhynchus hirudinaceus

Common name: Thorny-headed worm

Predilection site: Duodenum and proximal small intestine

Phylum: Acanthocephala

Family: Oligacanthorhynchidae

Description: Male worms are up to 10 cm and the females around 40–60 cm in length and are slightly curved and white/pinkish in colour when fresh (see Fig. 1.64). The worms are thick (5–10 mm in width) flattened and the cuticle is transversely wrinkled. This pseudo-segmentation can sometimes cause misidentification as a tapeworm. There is no alimentary canal. The anterior of the worm possesses a small retractable proboscis, which is covered with about six transverse rows of recurved hooks. The sizes of the hooks decrease posteriorly.

The eggs are ovoid, yellowish-brown in colour, with a thick shell, the outer layer of which is irregularly mamillated (see Fig. 4.5) and measure 50–75 by 40–55 µm.

Final hosts: Pig, wild boar, occasionally dog, cat, wild carnivores and human

Intermediate hosts: Various dung beetles and water beetles

Geographical distribution: Worldwide, but absent from certain areas, for example parts of western Europe

For more details see Chapter 11.

Coccidiosis

Dogs and cats are infected with coccidian parasites belonging to the genus *Cystisospora* (*Isospora*). In the dog, the common species are *Cystisospora canis* and *C. ohioensis*. In the cat the common species are *I. felis* and *I. rivolta*.

Pathogenesis: There is no real evidence that these species are pathogenic on their own, but infection may be exacerbated by intercurrent viral disease, or other immunosuppressive agents.

Clinical signs: Diarrhoea in young puppies or kittens.

Diagnosis: Coccidiosis may be diagnosed on postmortem by finding coccidial stages in the intestines. Affected animals with diarrhoea or dysentery may be shedding oocysts in the faeces. The presence of oocysts is not in itself sufficient for diagnosis but should be considered with presenting signs of sudden onset of enteritis. Oocysts may need to be differentiated from the oocysts of other coccidial genera found in dogs (Table 12.6) and cats (Table 12.7 and Fig. 12.11).

Table 12.6 Coccidian parasites in the faeces of dogs.

| Coccidian species | Alternative name | Intermediate host | Oocyst condition* | Oocyst size (µm) | Sporocyst size (µm) |
|-------------------------------|--|-------------------|-------------------|------------------|---------------------------|
| <i>Sarcocystis bovicanis</i> | <i>Sarcocystis cruzi</i> <i>Sarcocystis fusiformis</i> | Cattle | S | 19–21 × 15–18 | 16.3 × 10.8 [†] |
| <i>Sarcocystis ovicanis</i> | <i>Sarcocystis tenella</i> | Sheep | S | | 14.8 × 9.9 [†] |
| <i>Sarcocystis suicanis</i> | <i>Sarcocystis porcicanis</i> <i>Sarcocystis mieschiriana</i> | Pig | S | | 12.7 × 10.1 [†] |
| <i>Sarcocystis equicanis</i> | <i>Sarcocystis bertrami</i> | Horse | S | | 15.2 × 10 [†] |
| <i>Sarcocystis fayeri</i> | | Horse | S | | 12.0 × 7.9 [†] |
| <i>Sarcocystis capracanis</i> | | Goat | S | | 12–15 × 8–10 [†] |
| <i>Sarcocystis hircicanis</i> | | Goat | S | | |
| <i>Sarcocystis cameli</i> | | Camel | S | | 12 × 9 [†] |
| <i>Sarcocystis hovarhi</i> | <i>Sarcocystis gallinarum</i> | Chicken | S | | 10–13 × 7–9 [†] |
| <i>Hammondia heydorni</i> | <i>Toxoplasma heydorni</i> | — | U | 13 × 11 | |
| <i>Cystisospira canis</i> | | — | U | 38 × 30 | 2 × 16 |
| <i>Cystisospira ohioensis</i> | | — | U | 23 × 19 | 14.5 × 10 |

* Sporulated (S) or unsporulated (U) oocysts in faeces.

† Sporocysts generally found free in faeces.

Pathology: Coccidial stages are found in the epithelial cells lining the villi of the small intestine. In heavy infections there is villous stunting and reduction in the absorptive area of the lower small intestine leading to diarrhoea.

Epidemiology: Crowding and lack of good sanitation promote spread of coccidiosis. Breeding establishments, kennels and rescue centres are potential sources of infection. Older dogs and cats are generally immune from disease, but may seed the environment with oocysts leading to infection in young puppies and kittens that have no previous exposure.

Treatment: Information on treatment in the dog and cat is scanty, although by analogy with other host species the use of sulphonamides, such as sulphadimidine, should be tried.

Control: Good sanitation and isolation are effective measures in preventing coccidiosis. In kennels or rescue centres, animal accommodation should be cleaned daily. Standard disinfectants are ineffective against coccidial oocysts but ammonia-based products are effective.

Notes: At one time it was thought that species of the genus *Cystisospira* (*Isospora*) were freely transmissible between dogs and cats, but it is now established that this is not the case.

Cystisospira canis

Synonym: *Isospora canis*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal to slightly ovoid, 34–42 by 23–36 µm (mean 38 × 30 µm), with a smooth pale wall without a micropyle, polar granule or residuum but with a tiny blob adherent to the oocyst wall at the broad end. The two sporocysts are ellipsoidal 18–28 by 15–19 µm with a smooth colourless wall and a prominent residuum. Each sporocyst contains four sausage-shaped sporozoites with clear sub-central globules.

Host: Dog

Life cycle: Three merogony generations occur in the subepithelium of the lamina propria of the small intestine. Gamonts appear within the epithelial cells about 7 days post infection. The prepatent period is 9–11 days and infections can remain patent for about 4 weeks.

Table 12.7 Coccidian parasites in the faeces of cats.

| Coccidian species | Alternative name | Intermediate host | Oocyst condition* | Oocyst size (µm) | Sporocyst size (µm) |
|-------------------------------|--|-------------------|-------------------|------------------|-------------------------|
| <i>Sarcocystis bovisfelis</i> | <i>Sarcocystis hirsuta</i> | Cattle | S | 12–18 × 11–14 | 12.5 × 7.8 [†] |
| <i>Sarcocystis ovifelis</i> | <i>Sarcocystis tenella</i> | Sheep | S | | 12.4 × 8.1 [†] |
| <i>Sarcocystis hircifelis</i> | <i>Sarcocystis moulei</i> | Goat | S | | 12.4 × 9.1 [†] |
| <i>Sarcocystis porcifelis</i> | | Pig | S | | 13.5 × 8 [†] |
| <i>Sarcocystis cuniculi</i> | <i>Sarcocystis cuniculorum</i> | Rabbit | S | | 13 × 10 [†] |
| <i>Sarcocystis muris</i> | | Mouse | S | | 10.3 × 8.5 [†] |
| <i>Besnoitia besnoiti</i> | <i>Sarcocystis besnoiti</i> | Ruminants | U | 14–16 × 12–14 | |
| <i>Toxoplasma gondii</i> | | | U | 13 × 12 | 9 × 6.5 |
| <i>Hammondia hammondi</i> | <i>Toxoplasma hammondi</i> <i>Cystisospira hammondi</i> | Rodents | U | 13.2 × 10.6 | 9.8 × 6.5 |
| <i>Cystisospira felis</i> | <i>Cystisospira felis</i> | — | U | 41.6 × 30.5 | 22.6 × 18.4 |
| <i>Cystisospira rivolta</i> | <i>Cystisospira rivolta</i> | — | U | 25 × 21.1 | 15.2 × 11.6 |

* Sporulated (S) or unsporulated (U) oocysts in faeces.

† Sporocysts generally found free in faeces.

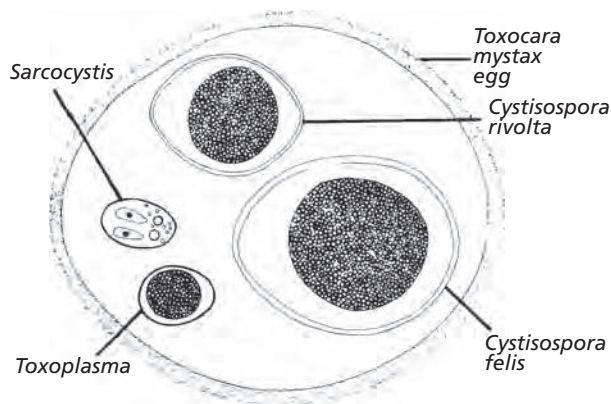

Fig. 12.11 Diagram of cat oocysts relative to ascarid eggs of *Toxocara mystax*.

Cystispora ohioensis

Synonym: *Isospora ohioensis*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal to oval, 20–27 by 14–24 μm (mean 23 \times 19 μm), with a smooth colourless to pale yellow wall without a micropyle, polar granule or residuum. The two sporocysts are ellipsoidal, 12–19 by 9–13 μm (mean 14.5 \times 10 μm), with a residuum and four sporozoites with one or more clear globules.

Host: Dog

Life cycle: All stages occur in the epithelium of the small intestine; gamonts can also be found in the caecum and large intestine from 4 to 5 days post infection. The prepatent period is 4–5 days and patency is 3–5 weeks.

Cystispora felis

Synonym: *Isospora felis*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, 32–53 by 26–43 μm (mean 43 \times 32 μm), with a smooth, yellowish to pale-brown wall without a micropyle, polar granule or residuum. Each sporulated oocyst contains two sporocysts each with four sporozoites (Fig. 12.12). The two sporocysts are ellipsoidal, 20–27 by 17–22 μm , with a smooth colourless wall and a prominent residuum. Each sporocyst contains four sausage-shaped sporozoites with clear sub-central globules.

Host: Cat

Life cycle: All stages are found above the host cell nuclei in the epithelium of the lower small intestine. Gamonts appear from 6 days

Fig. 12.12 Oocysts of *Cystispora felis*.

after infection. The prepatent period is 7–10 days. Infections can remain patent for about 1–3 weeks.

Cystispora rivolta

Synonym: *Isospora rivolta*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal to ovoid, 21–29 by 18–26 μm (mean 25 \times 21 μm), with a smooth colourless to pale-brown wall without a micropyle, polar granule or residuum. The two sporocysts are ellipsoidal, 14–16 by 10–13 μm , with a residuum and four sporozoites each with clear sub-central globules.

Host: Cat

Life cycle: Meront stages are found in the epithelial cells and crypt cells of the lower small intestine, caecum and colon. Gamonts appear 3–4 days post infection. The prepatent period is 4–7 days and patency can persist for up to 9 weeks.

Epidemiology: Rodents may ingest sporulated oocysts and become infected with asexual stages, thereby acting as reservoirs of infection. A number of rodent species can act as transport hosts. The life cycle is normally direct, although there is some evidence that a predator–prey relationship may be involved and that dogs and cats can acquire infection from the tissues of rodents.

Geographical distribution: Worldwide

Pathogenesis: The pathogenicity of *C. rivolta* is generally thought to be low, although severe diarrhoea in young kittens has been associated with high oocyst counts.

Sarcocystosis

The previously complex nomenclature for the large number of *Sarcocystis* spp. has largely been discarded by many workers in

favour of a new system based on their biology. The new names generally incorporate those of the **intermediate** and **final hosts** in that order.

At present the most important species recognised with the dog as a final host are:

- *Sarcocystis bovicanis* (*Sarcocystis cruzi*)
- *Sarcocystis ovicanis* (*Sarcocystis tenella*)
- *Sarcocystis capracanis*
- *Sarcocystis hircicanis*
- *Sarcocystis suicanis* (*Sarcocystis porcicanis*, *Sarcocystis miescheriana*)
- *Sarcocystis equicanis* (*Sarcocystis bertrami*)
- *Sarcocystis fayeri*
- *Sarcocystis hovarathi*
- *Sarcocystis cameli*

The most important species recognised with the cat as a final host are:

- *Sarcocystis bovifelis* (*Sarcocystis hirsuta*)
- *Sarcocystis ovifelis* (*Sarcocystis tenella*, *Sarcocystis medusififormis*)
- *Sarcocystis porcifelis* (*Sarcocystis suisfelis*)

Pathogenesis: Infection in the dog and cat is normally non-pathogenic although mild diarrhoea has occasionally been reported with some infections.

Clinical signs: Occasional diarrhoea

Diagnosis: Identification of oocysts in dog or cat faeces and differentiation from other coccidial species of dogs and cats (see Tables 12.6 and 12.7).

Pathology: Infection in the final host is not normally associated with pathological changes. Oocysts may be seen in the lamina propria and within the epithelium at the tips of the villi.

Epidemiology: Little is known of the epidemiology, but from the high prevalence of symptomless infections observed in abattoirs, it is clear that where dogs and cats are kept in close association with farm animals or their feed, then transmission is likely. Sheepdogs and farm cats are known to play an important part in the transmission of *Sarcocystis* and care should be exercised that only cooked meat is fed to dogs and cats. Acute outbreaks of *Sarcocystis* in livestock are probably most likely when livestock which have been reared without contact with farm dogs in particular are subsequently exposed to large numbers of the sporocysts from dog faeces. The longevity of the sporocysts shed in the faeces is not known.

Treatment and control: There is no effective treatment for infection in dogs or cats. The only control measures possible are those of simple hygiene. Farm dogs and cats should not be housed in, or allowed access to, fodder stores, nor should they be allowed to defecate in pens where livestock are housed. It is also important that they are not fed uncooked meat.

Sarcocystis bovicanis

Synonyms: *Sarcocystis cruzi*, *Sarcocystis fusiformis*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Fig. 12.13 Oocysts of *Sarcocystis bovicanis*.

Description: Sporulated oocysts are fully sporulated and dumb-bell shaped when passed in the faeces, 19–21 by 15–18 μm , with a thin oocyst wall sunken between two sporocysts, without a micropyle, polar granule or oocyst residuum (Fig. 12.13). However, it is usually the sporulated sporocyst that is found free in the faeces. Sporocysts are ellipsoidal, 14.3–17.4 by 8.7–13.3 μm (mean 16.3 \times 10.8 μm), smooth, colourless without a Stieda body but with a residuum and each has four sporozoites.

Final hosts: Dog, fox, wolf, coyote

Intermediate hosts: Cattle

Geographical distribution: Worldwide

Sarcocystis ovicanis

Synonyms: *Sarcocystis tenella*, *Isospora bigemina*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: Oocysts are sporulated when passed in the faeces and contain two sporocysts each with four sporozoites; usually the sporulated sporocyst is found free in the faeces. In *S. ovicanis*, the sporulated sporocysts measure approximately 13.1–16.1 by 8.5–10.8 μm (mean 14.8 \times 9.9 μm).

Final host: Dog

Intermediate host: Sheep

Geographical distribution: Worldwide

Sarcocystis capracanis

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: The oocysts have not been described. The sporulated sporocysts are ellipsoidal and measure approximately 12–15 by 8–10 μm .

Final host: Dog

Intermediate host: Goat

Geographical distribution: Worldwide

Sarcocystis hircanicis

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: The oocysts have not been described. The sporulated sporocysts are ellipsoidal and measure approximately 15–17.3 by 10.5–11.3 μm .

Final host: Dog

Intermediate host: Goat

Geographical distribution: Worldwide

Sarcocystis suicanis

Synonyms: *Sarcocystis porcicanis*, *Sarcocystis miescheriana*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: Sporulated sporocysts found free in the faeces measure approximately 12.7 by 10.1 μm .

Final host: Dog

Intermediate host: Pig

Geographical distribution: Worldwide

Sarcocystis equicanis

Synonym: *Sarcocystis bertrami*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: The sporulated sporocysts measure 15–16.3 by 8.8–11.3 μm (mean 15.2–10 μm).

Final host: Dog

Intermediate host: Horse

Geographical distribution: Worldwide

Sarcocystis fayeri

Synonym: *Sarcocystis bertrami*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: In *S. fayeri*, the sporulated sporocysts measure 11–13 by 7–8.5 μm (mean 12.0 \times 7.9 μm).

Final host: Dog

Intermediate host: Horse

Geographical distribution: Worldwide

Sarcocystis hovarthi

Synonym: *Sarcocystis gallinarum*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: The oocysts have not been described. The sporulated sporocysts are ellipsoidal and measure approximately 10–13 by 7–9 μm .

Final host: Dog

Intermediate host: Chicken

Geographical distribution: Presumed worldwide

Sarcocystis cameli

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: The oocysts have not been described. The sporulated sporocysts are ellipsoidal and measure approximately 12 by 9 μm .

Final host: Dog

Intermediate hosts: Camel (Bactrian and dromedary)

Geographical distribution: North Africa (Egypt, Morocco, Sudan)

Sarcocystis bovifelis

Synonyms: *Sarcocystis hirsuta*, *Sarcocystis fusiformis*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: Oocysts are smooth, colourless, 12–18 by 11–14 μm , and contain two sporocysts each with four sporozoites and are dumb-bell like in appearance, with no micropyle, polar granule or oocyst residuum. Sporocysts are ellipsoidal, 11–14 by 7–9 μm (mean 12.5 \times 7.8 μm), without a Stieda body but with a residuum.

Final host: Cat

Intermediate host: Cattle

Geographical distribution: Worldwide

Sarcocystis ovifelis

Synonyms: *Sarcocystis tenella*, *Sarcocystis gigantea*, *Sarcocystis medusiformis*, *Isospora bigemina*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description In *S. ovifelis*, the sporulated sporocysts are ellipsoidal and measure 10.8–13.9 by 7.7–9.3 μm (mean 12.4 \times 8.1 μm).

Final host: Cat

Intermediate host: Sheep

Geographical distribution: Worldwide

Sarcocystis porcifelis

Synonym: *Sarcocystis suifelis*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: The sporulated sporocysts are ellipsoidal and measure 13.2–13.5 by 7.2–8 μm , without a Stieda body but with a residuum.

Final host: Cat

Intermediate host: Pig

Geographical distribution: Worldwide

Hammondia heydorni

Synonyms: *Cystispora hammondi*, *Toxoplasma hammondi*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: Oocysts are 13 by 11 μm without a micropyle or residuum and appear dumb-bell shaped after sporulation. The sporocysts have no Stieda body but have a residuum.

Final host: Dog

Intermediate hosts: Cattle, sheep, goat, rodents, guinea pig

Geographical distribution: Presumed worldwide

Pathogenesis: Non-pathogenic

Clinical signs: Diarrhoea in young puppies

Diagnosis: Identification of oocysts in dog faeces and differentiation from other coccidial species of dogs (see Table 12.6).

Pathology: Not reported

Epidemiology: The dog is infected following the consumption of zoite-containing tissues of the intermediate host. Direct dog-to-dog transmission does not occur.

Treatment: Not indicated

Control: The only control measures possible are those of simple hygiene. Dogs should also not be fed raw or uncooked meat.

Hammondia hammondi

Synonyms: *Isospora hammondi*, *Toxoplasma hammondi*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: Unsporulated oocysts are colourless, spherical to subspherical, 11–13 by 10–13 μm , without a micropyle or residuum, and subspherical to ellipsoidal, 13–14 by 10–11 μm (mean 13 \times 11 μm) after sporulation. The sporocysts are ellipsoidal, 8–11 by 6–8 μm (mean 10 \times 6.5 μm), and have no Stieda body but have a residuum. The sporozoites are elongate and curved with a nucleus near the centre.

Final host: Cat

Intermediate hosts: Rodents (mouse, rat, guinea pig)

Geographical distribution: Presumed worldwide

Pathogenesis: Non-pathogenic to either host, but it is important to recognise that the oocysts of *Hammondia* closely resemble those of *Toxoplasma* and that their differentiation in cat faeces is a specialist task.

Clinical signs: No associated clinical signs

Diagnosis: Identification of oocysts in cat faeces and differentiation from other coccidial species of cats (see Table 12.7).

Pathology: Not reported

Epidemiology: The cat is infected following the consumption of zoite-containing tissues of the intermediate host. Direct cat-to-cat transmission does not occur.

Treatment: Not indicated

Control: The only control measures possible are those of simple hygiene. Cats should not be fed raw or uncooked meat.

Besnoitia besnoiti

Synonyms: *Sarcocystis besnoiti*, *Globidium besnoiti*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: Oocysts are ovoid, 14–18 by 12–14 μm , unsporulated and without a micropyle when passed in the faeces of cats. After sporulation they contain two sporocysts each with four sporozoites. The prepatent period in cats is 4–25 days and the patent period 3–15 days.

Final hosts: Cat, wild cats (lion, cheetah, leopard)

Intermediate hosts: Cattle, goat, wild ruminants (wildebeest, impala, kudu)

Life cycle: The ruminant intermediate hosts are infected by the ingestion of oocysts shed into the environment by infected cats. Cats are infected following ingestion of cysts present in the subcutaneous tissues of infected intermediate hosts.

Geographical distribution: Worldwide, although important in tropical and subtropical countries, especially in Africa

Pathogenesis and clinical signs: *Besnoitia besnoiti* is non-pathogenic in the cat final host.

Diagnosis: Identification of oocysts in cat faeces and differentiation from other coccidial species of cats (see Table 12.7).

Epidemiology: The natural mode of transmission is by ingestion of pseudocysts present in the skin of animal carcasses.

Treatment: There is no effective treatment for infection in cats.

Control: As for *Sarcocystis* species.

Cryptosporidiosis

Recent molecular characterisations have shown that there is extensive host adaptation in *Cryptosporidium* evolution, and many mammals or groups of mammals have host-adapted *Cryptosporidium* genotypes that differ from each other in both DNA sequences and infectivity. These genotypes are now delineated as distinct species and include *C. hominis* (previously termed human genotype or genotype 1); *C. parvum* (also termed bovine genotype or genotype 2); and *C. canis* (dog genotype). Other genotypes have been associated with mouse, pig, bear, deer, marsupial, monkey, muskrat, skunk, cattle and ferret. Most of these organisms probably represent individual *Cryptosporidium* species.

Pathogenesis: Chronic diarrhoea may occur in dogs that are immunosuppressed because of concurrent illness or toxicity. Puppies with distemper virus, for example, have developed persistent diarrhoea and persistently excreted *Cryptosporidium* oocysts. Infection with *C. felis* in cats is not considered pathogenic.

Clinical signs: Infection with *Cryptosporidium* is generally asymptomatic but may cause acute diarrhoea in neonatal animals or more chronic diarrhoea in young immunosuppressed animals or in animals with intercurrent and debilitating diseases such as distemper in dogs or feline leukaemia virus (FeLV)/feline immunodeficiency virus (FIV) in cats.

Diagnosis: Oocysts may be demonstrated using Ziehl–Neelsen stained faecal smears in which the sporozoites appear as bright-red granules. Speciation of *Cryptosporidium* is difficult, if not impossible, using conventional techniques. A range of molecular and immunological techniques has been developed that includes the use of immunofluorescence or ELISA. More recently, DNA-based techniques have been used for the molecular characterisation of *Cryptosporidium* species.

Pathology: The meronts and gamonts develop in a parasitophorous envelope apparently derived from the microvilli and so the cell disruption seen with other coccidia does not apparently occur. However, mucosal changes are obvious in the ileum where there is stunting, swelling and eventually fusion of the villi. This has a marked effect on the activity of some of the membrane-bound enzymes.

Epidemiology: A variety of mammals act as hosts to *C. parvum* but *C. canis* appears to be adapted to dogs and *C. felis* to cats. Transmission appears to be mainly by the faecal–oral route.

Treatment: There is no known treatment. Supportive treatment and therapy of any concurrent illness may be required.

Control: Good hygiene and management are important in preventing disease from cryptosporidiosis.

Cryptosporidium parvum

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Hosts: Cattle, sheep, goat, horse, deer, dog, cat, human

Description: Mature oocysts are ovoidal or spheroidal, 5.0 by 4.5 μm (range 4.6–5.4 by 3.8–4.7 μm) and have a length/width ratio of 1.19.

Geographical distribution: Worldwide

Cryptosporidium canis

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Hosts: Dog, fox, human

Description: Mature oocysts are colourless, ovoidal or spheroidal, 4.95 by 4.71 μm and have a length/width ratio of 1.05.

Geographical distribution: Thought to be worldwide

Cryptosporidium felis

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Hosts: Cat, cattle, human

Description: Oocysts are morphologically indistinguishable from those of *C. parvum*.

Geographical distribution: Thought to be worldwide

Other protozoa

Giardia is important because of water-borne outbreaks that have occurred in human populations. There is still some controversy over the classification of *Giardia* spp. The main species is *Giardia intestinalis*, although phylogenetic data suggest that *G. intestinalis* is a species complex composed of several species that are host-specific. The current molecular classification places isolates into eight distinct assemblages. Some authors give separate specific names to *Giardia* organisms isolated from dogs and cats, for example *Giardia duodenalis* (Assemblage A), *Giardia enterica* (Assemblage B), *Giardia canis* (Assemblage C, D) and *Giardia cati* (Assemblage F), although species specificity of many isolates is unknown.

Giardia intestinalis

Synonyms: *Giardia duodenalis*, *Giardia lamblia*, *Lamblia lamblia*

Predilection site: Small intestine

Phylum: Fornicata

Class: Treponadea

Family: Giardiidae

Description: The trophozoite has a pyriform to ellipsoidal, bilaterally symmetrical body, 12–15 by 5–9 µm. The dorsal side is convex and there is a large sucking disc on the ventral side. There are two anterior nuclei, two slender axostyles, eight flagellae in four pairs and a pair of darkly staining median bodies (see Fig. 2.21). The median bodies are curved bars resembling the claws of a hammer. Cysts are ovoid, 8–12 by 7–10 µm and contain four nuclei (Fig. 12.14).

Fig. 12.14 *Giardia* cysts.

Hosts: Human, cattle, sheep, goat, pig, alpaca, dog, cat, guinea pig, chinchilla

Geographical distribution: Worldwide

Pathogenesis: While *Giardia* cysts are commonly excreted in the faeces of dogs and cats, there is no consistent relationship with diarrhoea or other signs of gastrointestinal problems, although they could act as reservoirs of infection for humans.

Clinical signs: When disease does occur, the signs often include chronic pasty diarrhoea, weight loss, lethargy and failure to thrive.

Diagnosis: *Giardia* cysts can be detected in faeces by a number of methods. Traditional methods of identification involve direct examination of faecal smears, or faecal concentration by formalin-ethyl acetate or zinc sulphate methods and subsequent microscopic examination. It is generally recommended that three consecutive samples be examined as cysts are excreted intermittently.

Pathology: There may be villous atrophy, crypt hypertrophy and an increased number of intraepithelial lymphocytes. Trophozoites may be seen between villi, attached by their concave surface to the brush border of epithelial cells.

Epidemiology: Molecular studies have revealed a substantial level of genetic diversity in *G. intestinalis* isolates. Human isolates fall into two major groups (Assemblage A and B) with a wide host range in other mammals and it may prove to be the case that some separate species names may be applicable. Other assemblages may also represent distinct species. Limited epidemiological studies suggest that in animal isolates direct animal-to-animal contact and faecal soiling are the most likely methods of transmission, although water contamination can also be considered as a possible route. Zoonotic transmission has been reported from dogs.

Treatment and control: Several benzimidazole anthelmintics (e.g. albendazole, fenbendazole) and nitroimidazoles (metronidazole, tinidazole) are effective and may prove to be of benefit in the treatment of *Giardia* infections in animals. As infection is transmitted by the faecal–oral route, good hygiene and prevention of faecal contamination of feed and water are essential. A vaccine based on disrupted axenically cultured trophozoites is available commercially (*GiardiaVax*®) for use in dogs and cats.

LARGE INTESTINE

Trichuris vulpis

Synonym: *Trichocephalus vulpis*

Common name: Whipworms

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: The adults are whitish and about 4.5–7.5 cm long with a thick broad posterior end tapering rapidly to a long filamentous anterior end that is characteristically embedded in the mucosa (Fig. 12.15).

Fig. 12.15 *Trichuris vulpis* adults recovered from an infected intestine.

Description, microscopic: The male tail is coiled and possesses a single spicule in a protrusible sheath. The sheath bears small spines only on its anterior portion. The characteristic eggs are lemon-shaped, with a thick smooth shell, slightly barrel-shaped side walls and conspicuous protruding transparent polar plugs at both ends. They measure 80–90 by 36–42 μm and in the faeces these eggs appear yellow or brown in colour with granular unsegmented contents (see Fig. 4.6).

Hosts: Dog, fox, cat

Geographical distribution: Many parts of the world

Pathogenesis: Most infections are light and asymptomatic. Occasionally, when large numbers of worms are present, they cause a haemorrhagic colitis and/or a diphtheritic inflammation of the caecal mucosa. This results from the subepithelial location and continuous movement of the anterior end of the whipworm as it searches for blood and fluid.

Clinical signs: Sporadic disease due to heavy infection is more common in dogs and is associated with an acute or chronic inflammation of the caecal mucosa with watery diarrhoea that often contains blood. Anaemia may be present and animals can lose weight.

Diagnosis: Since the clinical signs are not pathognomonic, diagnosis may depend on finding numbers of lemon-shaped *Trichuris* eggs in the faeces. Egg output is often low in *Trichuris* infections. However, since clinical signs may occur during the prepatent period, diagnosis may depend on necropsy or a favourable response to anthelmintic treatment. Occasionally, expelled adult worms may be present in faeces.

Pathology: In severe cases, the mucosa of the large intestine is inflamed and haemorrhagic with ulceration and formation of diphtheritic membranes.

Epidemiology: The most important feature is the longevity of the eggs. Older dogs tend to have higher whipworm burdens than young dogs.

Treatment: The pro-benzimidazoles and benzimidazoles, administered over several days, are effective against adult *Trichuris*, but less so against the larval stage. Milbemycins are effective.

Control: Prophylaxis is rarely necessary. Attention should be given to areas where eggs might continue to survive for long periods. Such areas should be thoroughly cleaned and disinfected or sterilised by wet or dry heat.

Notes: The adults are usually found in the caecum but are only occasionally present in sufficient numbers to be clinically significant.

Two other species, *Trichuris serrata* and *Trichuris campanula*, are occasionally found in the cat, mainly in North and South America and the Caribbean. Details on the life cycle, pathogenesis, treatment and control are essentially similar to those for *T. vulpis*.

Entamoeba histolytica

Synonyms: *Entamoeba dysenteriae*, *Endamoeba histolytica*

Predilection site: Large intestine, liver

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Two forms of the parasite exist. Trophozoites of the large form are 20–30 μm in diameter; those of the small form are 12–15 μm . The nucleus, when stained, has a small central endosome with a ring of small peripheral granules. The cysts of both forms are 10–12 μm in size, contain four nuclei when mature and often contain rod-like chromatin bodies with rounded ends.

Hosts: Human, apes, monkeys, dog, cat, pig, rat

Geographical distribution: Worldwide

Pathogenesis: Two forms of the parasite exist. Non-pathogenic forms of the organism normally live in the lumen of the large intestine. Pathogenic forms invade the mucosa causing ulceration and dysentery. From there they may be carried via the portal system to the liver and other organs where large abscesses may form. The amoeba-like trophozoites secrete proteolytic enzymes and produce characteristic flask-shaped ulcers in the mucosa of the large intestine. Their erosion may allow the parasites to enter the bloodstream when the most common sequela is the formation of amoebic abscesses in the liver. The veterinary significance of amoebiasis is that natural infections, usually without clinical signs, can occur occasionally in dogs from the human reservoir of active or carrier infections. Kittens are also susceptible to experimental infection, although they do not produce cysts. Monkeys have their own strains of *E. histolytica* and these can be infective to humans.

Clinical signs: Infection causes diarrhoea or dysentery.

Diagnosis: Motile organisms and cysts of *E. histolytica* may be detected in smears from faeces. Trophozoites and cysts can be stained with iodine, trichrome or iron haematoxylin. The organisms can also be cultured in a number of media including Boeck and Drbohlav's, Dobell and Laidlaw's, TYI-S-33 and Robinson's medium. Isoenzyme markers can be used to differentiate the two forms seen, but there is some debate as to whether the two types represent different species or if they can change from one type to another under certain circumstances.

A number of serological tests have been evaluated for the diagnosis of *E. histolytica* infections. These include ELISA, latex agglutination,

complement fixation and indirect haemagglutination. A number of PCR methods have also been used to detect *E. histolytica* in clinical samples. These are based on the amplification of specific DNA sequences that correlate to the pathogenic/non-pathogenic isoenzyme categorisation and appear to be very sensitive and specific.

Pathology: Pathogenic strains of amoebae penetrate the mucosa of the large intestine and multiply to form small colonies that extend into the submucosa and muscularis. In the absence of bacterial infection there is little reaction, but in complicated infections there is hyperaemia and inflammation with predominantly neutrophils. Amoebae may pass into the lymphatic system and mediastinal lymph nodes and from there migrate in the portal system to the liver where they may cause abscessation. Abscesses may also form in other organs including the lungs and brain.

Epidemiology: *Entamoeba histolytica* is primarily a parasite of primates; humans are the reservoir for animals. Infection in dogs has only been reported sporadically and often through human contacts.

Treatment: Treatment, if required, relies on the combined use of metronidazole and diiodohydroxyquin.

Control: Dogs are not a significant reservoir of infection for humans so that prophylaxis ultimately depends on personal and sanitary hygiene in the human population.

Pentatrichomonas hominis

Synonyms: *Pentatrichomonas felis*, *Cercomonas hominis*, *Monocercomonas hominis*, *Trichomonas felis*, *Trichomonas intestinalis*

Predilection site: Large intestine

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is pyriform, 8–20 µm long and there are usually five anterior flagella. Four of the anterior flagella are grouped together, and the fifth is separate and directed posteriorly. A sixth flagellum runs along the undulating membrane and extends beyond the body as a free trailing flagellum. The undulating membrane extends the length of the body. The axostyle is thick and hyaline with a sharply pointed tip. The pelta is crescent shaped.

Hosts: Human, monkey, dog, cat, rat, mouse, hamster, guinea pig

Geographical distribution: Worldwide

Pathogenesis: *Pentatrichomonas hominis* is considered non-pathogenic.

Diagnosis: Morphological identification of the organisms from fresh and stained faecal preparations. The organism can also be cultured in trichomonads culture medium.

Treatment and control: Not required

Tritrichomonas foetus

Predilection site: Ileum, caecum, colon

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The organisms found in cats are morphologically indistinguishable from those seen in cattle (see Fig. 8.41). Trophozoites are pear-shaped, approximately 10–25 µm long and 3–15 µm wide, and have a single nucleus and four flagella.

Hosts: Cat, cattle

Geographical distribution: Unknown but possibly worldwide. Infection in cats has been reported in USA and parts of Europe (Germany, Austria, France and UK).

Diagnosis: There are three routine diagnostic methods: direct microscopy, culture of the organism and PCR analysis of faeces. In some countries, a liquid culture system is available (InPouch TF-Feline). The pouch can be inoculated with a small amount of faeces obtained within 1–2 hours of collection, and ideally incubated at 37°C for between 18 and 24 hours and then at room temperature. The pouch can be examined microscopically (via an in-built viewing chamber) for the motile organisms every 2 days for 12 days. This test is considerably more sensitive than direct examination of faeces, and helpful in detecting infections when direct smears are negative.

Pathogenesis: The organisms are mainly localised to the epithelial surface, occasionally in the crypts of the colon, and cause an accompanying lymphocytic and neutrophilic inflammatory response. In some cases, the organisms have been seen to invade the lamina propria of the colon resulting in a more severe inflammatory response. The organism has also been found in the uterus of a cat with pyometra, suggesting a possible link to reproductive tract disease in cats.

Clinical signs: Infection causes colitis with increased frequency of defecation; faeces are semi-formed to liquid, sometimes with fresh blood or mucus. With severe diarrhoea, the anus may become inflamed and painful, and the cat may become faecally incontinent. Although cats of all ages can be affected, *T. foetus*-associated diarrhoea is most commonly seen in young cats and kittens.

Epidemiology: In cats, transmission is likely via the faecal–oral route. Infection is most commonly seen in colonies of cats and multi-cat households. In these situations, the organism is presumably spread between cats by close contact.

Treatment: The use of a number of antibiotics has been reported to improve clinical symptoms possibly through reduction in resident bacterial microflora on which the organisms feed. Ronidazole has been shown to have a direct effect on the organisms leading to a reduction in diarrhoea, although its use is cautioned because of possible neurotoxic side effects in cats in higher doses.

Control: Dietary changes may improve faecal consistency and diarrhoea. Diarrhoea will usually resolve spontaneously in untreated cats although this may take several months.

Notes: *Tritrichomonas foetus* has been found worldwide, and is an important cause of infertility, abortion and endometritis in cattle, although the organism has been eradicated from many cattle populations through the use of artificial insemination. A morphologically identical organism (*T. suis*) has been identified in pigs, in which it commonly causes asymptomatic infection of the nasal cavity, stomach and intestine. This organism is now considered synonymous with *T. foetus*. Reports of trichomonad-associated large bowel

diarrhoea started to emerge in cats in the USA in 2000, which were subsequently confirmed to be *T. foetus*.

Parasites of the respiratory system

Two species of the genus *Mammomonogamus*, which is closely related to *Syngamus*, are parasitic in the nasal cavities of cats. Infections are usually asymptomatic but affected animals may sneeze and have a nasal discharge due to irritation of the nasal mucosa. Adult worms are red in colour, 1–2 cm long and permanently joined *in copula*. Diagnosis is based on clinical signs and the finding of eggs in the faeces or adult worms on postmortem. Details of the life cycle are unknown and there is no known effective treatment.

Mammomonogamus ierei

Synonym: *Syngamus ierei*

Predilection site: Nasal cavities

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description: Male worms measure 3–6.3 mm and the larger females 8.7–23.5 mm in length. Males possess spicules ranging from 23 to 30 µm in length and cup-shaped buccal capsules that open at the anterior end. Located deep in the buccal cavity are 8–10 teeth that are not thought to be used for attachment.

Host: Cat

Geographical distribution: Caribbean

Mammomonogamus mcgaughei

Synonym: *Syngamus mcgaughei*

Predilection site: Frontal sinuses, pharynx

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Host: Cat

Geographical distribution: Sri Lanka

Eucoleus aerophila

Synonym: *Capillaria aerophila*

Common name: Tracheal worm

Predilection site: Trachea, bronchi, occasionally nasal passages and frontal sinuses

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: These are very fine, whitish, filamentous worms, the narrow stichosome oesophagus occupying about one-third to half the body length. Males measure around 24 mm and females 32 mm.

Description, microscopic: The males have a long thin single spicule and often possess a primitive bursa-like structure. The females contain eggs that resemble those of *Trichuris* in possessing bipolar plugs. The elongate, oval, medium-sized eggs are barrel-shaped, and possess a thick granular slightly striated shell. The poles of each egg have a protruding transparent plug. Eggs measure about 59–80 by 30–40 µm and have a greenish to yellowish-brown colour and contain granular unsegmented contents (see Fig. 4.6). These eggs can be differentiated from those of *Trichuris vulpis*, which are larger and possess a smooth shell, and from those of *Capillaria plica*, which are almost colourless and are passed in the urine.

Final hosts: Fox, particularly those reared on fur farms, and mustelids; occasionally dog, cat and human

Intermediate hosts: Earthworms

Geographical distribution: Worldwide

Pathogenesis: The nematode causes irritation to the respiratory mucosa with a resultant increase in secretion. There may be some constriction of the lumen of the air passages and some areas may show emphysema. Heavy infections can induce bronchopneumonia with occasional abscess formation in the lung tissue. Secondary bacterial infection can sometimes occur and this is often fatal in younger animals.

Clinical signs: Light infections are usually asymptomatic. The clinical signs of moderate to severe infection are those of rhinotracheitis and/or bronchitis and in this respect are similar to those caused by *Oslerus* or *Crenosoma* infection. In such cases, there may be a nasal discharge, a wheezing cough and/or sneezing. Dyspnoea can be observed in heavy infections.

Diagnosis: The presence of eggs in faeces or sputum and a nasal discharge are indicative of infection. Note that the eggs are morphologically similar to those of *Capillaria plica* (see Parasites of the reproductive/urogenital system).

Pathology: The effects depend on the number of worms present. Mild infections cause a mild catarrhal inflammation while heavy infections cause more severe irritation and obstruction to the lumen of the airways.

Epidemiology: Although infection can be acquired through the consumption of infective earthworms, the major route of transmission is usually via the ingestion of embryonated infective eggs. *Eucoleus aerophila* is particularly a problem in farmed animals reared for their fur. Disease is usually seen in foxes of less than 18 months of age.

Treatment: Modern benzimidazoles or ivermectin are effective. Levamisole 7.5 mg/kg on two consecutive days and repeated 14 days later is also effective.

Control: On fox-rearing farms, care should be taken to ensure that runs are created in areas where the soil is dry and free-draining. Alternatively, the animals should be housed in cages raised above the soil. Breeding pens need to be cleaned thoroughly to reduce the accumulation of infective eggs. Periodic treatment with anthelmintic is essential.

Eucoleus boehmi**Synonym:** *Capillaria boehmi***Common name:** Sinus worm**Predilection site:** Frontal sinuses**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Trichuroidea**Description, gross:** These are fine, whitish, filametous worms with adults measuring 15 to 40 mm long.**Description, microscopic:** The males have a long thin single spicule. The females contain eggs that macroscopically resemble those of *E. aerophila* in possessing bipolar plugs. Microscopically, the eggs can be differentiated: the surface of *E. boehmi* eggs are pitted whereas those of *E. aerophila* are covered with a network of branching ridges.**Final hosts:** Fox and, very rarely, dog**Notes:** The taxonomy and systematics of these parasites have been changed many times because of a difficulty in designation of particular species' features and there are many synonyms in this group. Some species of *Capillaria* are now listed under the generic name *Eucoleus*, although they may universally still be referred to as *Capillaria*.***Crenosoma vulpis*****Common name:** Fox lungworm**Predilection site:** Trachea, bronchi and bronchioles**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Metastrongyloidea**Description, gross:** Slender white worms, up to 1.5 cm long. Males are 4–8 mm with well-developed bursae with a large dorsal ray. Females are 12–16 mm. The two horns of the uterus extend in opposite directions (amphidelphic). The ovejector sphincter is prominent. The host and site are usually sufficient for generic diagnosis.**Description, microscopic:** Microscopic confirmation is based on the presence of annular crenated folds of the cuticle, which bear small backwardly directed spines on their margins. Larvae are about 265–330 µm in length and have a straight pointed tail.**Final hosts:** Dog, fox, wolf and raccoon**Intermediate hosts:** Slugs, snails (*Helix*, *Cepea*, *Arianta*, *Agriolimax*, *Arion*)**Geographical distribution:** Worldwide**Pathogenesis:** The spiny cuticular folds abrade the mucosa of the air passages with resulting bronchopneumonia and occlusion of the smaller bronchi and bronchioles.**Clinical signs:** The symptoms are those of a chronic respiratory infection, with coughing, sneezing and nasal discharge associated with tachypnoea. Farmed foxes may become emaciated, with fur of

poor quality. In the infrequent acute infections there may be high mortality.

Diagnosis: Examination of faeces by smear, flotation or Baermann technique will reveal the L₁ with a straight tail, which differentiates it in fresh canine faeces from those of *Oslerus*, *Filaroides* and *Angiostrongylus*. The L₁ somewhat resembles that of *Strongyloides* spp. Infection should be differentiated from that caused by *Eucoleus aerophila* as the two disease entities are similar.**Pathology:** The gross lesions usually observed in dogs are greyish consolidations in dorsal regions of the caudal lobes. Histologically, the lesions are catarrhal eosinophilic bronchitis and bronchiolitis.**Epidemiology:** *Crenosoma vulpis* is more common in the fox than in the dog, and can be a problem in farmed foxes. The infection has a seasonality corresponding to fluctuations in population of its snail vectors so that though cubs may begin to acquire L₃ in early summer, the highest incidence of clinical crenosomosis is seen in autumn.**Treatment:** Diethylcarbamazine has been reported to be effective but is no longer widely available. Levamisole has reported activity at 8 mg/kg and ivermectin is likely to be active. Fenbendazole (50 mg/kg for 3–5 days) has had some success in removing *C. vulpis* in dogs.**Control:** The snail vectors may be eliminated by spraying fox runs with molluscicide and painting woodwork with creosote up to 20 cm from the ground. Faeces should be disposed of in a manner that will avoid access by molluscs.***Oslerus osleri*****Synonym:** *Filaroides osleri***Common name:** Dog lungworm**Predilection site:** Bronchi and trachea**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Metastrongyloidea**Description, gross:** Small, pale, slender worms up to 15 mm long; males are 5 mm and females 9–15 mm long.**Description, microscopic:** The tail of the male is rounded and bears a few papillae; spicules are short and slightly unequal. The larva has a short S-shaped tail and measures 232–266 µm in length. The medium-sized eggs have thin shells, measure around 80 by 50 µm and contain a larva.**Hosts:** Dog and other wild canids such as dingo**Geographical distribution:** Worldwide**Pathogenesis:** The worms are embedded in fibrous nodules (2–20 mm) in the trachea at the region of the bifurcation, and in the adjacent bronchi (Fig. 12.16). Rarely found deeper in the lungs. The nodules in which the worms live first appear at about 2 months from infection. They are pinkish-grey granulomas, and the small worms may be seen partly protruding from their surfaces. These nodules are fibrous in character and are very firmly applied to the mucosa; they may be up to 2.0 cm in diameter. Although the majority of worms occur near the tracheal bifurcation, a few may

Fig. 12.16 Fibrous nodules in the bronchus caused by infection with *Oslerus osleri*.

be found several centimetres from this area. Infection can cause chronic tracheobronchitis.

Clinical signs: Many infections are clinically inapparent, and the characteristic nodules are only discovered incidentally at necropsy. The major signs of *Oslerus* infection are respiratory distress and a dry rasping persistent cough, especially after exercise. The most severe cases have usually been seen in dogs of 6–12 months old, and obviously the infection is of greater importance in working dogs. Heavy chronic infections can impair appetite and lead to emaciation. In household pets, whose exercise is limited, the presence of the tracheal nodules is well tolerated, and animals show little respiratory distress.

Diagnosis: Swabs of pharyngeal mucus give variable results and repeated sampling may be necessary. However, in paroxysmal coughing, large amounts of bronchial mucus are often expelled, containing large numbers of larvae. Less rewarding techniques are those based on faecal examination, either by flotation or by the Baermann method. Although requiring general anaesthesia, bronchoscopy is the most reliable method, as it will indicate not only the presence, size and location of many of the nodules, but will also allow the collection of tracheal mucus for confirmatory examination for eggs and larvae; the latter are invariably coiled, sluggish and have an S-shaped tail. Large nodules may be detected by lateral thoracic radiography.

Pathology: Typical lesions are protruding submucosal nodules, greyish-white in colour, in the region of the tracheal bifurcation. Lesions vary in size from barely visible to larger nodules or protruding plaques that project over 1 cm into the lumen of the trachea. Smaller nodules contain immature worms, and the larger ones a mass of tightly coiled adults. The worms lie in tissue spaces between the cartilage rings of the trachea and large bronchi. Live worms provoke formation of a thin capsule and lymphocytic infiltration locally. Superficially the nodules are covered by intact epithelium, except for small pores through which the female worms protrude their tails to lay eggs. Dead worms provoke a foreign body reaction with neutrophils and a few giant cells.

Epidemiology: Transmission occurs when an infected bitch licks the pups and transfers the newly hatched L₁ present in the sputum. Though *Oslerus* has been recorded from many countries, there are few data on its local prevalence. In the UK, one survey has given a figure of 6% for all types of dog. In further surveys in the same area, greyhounds have shown a prevalence rate of 18%, but there is no evidence of breed susceptibility. In general the focus of infection appears to be the nursing bitch. Infection rates may be high in kennel-housed dogs.

Treatment: There are reports of amelioration of clinical signs, apparently due to a reduction in the size of the nodules, after prolonged treatment with some benzimidazoles. Fenbendazole and albendazole at increased dosage rates are licensed for the treatment of *Oslerus* infection in dogs. The signs of infection have been reportedly cleared with ivermectin or doramectin.

Control: This is difficult unless infected bitches can be identified and treated before whelping and during lactation. In the past the only certain method of control was the removal of pups from infected dams at birth, and hand rearing or fostering on uninfected bitches.

Notes: This genus was, until recently, part of the larger genus *Filaroides*, but has now been separated on morphological grounds from the other members. Though distinction has been made on morphology, it is also useful from the veterinary standpoint, for it separates the single harmful species, *Oslerus osleri* living in the upper air passages, from the relatively harmless species which are retained in the genus *Filaroides* and which live in the lung parenchyma.

Oslerus rostratus

Synonyms: *Anafilaroides rostratus*, *Filaroides rostratus*

Predilection site: Lung

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description: The adult males are about 28–37 mm long and the adult females 48–64 mm long. The vulva in the female is located just anterior to the anus.

Hosts: Cat, rodents

Geographical distribution: North America, Sri Lanka, Pacific Islands, southern Europe and the Middle East

Filaroides hirthi

Common name: Dog lungworm

Predilection site: Lung

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description, gross: The worms are very small (0.5–1.0 cm long), slender, hair-like and greyish, and are not only difficult to see with

the naked eye in the lung parenchyma but are unlikely to be recovered intact from the tissue. *Filaroides hirthi* is smaller than *F. milksi* (see next section).

Description, microscopic: The L₁, present in the faeces and sputum, is coiled and the tail has a notch, followed by a constriction, and has a terminal lance-like point. Larvae measure about 240–290 µm.

Hosts: Domestic dog, wild carnivores

Geographical distribution: North America, Europe and Japan

Pathogenesis: Infection is almost invariably asymptomatic, and is discovered only at postmortem examination. However, in the rare heavy infection, hyperpnoea may occur.

Clinical signs: Asymptomatic; rarely hyperpnoea in heavy infections.

Diagnosis: A squeeze preparation from a cut surface of the lung will show worm fragments, eggs and larvae and this, with the host and site, is sufficient for generic diagnosis. Only *F. hirthi* has been diagnosed in the live animal and this was in experimental dogs. The L₁, present in the faeces and sputum, is coiled and the tail has a notch, followed by a constriction, and has a terminal lance-like point. Zinc sulphate is an effective flotation solution for the detection of larvae.

Pathology: The chief lesions are the small, soft, greyish miliary nodules that are associated with the presence of worms and which are distributed subpleurally and throughout the lung parenchyma; in heavy infections, sometimes observed in experimental dogs subjected to immunosuppressive drugs, the nodules may coalesce into greyish masses.

Epidemiology: Little is known of the epidemiology. *Filaroides hirthi* was first observed in a breeding colony of experimental beagles, and it would be fair to suggest, in view of its mode of transmission, that a high prevalence could be expected in dogs from breeding kennels.

Treatment: Albendazole (orally at a dose rate of 25 mg/kg twice daily over 5 days) has been reported to be highly effective although treatment is rarely called for. Ivermectin has also shown efficacy.

Control: Unlikely to be required.

Filaroides milksi

Common name: Dog lungworm

Predilection site: Lung

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description: As for *F. hirthi*. *Filaroides milksi* is larger than *F. hirthi*.

Hosts: Domestic dog, wild carnivores

Geographical distribution: North America and parts of Europe

Aelurostrongylus abstrusus

Common name: Cat lungworm

Predilection site: Lung parenchyma and small bronchioles

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description, gross: Aggregations of worms, eggs and larvae are present throughout the lung tissue. The worms, about 0.5–1.0 cm long, are very slender and delicate, and are difficult to recover intact for examination.

Description, microscopic: The male bursa is short and the lobes are indistinct. The spicules are stout. Eggs have a thin shell, measure around 70–80 by 50–75 µm and they embryonate in the lung. L₁ in faeces are short and thick with a conical anterior and bear a subterminal spine on the S-shaped tail (see Fig. 1.50); they are about 360–400 µm long with granular contents.

Final host: Cat

Intermediate hosts: Many terrestrial molluscs, such as snails and slugs; paratenic hosts include rodents, birds, amphibians and reptiles.

Geographical distribution: Presumed worldwide

Pathogenesis: The worm generally has a low pathogenicity, and the majority of infections are discovered only incidentally at postmortem examination as multiple small greyish foci or bigger consolidated granulomas in the lungs.

Clinical signs: The clinical effects are slight, and in the resting cat are limited to a chronic mild cough. Following exercise or handling, there may be coughing, sneezing and nasal discharge with slight dyspnoea and production of mucoid sputum. In heavy experimental infections the most severe signs have appeared at 6–12 weeks after infection, when egg-laying is maximal. Heavy infections may be accompanied by dyspnoea, diarrhoea, anorexia and weight loss.

Diagnosis: Repeated faecal examination by smear, flotation or Baermann technique may be necessary to find the characteristic L₁, which bears a subterminal spine on its S-shaped tail. Examination of pharyngeal swabs may be a useful additional procedure. At necropsy a squeeze preparation from a cut surface of the lung will often show the worm material including the characteristic L₁. Radiography has revealed the increased vascular and focal parenchymal densities which would be expected from the changes described above.

Pathology: In most cases the lungs show only multiple small raised subpleural foci with greyish centres containing the worms and tissue debris, but in the rare severe infections larger nodules are present, up to 1.0 cm in diameter with caseous centres, projecting from the lung surface; these nodules may coalesce to form areas of consolidation. Microscopically the alveoli may be blocked with worms, eggs, larvae and cellular aggregations, which may progress to granuloma formation. A characteristic change is muscular hypertrophy and hyperplasia, which affects not only the bronchioles and alveolar ducts but also the media of the pulmonary arteries. In these heavy infections the pleural cavity can be filled with a whitish fluid and occasionally fatalities have been reported. With the exception of the muscular changes, which appear to be irreversible, resolution is rapid and the lungs appear almost completely normal within 6 months of experimental infection, though a few worms may still be present.

Epidemiology: *Aelurostrongylus* infection is widespread, partly because it is almost indiscriminate in its ability to develop in slugs and

snails, and partly because of its wide range of paratenic hosts. So far all surveys have shown prevalences greater than 5%.

Treatment: Fenbendazole 50 mg/kg daily for 3 days has proved effective.

Control: In household pets, and especially those of a nomadic disposition or living in rural locations, access to the intermediate and paratenic hosts is difficult to prevent and control is not often easy or practical.

Notes: Other nematodes can invade the lungs of cats and other felines, such as the bobcat, ocelot and mountain lion, but generally they are considered to be of low pathogenicity unless present in high numbers. *Metathalazia californica* occurs in the lung parenchyma and may be encapsulated by fibrous tissue. *Vogeloides felis* is found in the bronchioles.

Paragonimus westermani

Common name: Oriental lung fluke

Predilection site: Lung

Phylum: Platyhelminthes

Class: Trematoda

Family: Paragonimidae

Description, gross: The parasite is rounded and thick, reddish-brown in colour, 7.5–16 by 4–8 mm, and covered in scale-like spines. The ventral sucker is situated slightly anterior to the middle of the fluke.

Description, microscopic: Species differentiation is based on the shape of the spines. Those in *P. westermani* are large and have bifid points. Eggs are yellowish-brown in colour, operculate, 75–118 by 42–67 µm, and the shell is thickened at the opposite end to the operculum (see Fig. 15.39).

Final hosts: Dog, cat, pig, goat, cattle, fox, other carnivores, human, primates

Intermediate hosts: Host 1: snails (*Melania*, *Ampullaria*, *Pomatiopsis*). Host 2: crabs and crayfish

Geographical distribution: Asia, North America

Pathogenesis: Parasites in the lungs are not usually of great importance, but some may lodge in the brain or other organs causing more severe damage. Pulmonary signs are comparatively rare in cats or dogs and the veterinary interest is in the potential reservoir of infection for humans. Extrapulmonary infections may produce CLM and abscess formation in the skin and viscera. Brain and spinal cord involvement may lead to seizures, paraplegia and occasional deaths.

Clinical signs: In lung infections there may be a cough and eggs may be found in the sputum in large numbers.

Diagnosis: Diagnosis is by identifying the presence of eggs in the sputum or faeces.

Pathology: In the lungs the parasitic cyst is surrounded by diffuse connective tissue and the cyst wall becomes infiltrated by leucocytes and giant cells. The cyst usually contains two parasites surrounded by a purulent fluid mixed with blood and eggs. Pleural adhesions sometimes occur and there is usually hyperplasia of the

bronchial epithelium and focal areas of inflammation in the lung parenchyma.

Epidemiology: Infection is maintained in endemic areas where intermediate hosts are abundant.

Treatment: High doses of albendazole, fenbendazole or niclofolan over a prolonged period can be effective in control. Praziquantel administered three times per day over 3 days can also remove flukes from the lungs.

Control: The complex life cycle makes control in endemic areas impossible.

Notes: There are over 10 species of *Paragonimus* which infect humans.

Paragonimus kellicotti

Common name: Lung fluke

Predilection site: Lung

Phylum: Platyhelminthes

Class: Trematoda

Family: Paragonimidae

Description, gross: The parasite is rounded, reddish-brown in colour, 7.5–16 by 4–8 mm and covered in scale-like spines. The ventral sucker is situated slightly anterior to the middle of the fluke.

Description, microscopic: Species differentiation is based on the shape of the spines. Those in *P. kellicotti* are very large and have a number of points. Eggs are golden-brown in colour, 80–118 by 48–60 µm, and have a partly flattened operculum.

Final hosts: Cat, pig, dog

Intermediate hosts: As for *P. westermani*

Geographical distribution: North America, South Africa

Pathogenesis: Similar to *P. westermani*.

Pneumonyssoides caninum

Synonym: *Pneumonyssus caninum*

Common name: Nasal mite

Predilection site: Nasal cavity, sinuses

Class: Arachnida

Subclass: Acari

Family: Halarachnidae

Description: The mites are oval and pale yellow, adults measuring approximately 1–1.5 by 0.6–0.9 mm. They have a smooth cuticle with relatively few setae. The mites have a single irregularly shaped dorsal plate and a small sternal plate. Genital plates are absent in this species and the genital opening is a transverse slit between the coxae of the fourth pair of legs. They have long legs, relative to their body size, that terminate in claws, short pretarsi (though these are relatively longer on the first pair of legs) and small suckers.

Host: Dog

Geographical distribution: Worldwide; particularly prevalent in Scandinavia

Pathogenesis: *Pneumonyssoides caninum* has been associated with head shaking and ‘inverted’ sneezing, as well as with chronic rhinitis, sinusitis and tonsillitis, although the majority of infections seem to be subclinical. In working and hunting dogs the most obvious result of nasal mite infection is a markedly impaired sense of smell. There is evidence that *P. caninum* can penetrate host tissues and move beyond the respiratory system to cause lesions in the liver and kidney.

Clinical signs: The presence of mites causes excessive nasal secretion and hyperaemia of the nasal mucosa. Extreme infestations may result in listlessness, loss of appetite, irritation and scratching at the eyes, chronic sneezing, bronchial cough and rhinitis or sinusitis.

Diagnosis: The mites can be seen crawling over the tissue surface of the nasal sinuses. Specific diagnosis may be achieved through microscopic examination.

Epidemiology: The infection is probably transmitted by direct nose-to-nose contact between animals. This species appears to be particularly common in Scandinavia; a prevalence of 24% in pet dogs at necropsy has been reported in Sweden.

Treatment and control: Treatment with ivermectin has proved effective.

Linguatula serrata

Common name: Tongue worm

Predilection site: Nasal cavity, sinuses, mesenteric lymph nodes

Phylum: Arthropoda

Class: Maxillopoda

Family: Linguatulidae

Description: Males measure up to 20 mm in length while females are 30–130 mm in length. Both sexes are transversely striated, expanded anteriorly and shaped like an elongated tongue (see Fig. 3.127). Anteriorly there are five small protruberances, one bearing a small mouth at its extremity, the others bearing tiny claws. The eggs measure about 90 by 70 µm. The larval stage is up to 500 µm in size and devoid of annulations and mouthparts.

Hosts: Principal hosts are tropical reptiles, such as snakes and crocodiles, but some species parasitise mammals and birds. *Linguatula serrata* occurs in dogs, cats and foxes, the adult occurring in the nasal passages and sinuses.

Geographical distribution: Worldwide: North America, Europe and Australia

Pathogenesis and clinical signs: Infrequently, heavy infections in dogs may cause sneezing, coughing and a nasal discharge. The parasites live for about 15 months in the host, after which the animal usually recovers.

Diagnosis: Eggs may be found in the faeces or the nasal discharge. Encysted nymphs may be visible in cut surfaces of mesenteric glands.

Treatment and control: There is no specific treatment recommended, although systemic insecticides should be considered. It is possible to remove the parasites surgically. Infection can be avoided by preventing animals from eating potentially infected material.

Pneumocystis carinii

Synonym: *Pneumocystis jiroveci*

Common name: Pneumocystosis

Predilection site: Lung

Kingdom: Fungi

Phylum: Ascomycota

Class: Pneumocystidomycetes

Family: Pneumocystidaceae

Description: Two major forms of *P. carinii* have been consistently identified from histological and ultrastructural analysis of organisms found in human and rat lung. These are a trophic form and a larger cyst stage containing eight intracystic stages.

Hosts: Human, cattle, rat, ferret, mouse, dog, horse, pig and rabbit

Geographical distribution: Worldwide

Pathogenesis: *Pneumocystis* is one of the major causes of opportunistic mycoses in the immunocompromised, including those with congenital immunodeficiencies, retrovirus infections such as AIDS, and cases receiving immunosuppressive therapy.

Clinical signs: Not reported in dogs

Diagnosis: Gomori’s methenamine silver (GMS) and Giemsa stains may be used for microscopic visualisation of *Pneumocystis*. Toluidine blue (TBO) is the most effective for cyst stages while Giemsa stains are used to show trophozoites. Axenic culture methods have been described; however, *in vitro* cultivation, especially from clinical samples, is not always successful. Fluorescence antibody staining techniques can be used to detect both cyst and trophozoite stages of *P. carinii*. A number of PCR methods have been reported which amplify specific regions of DNA from *P. carinii* and are approximately 100 times more sensitive than conventional staining techniques.

Pathology: The lesion is characterised by a massive plasma cell or histiocyte infiltration of the alveoli in which the organisms may be detected by a silver staining procedure. A foamy eosinophilic material is observed in the lungs during infection. This material is composed of masses of the organism, alveolar macrophages, desquamated epithelial alveolar cells, polymorphonuclear leucocytes and other host cells.

Epidemiology: The organism is apparently quite widely distributed in latent form in healthy individuals and in the dog, as well as a wide variety of other domestic and wild animals. The organism is thought to be transmitted by aerosol, although the natural habitats and modes of transmission of infections in humans are current areas of research. *Pneumocystis* DNA has been detected in air and water, suggesting that the free forms of the organism may survive in the environment long enough to infect a susceptible host. However, little information on the means of transmission exists currently. In humans, infections appear to spread between immunosuppressed patients colonised with *Pneumocystis*, and immunocompetent

individuals transiently parasitised with the organism. Human and non-human *Pneumocystis* species have been shown to be different and host-specific, suggesting that zoonotic transmission does not occur.

Treatment: Trimethoprim–sulphamethoxazole is the drug of choice for treatment and prophylaxis of *Pneumocystis* infections. Pentamidine and atovaquone are the alternative therapeutic agents in humans.

Control: Control is difficult given that the details of the routes of transmission are unknown. Infection is generally asymptomatic in animals and is only likely to be detected in immunocompromised individuals.

Notes: Initially reported as a morphological form of *Trypanosoma cruzi*, this microorganism later proved to be a separate genus and was named *Pneumocystis carinii* and classified as a protozoan until the late 1980s. Following further taxonomic revision, *Pneumocystis* is now classified as a fungus, not a protozoan. The taxonomy is still complicated in that *Pneumocystis* from humans and other animals are quite different and there appear to be multiple species in this genus. Genetic variations and DNA sequence polymorphisms are often observed, suggesting the existence of numerous strains even within a single species of *Pneumocystis*.

Parasites of the liver

Fasciola hepatica

For more details see Chapter 9.

Capillaria hepatica

Synonyms: *Callodium hepatica*, *Hepaticola hepatica*

Predilection site: Liver

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: These very fine filamentous worms generally measure between 1 and 5 cm in length.

Description, microscopic: The males have a long thin single spicule and often possess a primitive bursa-like structure. The medium-sized eggs are barrel-shaped and almost colourless. They have thick shells that are slightly striated with minute pores and the bipolar plugs protrude. Eggs measure about 48–62 by 29–37 μm and contain a morula.

Hosts: Rat, mouse, squirrel, rabbit and farmed mustelids; occasionally dog, cat and human

Geographical distribution: Worldwide (in rodents)

Pathogenesis: Adult worms are found in the parenchyma of the liver where they provoke traumatic hepatitis. Eggs are laid in groups in the liver parenchyma from which there is no natural access to the exterior. Granulomas develop around the eggs, accompanied by fibrosis. Heavy infections can cause hepatitis and/or cirrhosis and ascites. The liver may be enlarged and severe infections can be fatal.

Heavy infections in humans induce similar hepatic lesions to those seen in other mammalian hosts and hepatic capillaritis is usually fatal.

Clinical signs: Mild infections are usually asymptomatic. At necropsy, the liver may have yellowy-white streaks on the surface.

Diagnosis: Most infections are discovered at routine necropsy. Granulomatous tissue in the liver parenchyma can be examined for the presence of eggs or worm fragments after squashing between microscope slides.

Pathology: The eggs, which are deposited in clusters, provoke the development of localised granulomas, which are visible through the capsule as yellowish streaks or patches.

Epidemiology: Although the prevalence of *C. hepatica* is high in the liver of rodents, it lacks host specificity and occurs in a variety of mammals. Human infection is acquired through ingestion of soil, containing embryonated eggs, or by consuming contaminated food or water.

Treatment: Oral administration of a modern benzimidazole over several days can be effective at preventing egg deposition in the liver tissues. Once egg deposition has occurred, treatment may not be effective.

Control: Destruction of rodents will assist in control.

Clonorchis sinensis

Synonym: *Opisthorchis sinensis*

Common name: Chinese or Oriental liver fluke

Predilection site: Bile ducts, pancreatic ducts and occasionally small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Opisthorchiidae

Description, gross: The adult fluke is flat, transparent pinkish, wide posteriorly and tapering anteriorly and may reach a size of 25 by 5 mm (see Fig. 1.77).

Description, microscopic: The cuticle is spiny in the young fluke but smooth in the adult. The testes are multi-branched and are posterior to the ovary and uterus. A cirrus sac is absent. Eggs have a thick light yellowish-brown wall and measure 27–35 by 12–20 μm ; they contain a miracidium when they are laid, the internal structure of which is asymmetrical. The convex operculum of the egg slots into a prominent rim of the shell (Fig. 12.17). A small hook-like structure is frequently present on the opposite pole.

Final hosts: Human, dog, cat, pig, mink, badger

Intermediate hosts: Two are required. Host 1: operculated snails (*Parafossalurus*, *Bulimus* spp., *Bithynia*, *Melania* and *Vivipara*). Host 2: fishes belonging to several genera of the family Cyprinidae (more than 40 have been reported naturally infected).

Geographical distribution: China, Taiwan, Korea, Vietnam, Japan, India and parts of the former Soviet Union

Pathogenesis: The worms live in the narrow proximal parts of the bile ducts. The young flukes particularly, with their cuticular spines,

Fig. 12.17 *Clonorchis sinensis* egg.

cause cholangitis, pericholangitis, cholecystitis with desquamation of the epithelium, and may in rare cases bring about bile stasis by blocking up the passages, resulting in jaundice.

Clinical signs: Symptoms are not generally seen except in heavy infections. The symptoms in humans include anaemia, emaciation, ascites, jaundice and diarrhoea.

Diagnosis: Diagnosis is based on the identification of the characteristic eggs in faecal samples, which have to be differentiated from the eggs of other trematodes such as *Heterophyes*, *Metagonimus* and other *Opisthorchis* species. Several serological tests have been developed, but most are non-specific. A reported ELISA may be of value.

Pathology: Light infestations may cause little pathology, but in heavier infections there is fibrosis of the smaller bile ducts and cholangio-hepatitis and severe biliary fibrosis may develop. Papillomatous or even adenomatous proliferation of the epithelium of the bile ducts occurs, together with cirrhosis of the liver and this frequently leads to the formation of cysts enclosing eggs and flukes.

Epidemiology: Carnivores or humans usually acquire infection by eating raw fish. In some fish, the metacercariae are found only under the scales and animals that are fed with the scales and offal of such fish become infected, while humans who eat the rest of the fish do not. Infection is usually aggregated in a small number of individuals.

Treatment: Praziquantel 25 mg/kg on three consecutive days has been reported to be effective.

Control: Cats and dogs act as reservoirs for human infection. Prevention relies on not feeding or eating raw, undercooked or improperly pickled, salted, smoked or dried fish. Freezing fish for a week at -10°C may be beneficial, but even frozen fish has been incriminated with outbreaks of infection in non-endemic areas. In endemic areas, treatment of all infected persons and improved sanitation would help control infection. In those areas where fish are raised in ponds, human and animal faeces should be composted or sterilised before being applied as fertiliser to ponds.

Notes: Opisthorchiids may be mistaken for microcoeliids as they are similar in size and location. However, in the former the ovary is anterior to the testes, whereas in the latter it is posterior to the testes.

Opisthorchis felineus

Synonyms: *Opisthorchis tenuicollis*, *Opisthorchis viverrini*

Common name: Cat liver fluke

Predilection site: Bile ducts, pancreatic ducts and occasionally small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Opisthorchiidae

Description, gross: Adult flukes are reddish in colour, with a smooth cuticle and measure 7–12 by 1.5–2.5 mm (see Fig. 1.78).

Description, microscopic: The testes are lobed and not branched. Eggs are about 26–30 by 11–15 μm in size, and contain a miracidium when they are laid, the internal structure of which is asymmetrical. The operculum of the egg fits into a prominent rim of the shell and may have a tubercular appendage (Fig. 12.18).

Final hosts: Cat, dog, fox, pig, human, cetaceans (seals, porpoises)

Intermediate hosts: Two are required. Host 1: operculated snails (*Bithynia*). Host 2: freshwater fish belonging to several genera (*Leuciscus*, *Blicca*, *Tinca*, *Barbus*). In Europe, metacercariae are common in freshwater fish such as orfe, bream, tench and barbel.

Geographical distribution: Southern Asia, Europe, Russia, Canada

Pathogenesis: Most infections are asymptomatic, depending on the level and duration of infection. Adult fluke in the bile ducts, gall-bladder and occasionally the pancreatic duct cause thickening of

Fig. 12.18 *Opisthorchis felineus* egg.

the ducts predisposing to cholangiocarcinoma and hepatocellular carcinoma.

Pathology: Light infestations may cause little pathology, but in heavier infections there is fibrosis of the smaller bile ducts, and cholangio-hepatitis and severe biliary fibrosis may develop in advanced cases. Adenocarcinoma of the liver or pancreas in cats and humans has been reported.

Notes: There is some uncertainty regarding the proper classification of opisthorchiid flukes and many texts suggest the reported species of *Opisthorchis* are synonymous.

Metorchis albidus

Synonyms: *Distoma albicum*, *Opisthorchis albidus*

Common name: Liver fluke

Predilection site: Bile ducts, gallbladder

Phylum: Platyhelminthes

Class: Trematoda

Family: Opisthorchiidae

Description, gross: The fluke is spatulate, pointed anteriorly, rounded and flat posteriorly, 2.5–3.5 by 1.0–1.6 mm with a spinous cuticle.

Description, microscopic: The genital pore is in front of the ventral sucker. The testes are located diagonally in the posterior region of the body and they are lobed. The ovary is fairly circular and lies just in front of the anterior testis. The operculate eggs are small, 24–30 by 13–16 μm .

Final hosts: Dog, cat, fox, seal, occasionally poultry and human

Intermediate hosts: Two are required. Host 1: freshwater snails. Host 2: fish (*Blicca bjorkna*)

Geographical distribution: Europe, Asia, North America

Metorchis conjunctus

Common name: Liver fluke

Predilection site: Bile ducts, gallbladder

Phylum: Platyhelminthes

Class: Trematoda

Family: Opisthorchiidae

Description, gross: Adult flukes measure 1–6.5 mm long by 0.6–2.6 mm broad.

Description, microscopic: The suckers are equal in diameter. The genital pore lies at the anterior margin of the acetabulum. The cuticle of the young fluke possesses spines.

Final hosts: Dog, cat, fox, mink, raccoon

Intermediate hosts: Two are required. Host 1: freshwater snails (*Amnicola*). Host 2: fish (*Catostomus*)

Geographical distribution: North America

Platynosomum fastosum

Synonym: *Eurytrema fastosum*

Common names: Cat liver fluke, 'lizard poisoning'

Predilection site: Bile and pancreatic ducts

Phylum: Platyhelminthes

Class: Trematoda

Family: Dicrocoeliidae

Description, gross: The adult fluke is lanceolate and measures 4–8 by 1.5–2.5 mm.

Description, microscopic: The eggs are brown, oval, thick-shelled and operculate and measure about 34–50 by 23–35 μm . They are embryonated when laid.

Final host: Cat

Intermediate hosts: Land snails (*Sublima*) and wood lice. Lizards are obligate paratenic hosts.

Geographical distribution: South America, the Caribbean, southern USA, Hawaii, West Africa, Malaysia and the Pacific Islands

Pathogenesis: Most infections are well tolerated by the cat, causing only a mild inappetence, but in heavy infestations, so-called 'lizard poisoning', cirrhosis and jaundice have been reported with diarrhoea and vomiting in terminal cases.

Clinical signs: In mild cases, vague chronic signs of unthriftiness may be observed. Severe infections cause anorexia, vomiting, diarrhoea and jaundice leading to death.

Diagnosis: Based on faecal examination for eggs and necropsy examination of the bile and pancreatic ducts for the presence of flukes.

Pathology: Liver cirrhosis and cholangitis have been reported and the bile ducts are often markedly distended.

Epidemiology: Infection is maintained in endemic areas where intermediate hosts and lizards are abundant.

Treatment: Praziquantel (20 mg/kg) and nitroscanate (100 mg/kg) are reported to be effective treatments.

Control: Preventing cats from hunting lizards can control infection.

Eurytrema procyonis

Predilection site: Bile and pancreatic ducts

Phylum: Platyhelminthes

Class: Trematoda

Family: Dicrocoeliidae

Description, gross: The adult measures 2.9 mm long by 1.2 mm wide. The oral sucker is subterminal with a dorsal lip-like projection.

Description, microscopic: The eggs are small, 45 by 35 μm , asymmetrical, dark brown with an operculum and a miracidium.

Hosts: Cat, fox, raccoon

Geographical distribution: North America

Pathogenesis: Infection is usually well tolerated, and causes no apparent ill-health. Infection in the cat has been reported to cause weight loss and vomiting due to pancreatic fibrosis and atrophy.

Clinical signs: Mild infections are usually asymptomatic.

Diagnosis: Based on faecal examination for eggs and necropsy examination of the bile and pancreatic ducts for the presence of flukes.

Pathology: Periductal fibrosis may produce cord-like ducts and there may be atrophy of glandular acini.

Epidemiology: This is a common parasite of the pancreatic ducts of the raccoon. Cats presumably become infected by ingestion of the intermediate host.

Treatment: Praziquantel may be effective against these flukes.

Control: This is difficult because of the longevity of the eggs, the wide distribution of the intermediate hosts and the number of reservoir hosts.

Several other species of liver flukes of the family Opisthorchiidae are found in dogs and cats and are summarised in Table 12.8. Details are essentially similar to those of other opisthorchiid flukes.

Leishmania donovani infantum

Subspecies: *Leishmania infantum* (*Leishmania chagasi*)

Synonym: *Leishmania donovani* complex

Common names: Visceral leishmaniosis, kala-azar, infantile or Mediterranean leishmaniosis (*L. infantum*)

Predilection site: Skin, liver, spleen

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Description: *Leishmania* amastigotes are small, round or oval bodies, 1.5–3.0 by 2.5–6.5 µm, located within macrophages and possessing a large nucleus and rod-shaped kinetoplast associated with a rudimentary flagellum (see Fig. 2.8a).

Hosts: Human, dog, fox (*Vulpes vulpes*), black rat (*Rattus rattus*), raccoon (*Nyctereutes procyonoides*), jackal (*Canis aureus*), wolf and fennic fox (*Fennecus zerda*), bush dog (*Lycalopex vetulus*)

Geographical distribution: Southern France (Cevennes Hills), central and western Mediterranean basin (Europe and Africa), Iran (*L. infantum*), central and southern America (Mexico to northern Argentina) (*L. chagasi*)

Pathogenesis: In dogs, *L. donovani infantum* may cause either visceral or cutaneous lesions, the latter being more common (Fig. 12.19). It may take many months or even years for infected dogs to develop clinical signs, so that the disease may only become apparent long after dogs have left endemic areas. The disease is usually chronic with low mortality, although it can manifest as an acute, rapidly fatal form. Recovery depends on the proper expression of cell-mediated immunity; if this does not occur, the active lesion persists, leading to chronic enlargement of the spleen, liver and lymph nodes and persistent cutaneous lesions.

Clinical signs: In the cutaneous form in the dog, lesions are confined to shallow skin ulcers often on the lip or eyelid, from which recovery is often spontaneous. In the visceral form, dogs initially develop ‘spectacles’ due to depilation of hair around the eyes and this is followed by generalised loss of body hair and eczema, leishmanial organisms being present in large numbers in the infected skin. Intermittent fever, anaemia, cachexia and generalised lymphadenopathy are also typical signs. Long periods of remission followed by the reappearance of clinical signs are not uncommon.

Diagnosis: This depends on the demonstration of the amastigote parasites in smears or scrapings from affected skin or from lymph node or marrow biopsies. Confirmation in an individual case may be difficult, particularly if signs are non-specific. Intracellular or extracellular amastigotes can be identified in Giemsa or Leishman’s

Table 12.8 Liver flukes of dogs and cats.

| Species | Hosts | Intermediate hosts | Distribution |
|-----------------------------------|---|--|---|
| <i>Opisthorchis sinensis</i> | Human, dog, cat, pig, mink, badger | 1: Freshwater snails (<i>Parafossalurus</i> , <i>Bulimus</i> spp., <i>Bithynia</i> , <i>Melania</i> and <i>Vivipara</i>) 2: Fishes (Cyprinidae) | China, Taiwan, Korea, Vietnam, Japan, India and parts of the former Soviet Union |
| <i>Opisthorchis felineus</i> | Cat, dog, fox, pig, human, cetaceans (seals, porpoises) | 1: Freshwater snails (<i>Bithynia</i>) 2: Fishes (<i>Leuciscus</i> , <i>Blicca</i> , <i>Tinca</i> , <i>Barbus</i>) | Southern Asia, Europe, Russia, Canada |
| <i>Metorchis albidus</i> | Dog, cat, fox, seal | 1: Freshwater snails (<i>Amnicola limosa porosa</i>) 2: Fishes (<i>Blicca bjorkna</i>) | Europe, Asia, North America |
| <i>Metorchis conjunctus</i> | Dog, cat, fox, mink, raccoon | 1: Freshwater snails (<i>Amnicola limosa porosa</i>) 2: Fishes (common sucker, <i>Catostomus commersoni</i>) | North America |
| <i>Platynosomum fastosum</i> | Cat | Land snails (<i>Sublima</i>) | South America, the Caribbean, southern USA, West Africa, Malaysia and the Pacific Islands |
| <i>Platynosomum concinnum</i> | Cat | Crustacean (wood louse) | |
| <i>Platynosomum illiense</i> | Cat | Lizard (paratenic) | |
| <i>Parametorchis complexus</i> | Cat, dog | Not known but probably similar to other liver flukes | North America |
| <i>Eurytrema procyonis</i> | Cat, fox, raccoon | Unknown, thought to be snail (<i>Mesodon</i>) | North America |
| <i>Pseudamphistomum truncatum</i> | Dog, cat, fox, rarely human | 1: Snail, unknown 2: Fishes (<i>Leuciscus</i> , <i>Sardinius</i> , <i>Blicca</i> , <i>Abramis</i>) | Europe, India |

Fig. 12.19 Forelimbs of dog with cutaneous lesions of *Leishmania infantum*.

stained aspirates, impression or biopsy samples from lymph node, bone marrow, spleen or skin lesions. PCR and immunocytochemistry methods have been developed for use on these samples and offer greater sensitivity. Serological assays using the indirect fluorescent antibody test (IFAT), ELISA and western blot have also been developed. Specialist laboratories can carry out culture and species identification using isoenzyme analysis and rapid amplification of polymorphic DNA (RAPD) PCR.

Pathology: Visceral leishmaniasis is essentially a reticuloendotheliosis. Reticuloendothelial cells are increased in number and invaded by the parasites. The enormously enlarged spleen is congested with prominent Malpighian corpuscles. The liver is enlarged with fatty infiltration of Kupffer cells. Macrophages, myelocytes and neutrophils of the bone marrow are filled with parasites. Lymph nodes are usually enlarged and the intestinal mucosa is infiltrated with macrophages filled with parasites.

Epidemiology: Dogs are commonly infected and transmission is by sandflies of the genus *Phlebotomus* (*P. ariasi*, *P. perniciosus*, *P. longicuspis*, *P. chinensis*, *P. mongolensis* and *P. caucasicus*) in the Mediterranean area and the genus *Lutzomyia* (*L. longipalpis*, *L. evansi*) in Central and South America. The dog is the principal urban reservoir, with infection rates as high as 20% in some countries, and the most important source of human infection. It is probable that most dogs in endemic areas are exposed to disease and will either develop clinical or subclinical infection or become immune and resistant to infection. Leishmaniasis is diagnosed in dogs in countries where sandfly vectors do not occur, suggesting a currently unknown mechanism of transmission. Vertical transmission from dam to offspring has been reported and transmission by infected blood transfusion has been described.

Treatment: Several drugs are used for treating canine leishmaniasis (Table 12.9). These include the pentavalent antimonials, of which meglumine antimoniate is the main drug, used either alone or in combination with other drugs, particularly allopurinol. Allopurinol can also be given alone following initial therapy with meglumine antimoniate. Other drugs that have been used include amphotericin B, pentamidine, allopurinol and ketoconazole.

Control: From the public health aspect, the destruction of infected dogs, and stray dogs generally, is desirable, although often unacceptable. In some areas, the population of sandflies has been

Table 12.9 Drugs used in the treatment of leishmaniasis in dogs.

| Drug | Drug group | Dose rate | Notes |
|-----------------------|------------------------|---|--|
| Meglumine antimoniate | Pentavalent antimonial | 100 mg/kg s.c. for 3–4 weeks | Nephrotoxic. May cause pain and muscle fibrosis at injection site |
| Allopurinol | Pyrimidine derivative | 20 mg/kg orally daily 20 mg/kg orally daily combined with meglumine antimoniate (100 mg/kg daily s.c. for 20 days), then continue with 20 mg/kg allopurinol indefinitely | |
| Amphotericin B | Polyene macrolide | 0.5–0.8 mg/kg i.v. or s.c. two to three times weekly | Nephrotoxic. Administer until cumulative dose of 15 mg/kg is reached |
| | | 1–2.5 mg/kg i.v. in lipid emulsion twice weekly | Administer until cumulative dose of 10 mg/kg is reached |
| | | 3 mg/kg/day i.v. in liposomalised formulation | Administer until cumulative dose of 15 mg/kg is reached |

reduced as a result of mosquito control for malaria, and as a result the incidence of leishmaniasis has decreased. Generally, though, chemical control of sandfly vectors has had very limited success. A deltamethrin-impregnated collar offers some protection of dogs from sandfly bites and appears to decrease the rate of infection in dogs and people in endemic areas.

A subunit vaccine has been developed in South America for the control of visceral leishmaniasis in dogs. This vaccine is based on a surface fucose-mannose-ligand antigen complex. A parasite lyophilisate vaccine (Canileish®), which contains excretory/secretory proteins of *Leishmania infantum* is commercially available in Europe for the immunisation of dogs.

Notes: *Leishmania donovani donovani* is a highly fatal infection of humans and causes visceral leishmaniasis. In humans the incubation period may be several months with spasmodic fever. Hepatomegaly and splenomegaly follow with mortality of 75–95%.

Hepatozoon canis

Synonym: *Leucocytozoon canis*

Common name: Canine hepatozoonosis

Predilection site: Blood, liver, kidney

Phylum: Apicomplexa

Class: Conoidasida

Family: Hepatozoidae

Description: Gamonts, found in circulating neutrophils, are ellipsoidal in shape, about 11 by 4 µm, and are enveloped in a thick membrane (Fig. 12.20). Meronts are usually round to oval, about 30 µm in diameter, and include elongated micromerozoites with defined nuclei, which in cross-section have a 'wheel-spoke' appearance.

Host: Dog

Geographical distribution: Southern Europe, Middle East, Africa, Southeast Asia, South America

Fig. 12.20 Gamont of *Hepatozoon canis* in circulating neutrophil.

Pathogenesis: Most dogs infected with *H. canis* appear to undergo a mild infection associated with a limited degree of inflammatory reaction. However, infection may vary from asymptomatic in dogs with a low parasitaemia, to life-threatening in animals that present with a high parasitaemia. Symptoms may be exacerbated by the presence of concurrent infections with parvovirus, *Ehrlichia canis*, *Anaplasma platys*, *Toxoplasma gondii*, *Leishmania donovani infantum*, or immunosuppression in the young neonate or those with primary or induced immunodeficiency. High parasitaemias can cause direct injury to the affected tissues and affect the immune system, leading to extreme loss of weight and cachexia, although infected dogs may maintain a good appetite.

Clinical signs: Infection with *H. canis* may be subclinical in some animals but produce severe and fatal disease in others. Mild disease is common and is usually associated with low-level *H. canis* parasitaemia (1–5%), frequently in association with a concurrent disease. A more severe disease, characterised by lethargy, fever and severe weight loss, is found in dogs with high parasitaemia often approaching 100% of circulating neutrophils. Dogs presenting with both leucocytosis and high parasitaemia may have a massive number of circulating gamonts (>50,000/ μ L blood).

Diagnosis: Diagnosis is usually made on the identification of gamonts in the cytoplasm of neutrophils (more rarely monocytes) in Giemsa or Wright's stained blood smears. Between 0.5 and 5% of neutrophils are commonly infected, although this may reach as high as 100% in severe infections. IFAT and western blot have been developed using gamont antigens. Dogs with a high parasitaemia frequently have neutrophilia and a normocytic, normochromic non-regenerative anaemia.

Pathology: Infection may be found as an incidental finding in histopathological specimens in dogs from endemic areas. In dogs with low parasitaemias, few lesions are usually observed. In dogs with high parasitaemias, there may be hepatitis, pneumonia and glomerulonephritis associated with numerous meronts. Meronts and developing gamonts are also found in lymph nodes, spleen and bone marrow.

Epidemiology: The main vector of *H. canis* is the brown dog tick, *Rhipicephalus sanguineus*, which is found in warm and temperate regions all over the world. Infection is transmitted trans-stadially from nymph to adult stages of the tick vectors. Infection appears

to be mainly from ingestion of infected ticks. Vertical transmission has been reported.

Treatment: Infection is treated with imidocarb dipropionate 5–6 mg/kg every 14 days until gamonts are no longer present in blood smears. Oral doxycycline 10 mg/kg daily for 21 days in combination with imidocarb may also be used. Treatment may take up to 8 weeks to eliminate gamonts from peripheral blood and require regular haematological evaluation. Treatment of all infected dogs is recommended as parasitaemia may increase over time and develop into a severe infection. The prognosis for dogs with a low parasitaemia is generally good, but less favourable for those with a high parasitaemia.

Control: Prophylaxis depends on regular tick control using an effective acaricide and close examination of animals for the presence of ticks. In areas where the disease is endemic, dogs should be prevented from scavenging or eating raw meat or organs from wildlife.

Notes: The closely related *H. americanum* was initially reported to be a strain of *H. canis* but is now considered a separate species, based on clinical disease manifestations, pathology, and morphological and genetic differences.

Parasites of the circulatory system

Angiostrongylus vasorum

Synonym: *Haemostromylus vasorum*

Common name: French heartworm

Predilection site: Right ventricle, pulmonary artery

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description, gross: Slender worms up to 2.5 cm long. Females are 18–25 mm, while males are 14–18 mm with a small bursa in which the rays are distinguishable.

Description, microscopic: The ventral rays are fused for most of their length and the dorsal ray is stout with stout terminal branches. In the female, the white ovaries are coiled round the red intestine (Fig. 12.21) with the vulva in the posterior half of the body. Eggs are unsegmented when laid in the lung and measure about 70–80 by 40–50 μ m. First-stage larvae are 330–360 μ m in length and have a small cephalic button and a wavy tail with a subterminal notch (see Fig. 4.12e).

Final hosts: Dog, fox and other canids

Intermediate hosts: Terrestrial molluscs, mainly snails and slugs

Geographical distribution: Worldwide, except in the Americas, apart from the Atlantic coastal provinces of Canada; prevalent in western Europe

Pathogenesis: Canine angiostrongylosis is usually a chronic condition, extending over months or even years. Much of the pathogenic effect is attributable to the presence of the adult worms in the larger vessels and eggs and larvae in the pulmonary arterioles and

Fig. 12.21 Female *Angiostrongylus vasorum* in the pulmonary artery.

capillaries. Blockage of these vessels results in circulatory impediment, which may eventually lead to congestive cardiac failure.

Clinical signs: In recently established infections the resting dog usually shows no clinical signs, but if a substantial number of worms is present, the active animal will often show tachycardia, tachypnoea, and a heavy productive cough, the sputum sometimes showing blood. In longer-established severe infections signs are present even in the resting dog. There may be recurrent syncope. As a consequence of reduced blood-clotting capacity, slowly-developing painless swellings may appear in dependent areas, such as the lower abdomen and intermandibular space, and on the limbs where bruising has occurred. Chronic infections may be accompanied by reduced appetite, anaemia and ascites and deaths can occur. The rare acute infection, normally seen in young animals, manifests as dyspnoea and violent coughing, with white–yellow, occasionally bloody, sputum.

Diagnosis: The L₁, which may be present in faeces and sputum, has a small cephalic button, and a wavy tail with a subterminal notch, and its presence in association with respiratory and circulatory signs is accepted as confirmatory.

Pathology: The cut surface of the lung is mottled and reddish-purple. One reported systemic effect, unusual in helminth infections, is interference with the blood-clotting mechanism, so that subcutaneous haematomas may be present. In the larger blood vessels, there is endarteritis and periarteritis which progress to fibrosis and at necropsy the vessels have a pipe-stem feel on palpation. The vascular change may extend to the right ventricle, with endocarditis involving the tricuspid valve.

Epidemiology: Though worldwide in general distribution, *A. vasorum* is only prevalent in certain localities, and these are invariably rural. In Europe, endemic foci have been recognised in France, Spain, Eire and England.

Treatment: Mebendazole and fenbendazole (at increased dose rates), levamisole and ivermectin have proved effective.

Control: Control is impractical in most cases, due to the ubiquity of the molluscan intermediate hosts.

Dirofilaria immitis

Synonym: *Noctiella immitis*

Common name: Canine heartworm

Predilection site: Cardiovascular system: adults are in the right ventricle, right atrium, pulmonary artery and posterior vena cava

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Long, slender, white–grey worms 15–30 cm long. Adult females measure 25–30 cm, with the males about half as long. Many worms are usually found together in a tangled mass. The size and site are diagnostic for *D. immitis*.

Description, microscopic: The male tail has the typical loose spiral common to the filarioids (Fig. 12.22), and the tail bears small lateral alae. There are four to six pairs of ovoid papillae. The left spicule is long and pointed; the right spicule is smaller and ends bluntly. In the female the vulva is situated just behind the end of the oesophagus. The microfilariae in the blood are not ensheathed and are 307–332 µm in length by 6.8 µm wide. They have a tapered anterior end and blunt posterior end.

Final hosts: Dog, fox, wild canids; occasionally cat and other wild felids and rarely human

Intermediate hosts: Mosquitoes of the genera *Aedes*, *Anopheles* and *Culex*

Geographical distribution: Warm–temperate and tropical zones throughout the world including North and South America, southern Europe, India, China, Japan and Australia

Pathogenesis: Pathogenic effects are associated with the adult parasites (Fig. 12.23). Many dogs infected with low numbers of *D. immitis* show no apparent ill effects and it is only in heavy chronic infections that circulatory distress occurs, primarily due to obstruction to normal blood flow leading to chronic congestive right-sided heart failure. The presence of a mass of active worms can cause an endocarditis in the heart valves and a proliferative pulmonary endarteritis, possibly due to a response to parasite excretory products. In addition, dead or dying worms may cause pulmonary embolism. After a period of about 9 months the effect of the developing pulmonary hypertension is compensated for by right ventricular hypertrophy, which may lead to congestive heart failure with the usual

Fig. 12.22 Adult worms, *Dirofilaria immitis*.

Fig. 12.23 *Dirofilaria immitis* in a section of an infected heart.

accompanying signs of oedema and ascites. At this stage the dog is listless and weak.

A mass of worms may lodge in the posterior vena cava and the resulting obstruction leads to an acute, sometimes fatal, syndrome known as the vena caval syndrome. This is characterised by haemolysis, haemoglobinuria, bilirubinaemia, icterus, dyspnoea, anorexia and collapse. Death may occur within 2–3 days. Very occasionally there is blockage of the renal capillaries by microfilariae leading to a glomerulonephritis, possibly related to the deposition of immune complexes.

In cats, pulmonary hypertension, right-sided heart failure and caval syndrome are less common, and more commonly the presence of the parasites in the distal pulmonary arteries may induce a diffuse pulmonary pneumonia. Ectopic infections are more commonly seen in cats, with parasites reported in the eye, CNS and subcutaneous tissues.

Clinical signs: Heavily infected dogs are often listless and there is a gradual loss of condition and exercise intolerance. They have a chronic soft cough with haemoptysis, and in the later stages of the disease become dyspnoeic and may develop oedema and ascites. The acute vena caval syndrome described above is characterised by haemoglobinuria, icterus and collapse. Lighter infections in working dogs may be responsible for poor performance during periods of sustained exercise. Infected cats may show coughing; tachypnoea and dyspnoea and heavy infections can be fatal.

Diagnosis: This is based on the clinical signs of cardiovascular dysfunction and the demonstration of the appropriate microfilariae in the blood. However, non-microfilaraemic dogs may still harbour adult parasites. Affected dogs are seldom less than 1 year old and most are over 2 years. In suspected cases in which the microfilariae cannot be demonstrated, thoracic radiography may show the thickening of the pulmonary artery, its tortuous course and right ventricular hypertrophy. Angiography may also be used to demonstrate the vascular changes more clearly. At necropsy, adult worms are often present in the right heart chambers and adjacent large blood vessels.

Immunodiagnostic tests are also available commercially to identify cases that do not have a detectable microfilaraemia. For example there are a number of ELISA test kits for the detection of circulating heartworm antigens, or specific antibodies, that will identify most mature infections and which are highly specific.

The identification of the microfilariae in the blood (samples ideally taken in the early evening) is aided by concentrating the parasites following lysis, filtration and then staining with methylene blue or May–Grunwald Giemsa. Commercial kits are available for this technique. Alternatively one part of blood and nine parts of formalin are centrifuged and the sediment mixed with a blue stain and examined as a microscopic smear. The microfilariae have to be differentiated from those of *Acanthocheilonema reconditum*, a filarial parasite commonly found in the subcutis in dogs. Those of *D. immitis* are more than 300 µm in length and have a tapered head and a straight tail; those of *A. reconditum* are less than 300 µm in length and have a blunt head and a hooked posterior end. More precise differentiation may be achieved by using histochemical stains for acid phosphatase activity. *Dirofilaria immitis* shows distinct red acid-phosphate positive spots at the excretory pore and anus, while *A. reconditum* stains pink overall. Differential diagnosis may be achieved through the application of PCR-based recombinant DNA technology.

Heartworm infection in cats can be difficult to diagnose as a result of low parasite populations and a tendency to remain amicrofilaraemic.

Pathology: Heartworm disease is primarily a pulmonary vascular disease characterised by endarteritis with infiltration of leucocytes, mainly eosinophils, followed by myointimal proliferations which produce irregular rugose to villous projections that enmesh the worms. Thrombosis may be associated with either dead or live worms, and thromboembolism and pulmonary infarction following adulticide therapy. Pulmonary changes include haemosiderosis, diffuse interalveolar fibrosis and proliferation of alveolar epithelium. Dead worms commonly result in pulmonary granuloma formation. Additional lesions of heartworm disease include those of right heart failure, such as chronic congestion of the liver and occasionally ascites. Glomerulonephropathy occurs primarily due to glomerular deposition of immune complexes, leading to a mild to moderate proteinuria. Venal caval syndrome causes severe hepatic congestion leading to cavernous enlargement of hepatic venules with phlebosclerosis and thrombosis in the caudal vena cava and hepatic veins.

Epidemiology: Host species vary in their susceptibility to infection, the dog being the most susceptible natural host. Infection commonly occurs in dogs older than 1 year. Intrauterine infection of puppies can also occur. The important factors in the spread of heartworm disease can be divided into those affecting the host and those affecting the vector.

Host factors include a high density of dogs in areas where the vectors exist, the lengthy patent period of up to 5 years during which time circulating microfilariae are present, and the lack of an effective immune response against established parasites. Also, diurnal periodicity of microfilaraemia ensures that high numbers of microfilariae are circulating in the peripheral blood during the period of mosquito activity.

Vector factors include the ubiquity of the mosquito intermediate hosts, their capacity for rapid population increase and the short development period from microfilariae to L₃ at optimal temperatures.

At one point it was considered that the worms do not occur in areas where the temperature falls below 16°C, but more recently spread has occurred to colder zones in Canada and the USA.

Treatment: Drug treatment is complex, as the adult heartworms and the microfilariae differ in their susceptibility to anthelmintics. Treatment should not be undertaken without a physical examination of the dog and an assessment of heart, lung, liver and kidney function. Where these functions are grossly abnormal it may be necessary to give prior treatment for cardiac insufficiency. The usual recommendation is that infected dogs are first treated intravenously with thiacetarsamide twice daily over a 2-day period or intramuscularly with melarsamide over 2 days to remove the adult worms; toxic reactions are not uncommon following this treatment due to the dying and disintegrating heartworms and resultant embolism; activity of the dog should be restricted for a period of 2–6 weeks. This drug should be used with extreme care (Table 12.10).

A further treatment with a different drug is then given 6 weeks later to remove the microfilariae that are not susceptible to thiacetarsamide or melarsamide treatment. Several drugs are now available for this purpose; the traditional one was dithiazanine iodide, administered over 7 days, and either this or levamisole given orally over a 10–14 day period has proved effective. The avermectins are also highly efficient against microfilariae, as is milbemycin at the heartworm prophylactic dose of 500 µg/kg. These induce rapid clearance of microfilariae but are not licensed for this purpose because of occasional toxic or microfilaricidal side effects. Veterinarians who choose to use either drug as a microfilaricide should realise that this is an 'extra-label' application and that they take responsibility for administration of the correct dose and provide appropriate monitoring and aftercare.

With all these drugs there is a risk of adverse reactions to dying microfilariae. In some severe cases, heartworms have been removed surgically rather than risk adverse reactions following drug therapy. Following treatment it is usual to place dogs on a prophylactic programme and this is considered in the next section on control.

There are currently no licensed anthelmintics for treatment of cats.

Control: Mosquito control is difficult and therefore prophylaxis is based almost entirely on medication (Table 12.11). The drug widely used for this has been diethylcarbamazine, which in endemic areas is given orally to pups daily at 2–3 months of age. This kills developing larvae and so pre-empt the problems of treating patent infections and microfilaraemia. In tropical areas the drug is given all year round, but in more temperate zones, where the mosquito has a limited season, treatment commences 1 month prior to the mosquito season and ceases 2 months after it ends. Where prophylaxis is introduced in older dogs or after treatment of an infected dog, care must be exercised to ensure that the dog is free from microfilarial infection as anaphylactoid reactions may occur in infected

Table 12.10 Adulticides for dirofilariosis.

| Chemical | Trade name | Dose rate | Comments |
|-----------------------------|-------------|--|---|
| Thiacetarsamide sodium | Caparsolate | 2.2 mg/kg twice daily for 2 days | Intravenous injection. No longer available |
| Melarsomine dihydrochloride | Immiticide | 2.5 mg/kg i.m. repeated after 24 hours | In severely affected dogs, single injection given followed 1 month later by two injections 24 hours apart to reduce post-adulticide complications |

Table 12.11 Drugs available for heartworm prevention.

| Drug | Host | Recommended dosing interval | Route of administration |
|---|----------|-----------------------------|-------------------------|
| Ivermectin | Dog, cat | Monthly | Oral tablet |
| Ivermectin (+ pyrantel) | Dog | Monthly | Oral tablet |
| Ivermectin (+ imidacloprid) | Dog | Monthly | Spot-on |
| Milbemycin oxime | Dog | Monthly | Oral tablet |
| Milbemycin oxime (+ lufenuron) | Dog | Monthly | Oral tablet |
| Moxidectin | Dog | Monthly | Oral |
| Moxidectin microspheres | Dog | 6-month | Injectable |
| Selamectin | Dog, cat | Monthly | Spot-on |
| Diethylcarbamazine citrate (DEC) (oxibendazole) | Dog | Daily | Oral |

dogs after diethylcarbamazine treatment. Once prophylaxis is introduced, regular checks for microfilariae should be made every 6 months.

The most up-to-date methods of preventing heartworm infection involve monthly administration, throughout the mosquito season, of ivermectin or milbemycin especially formulated for this use in dogs.

Notes: Of the two species occurring in domestic carnivores, *D. immitis* is by far the more important. The adults, which are found in the right side of the heart and adjacent blood vessels of dogs, are responsible for a debilitating condition known as canine heartworm disease. Although primarily a problem of warm countries where the mosquito intermediate host abounds, the disease has become much more widespread in the past decade and the problem in North America is now so extensive that special heartworm clinics have been created.

With regard to dirofilariosis in humans, *D. immitis* and *D. repens* can cause aberrant infections. *Dirofilaria immitis* induces pulmonary coin lesions that are normally of little pathological significance. *Dirofilaria repens* (see Parasites of the integument) more commonly occurs in subcutaneous nodules, particularly in the ocular area.

Schistosomes

Schistosomes are flukes found in the circulatory system. The sexes are separate, the small adult female lying permanently in a longitudinal groove, the gynaecophoric canal, in the body of the male. The genus has been divided into four groups – *haematobium*, *indicum*, *mansoni* and *japonicum* – but the genus as currently defined is paraphyletic so revisions are likely.

Indicum group

Schistosoma spindale

Common names: Blood fluke, bilharziosis

Predilection site: Mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description: The male measures 5–16 cm and the female 7.2–16.2 mm long.

Hosts: Cattle, horse, pig and occasionally dog

Intermediate hosts: Snails (*Planorbis*, *Indoplanorbis* spp., *Lymnaea* spp.)

Geographical distribution: Parts of Asia and the Far East

Japonicum group

Schistosoma japonicum

Common names: Blood fluke, bilharziosis

Predilection site: Portal and mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description: The male is broad and flat and 9.5–20 mm long, carrying the female (12–26 mm long) in the hollow of its inwardly curved body. The suckers lie close together near the anterior end. The cuticle is spiny on the suckers and in the gynaeophoric canal. This characteristic and the vascular predilection site are sufficient for generic identification.

Final hosts: Cattle, horse, sheep, goat, dog, cat, rabbit, pig, human

Intermediate hosts: Snails belonging to the genus *Oncomelania*

Geographical distribution: South and East Asia

Other schistosomes

Schistosoma incognitum

Common names: Blood fluke, bilharziosis

Synonym: *Schistosoma suis*

Predilection site: Mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, microscopic: The eggs measure about 90 by 41 μm , and are yellowish-brown, sub-oval with one side flattened, with a small stout spine inclining towards the flattened margin.

Final hosts: Pig, dog

Intermediate hosts: Snails (*Radix* spp.)

Geographical distribution: Indian subcontinent

Heterobilharzia americana

Isolated infections with this schistosome occur in dogs, raccoon, bobcat and nutria in the Gulf States of North America. The intermediate host is a freshwater snail, *Lymnaea cubensis*. The schistosome eggs may produce granulomas in several organs.

Trypanosomes

Members of the genus *Trypanosoma* are haemoflagellates of overwhelming importance in cattle in sub-Saharan Africa but also occur in many other hosts including dogs and cats. See Chapter 2 (Trypanosomatidae) for a general description and Chapter 8 for detailed descriptions of individual species of trypanosomes and their control.

Trypanosoma brucei brucei

Common name: Nagana

Predilection site: Blood. *Trypanosoma brucei brucei* is also found extravascularly in, for example, the myocardium, CNS and reproductive tract.

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Trypanozoon*

Description: *Trypanosoma brucei brucei* is pleomorphic in form and ranges from long and slender, up to 42 μm (average 29 μm), to short and stumpy, 12–26 μm (mean 18 μm), the two forms often being present in the same blood sample. The undulating membrane is conspicuous, the kinetoplast is small and subterminal and the posterior end is pointed. In the slender form the kinetoplast is up to 4 μm from the posterior end, which is usually drawn out tapering almost to a point, and has a well-developed free flagellum. In the stumpy form the flagellum is either short or absent and the posterior end is broad and rounded with the kinetoplast almost terminal. Intermediate forms average 23 μm long and have a blunt posterior end and moderately long flagellum (see Fig. 2.6). A fourth form with a posterior nucleus may be seen in laboratory animals. In fresh unfixed blood films, the organism moves rapidly within small areas of the microscope field.

Hosts: Cattle, horse, donkey, zebu, sheep, goat, camel, pig, dog, cat, wild game species

Distribution: Sub-Saharan Africa

Clinical signs: The dog and cat are susceptible to *T. brucei brucei*. The disease is usually acute, and apart from signs of fever, anaemia and myocarditis, corneal opacity is often a feature. There may also be neurological changes resulting in aggressive signs, ataxia or convulsions.

Treatment: Dogs can be treated with either isometamidium or quinapyramine. Recommended doses are as follows: isometamidium 0.25–1 mg/kg i.m.; quinapyramine dimethylsulphate 5 mg/kg s.c.

Trypanosoma brucei evansi

Synonyms: *Trypanosoma evansi*, *Trypanosoma equinum*

Common names: Surra, el debab, mbori, murrina, mal de Caderas, doukane, dioufar, thaga

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Trypanozoon*

Description: *Trypanosoma evansi* is identical to, and structurally indistinguishable in appearance from, the slender forms of *T. brucei*. The mean length varies considerably, with typical forms 15–34 µm long (mean 24 µm). Most are slender or intermediate in shape, but stumpy forms occur sporadically. Strains that lack a kinetoplast, visible with the light microscope, have occasionally arisen spontaneously or can be produced by treatment with certain dyes, drugs or frozen storage.

Hosts: Horse, donkey, camel, cattle, zebu, goat, pig, dog, water buffalo, elephant, capybara, tapir, mongoose, ocelot, deer and other wild animals. Many laboratory and wild animals can be infected experimentally.

Life cycle: Transmission is by biting flies, no cyclical development occurring in the vector, the trypanosomes remaining in the proboscis.

Geographical distribution: North Africa, Central and South America, central and southern Russia, parts of Asia (India, Burma, Malaysia, southern China, Indonesia, Philippines)

Pathogenesis: Depending on the virulence of the strain and the susceptibility of the individual host, the disease may be acute in horses, camels and dogs. The syndrome is similar to that caused by the tsetse-transmitted trypanosomes. Anaemia is caused mainly by extravascular haemolysis through erythrophagocytosis in the mononuclear phagocytic systems of the spleen, liver and lungs, but as the disease becomes chronic there may be decreased haemoglobin synthesis. Leucopaenia and thrombocytopaenia are caused by mechanisms that predispose leucocytes and platelets to phagocytosis. Immunological mechanisms in the pathogenesis lead to extensive proliferation of activated macrophages, which engulf or destroy erythrocytes, leucocytes, platelets and haematopoietic cells.

Clinical signs: All domestic animals are susceptible but the disease is only fatal in horses, camels and dogs. The disease is manifested by pyrexia, progressive anaemia, loss of condition and depression. Recurrent episodes of fever occur during the course of disease. Oedematous swellings ranging from cutaneous plaques to frank oedema of the ventral abdomen and genitalia and petechial haemorrhages of the serous membranes are often observed. Nervous signs may occur and include circling, incoordination, staggering, head pressing, paraplegia, paralysis and prostration.

Diagnosis: The clinical signs of the disease, although indicative, are not pathognomonic. Confirmation of clinical diagnosis depends on the demonstration of trypanosomes in the blood. Occasionally, when the parasitaemia is massive it is possible to detect motile trypanosomes in fresh films of blood. More usually, both thick and thin smears of blood are air-dried and examined later. Thick smears, de-haemoglobinised before staining with Giemsa or Leishman's stain, offer a better chance of finding trypanosomes while the stained thin smears are used for differentiation of the trypanosome species.

More sensitive techniques utilise centrifugation in a microhaematocrit tube followed by microscopic examination of the interface

between the buffy coat and the plasma; alternatively, the tube may be snapped, the buffy coat expressed on to a slide, and the contents examined under dark-ground or phase-contrast microscopy for motile trypanosomes. With these techniques the packed red cell volume is also obtained, which is of indirect value in diagnosis if one can eliminate other causes of anaemia, especially helminthiasis.

A number of serological tests have been described, including IFAT and ELISA, and have been partially validated but require further evaluation and standardisation.

Pathology: The carcass is often pale and emaciated and there may be oedematous swellings in the lower part of the abdomen and genital organs with serous atrophy of fat. The liver, lymph nodes and spleen are enlarged and the viscera are congested. Petechiae may appear on lymph nodes, pericardium and intestinal mucosa. The liver is hypertrophic and congested with degeneration and necrosis of the hepatocytes, dilation of blood vessels and parenchymal infiltration of mononuclear cells. A non-suppurative myocarditis, sometimes associated with hydropericarditis, has been reported, accompanied by degeneration and necrosis of the myocardial tissue. Other lesions can include glomerulonephritis, renal tubular necrosis, non-suppurative meningo-encephalomyelitis, focal poliomyelomalacia, keratitis, ophthalmitis, orchitis, interstitial pneumonia and bone marrow atrophy. Splenic and lymph node hypertrophy occur during the acute phase but the lymphoid tissues are usually exhausted and fibrotic in the chronic stage.

Epidemiology: This species, although closely related to the salivarian trypanosome *T. brucei brucei*, is mechanically transmitted by biting insects; the usual vectors are horse flies (*Tabanus*) but *Stomoxys*, *Haematopota* and *Lyperosia* can also transmit the infection. In Central and South America the vampire bat is a vector and can transmit the disease (murrina).

Treatment: Dogs can be treated with quinapyramine.

Notes: The original distribution of this parasite coincided with that of the camel, and is often associated with arid deserts and semi-arid steppes.

Trypanosoma congolense congolense

Common names: Nagana, paranagana, Gambia fever, ghindi, gobial

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Nannomonas*

Description: *Trypanosoma congolense* is small, monomorphic in form and 8–20 µm long. The undulating membrane is inconspicuous, the medium-sized kinetoplast is marginal and the posterior end is blunt. There is no free flagellum (see Fig. 2.5). In fresh blood films the organism moves sluggishly, often apparently attached to red cells.

Hosts: Cattle, sheep, goat, horse, camel, dog, pig. Reservoir hosts include antelope, giraffe, zebra, elephant and warthog.

Distribution: Sub-Saharan Africa

Clinical signs: The dog and cat are susceptible to *T. congolense*. The disease is usually acute, and apart from signs of fever, anaemia and myocarditis, corneal opacity is often a feature. There may also be neurological changes resulting in aggressive signs, ataxia or convulsions.

Treatment: Dogs can be treated with quinapyramine.

Trypanosoma cruzi cruzi

Synonyms: *Schizotrypanum cruzi*, *Trypanosoma lesourdi*, *Trypanosoma rhesii*, *Trypanosoma prowazeki*, *Trypanosoma vickersae*

Common name: Chagas' disease

Predilection site: Blood, heart, muscle

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Schizotrypanum*

Description: Trypanosomes are monomorphic, 16–20 µm long, with a pointed posterior end and a curved stumpy body and a narrow undulating membrane with a trailing flagellum. The kinetoplast is large and subterminal, causing the body to bulge around it. Amastogotes are 1.5–4 µm in diameter and occur in groups.

Hosts: Human, dog, cat, primates, wild animals

Geographical distribution: South America

Pathogenesis: Tryptomastigote forms are found in blood, and amastigote forms are found in pseudocysts in skeletal and cardiac muscle, the reticuloendothelial system and other tissues. Infection causes generalised oedema, anaemia, hepatosplenomegaly and lymphadenitis.

Clinical signs: Depression, anorexia and weight loss can occur.

Diagnosis: In acute stages of the disease, tryptomastigotes can be found in thick blood smears stained with Giemsa. The size and morphology make it relatively easy to distinguish from other trypanosomes found in primates. Complement fixation or ELISA serological tests are available for humans and may be helpful in screening.

Epidemiology: Reduviid bugs commonly defecate after feeding, and animals become infected when they lick the insect bites or eat the infected bugs. Transmission also occurs by ingestion of infected animals, via infected maternal milk, by fly contamination or contamination by urine or saliva of heavily infected animals.

Treatment and control: There is no effective treatment. Control is based on eliminating the insect vector. Because the disease is zoonotic, owners should take precautions to avoid exposure or to contamination of mucous membranes or skin to infective secretions.

Babesia canis

Subspecies: *Babesia canis canis*, *Babesia canis rossi*, *Babesia canis vogeli*

Common name: Canine piroplasmiasis

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: Large piroplasms, pyriform in shape, 4–5 µm in length, pointed at one end and rounded at the other. Amoeboid forms have been described that are 2–4 µm in diameter and usually contain a vacuole.

Host: Dog

Geographical distribution: Southern Europe, Africa, Asia, USA, Central and South America

Pathogenesis: *Babesia canis* is recognised to represent at least three subspecies, *B. canis canis*, *B. canis rossi* and *B. canis vogeli*, each transmitted by different tick vectors (Table 12.12). The severity of infection is determined by the strain of parasite as well as other factors, such as age, immune status and presence of concurrent infections. Haemolytic anaemia is the principal pathogenic mechanism caused by the parasite but other factors, such as immune-mediated destruction of erythrocytes, may occur. Infection may be classified as uncomplicated or complicated. The former is usually associated with mild to moderate anaemia, lethargy, weakness and hepatosplenomegaly. Complicated babesiosis refers to manifestations that cannot be explained by the haemolytic crisis alone and is characterised by severe anaemia and organic dysfunction. Mortality in complicated babesiosis often exceeds 80%.

Clinical signs: The more severe forms of the disease in adult dogs are associated with virulent infections (*B. canis rossi*, *B. canis canis*), while pups are more severely affected irrespective of the species of *Babesia*. Peracute infections are a feature of *B. canis rossi* and are characterised by rapid-onset collapse, with findings typical of hypotensive shock: pale (sometimes cyanotic) mucous membranes, tachycardia, weak pulse, weakness and depression. Severe intravascular haemolysis produces haemoglobinuria and there may be widespread organ dysfunction associated with hypotension and hypoxaemia leading to coma and death.

In acute cases the first sign is fever, followed by marked anaemia, jaundice, inappetence, marked thirst, weakness, prostration and often death. Petechial and ecchymotic haemorrhages may be observed on the gums or ventral abdomen of some dogs. In chronic cases the fever is not high and there is little jaundice. Anaemia is severe and the affected animals are listless and become very weak and emaciated.

The disease may take on many different clinical forms. Involvement of the circulatory system may produce oedema, purpura and ascites, and there may be stomatitis and gastritis; involvement of the respiratory system may cause catarrh and dyspnoea. CNS involvement causes locomotor disturbances, paresis or epileptiform fits. Cerebral babesiosis may be confused with rabies.

Table 12.12 Subspecies of *Babesia canis* and their distribution.

| Subspecies | Distribution | Vector | Virulence |
|------------------------|--|---------------------------------|--------------------|
| <i>B. canis canis</i> | Southern and central Europe | <i>Dermacentor reticulatus</i> | Moderate to severe |
| <i>B. canis rossi</i> | Southern Africa | <i>Haemaphysalis leachi</i> | Severe |
| <i>B. canis vogeli</i> | Africa, Asia, North and South America, Australia, Europe | <i>Rhipicephalus sanguineus</i> | Mild to moderate |

Diagnosis: Examination of blood films, stained with Romanowsky stains such as Giemsa, will reveal the parasites in the red cells. Species identification between large and small *Babesia* is essential with regard to choice of therapeutic drugs.

A range of serological tests have been developed, with IFAT being the most reliable test. Titres exceeding 1 : 80 are considered to be indicative of infection. Cross-reactivity occurs between species, and there may also be cross-reactivity with *Neospora* and *Toxoplasma*.

Pathology: The spleen is enlarged, with dark-red soft pulp and prominent splenic corpuscles. The liver is enlarged and jaundiced, with pathological changes ranging from congestion to centrilobular necrosis. The heart, kidneys and muscles are icteric. There may be variable amounts of fluid in the pleural, pericardial and peritoneal cavities. Small haemorrhages are sometimes present on the heart, pleura, bronchi and intestines.

Epidemiology: *Babesia canis canis* is transmitted by *Dermacentor reticulatus*, *B. canis rossi* by *Haemaphysalis leachi* and *B. canis vogeli* by *Rhipicephalus sanguineus*.

Treatment: In every case, chemotherapy with imidocarb, phenamidine, diminazene aceturate or trypan blue is advisable immediately after clinical diagnosis, since death may occur rapidly (Table 12.13). Diminazene has a low therapeutic index and toxicity appears to be dose-related, although idiosyncratic reactions may occur. In addition to anti-babesial treatment, supportive care should be provided. In dogs with severe anaemia, blood transfusion should be considered.

Control: Prophylaxis depends on regular treatment of dogs with a suitable acaricide, and since *R. sanguineus* may live in kennels, these should also be frequently treated with a suitable acaricide. For dogs visiting tick-endemic regions, tick prevention should be practised (e.g. fipronil application). In addition, a degree of surveillance of dogs exposed to infection is advisable so that treatment can be administered as early as possible. A vaccine has recently been launched in Europe for use against *B. canis*. The vaccine contains surface proteins expressed by cultures of *B. canis* and *B. canis rossi* and provides up to 6 months' protection.

Babesia gibsoni

Common name: Canine piroplasmiasis

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: Small piroplasm, annular or oval in shape, and no more than one-eighth the diameter of the host erythrocyte.

Host: Dog

Geographical distribution: Asia, North Africa and occasionally North America

Pathogenesis: Highly pathogenic in dogs causing marked anaemia, remittent fever, haemoglobinuria, constipation, marked splenomegaly and hepatomegaly. The disease is usually chronic with remissions and relapses of fever. Death may not occur for many months.

Clinical signs: Similar to *B. canis*. In acute cases, the first sign is fever, followed by marked anaemia, jaundice, inappetence, marked thirst, weakness, prostration and often death.

Diagnosis: As for *B. canis*

Pathology: As for *B. canis*

Epidemiology: Tick vectors are *Haemaphysalis bispinosa* and *Rhipicephalus sanguineus*.

For both species of *Babesia*, an increasing number of cases are reported in parts of the world, such as northern Europe, where the disease did not previously exist and may be linked to establishment of ticks in previously non-enzootic regions, and with increasing international pet travel and trade.

Treatment: Diminazene is the drug of choice for the treatment of *B. gibsoni* since imidocarb is less effective against small babesial species (Table 12.14).

Control: As for *B. canis*. No vaccine is available for this species.

Notes: Phylogenetic analysis of DNA sequences has identified two strains of *Babesia gibsoni*: 'Asia' and 'California'. More recently, *Babesia annae* has been identified and appears to be endemic in Galicia, Spain and transmitted by the tick *Ixodes hexagonus* (see below).

Babesia felis

Synonyms: *Nuttallia felis*, *Babesia cati*

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Table 12.13 Babesicides for use in dogs against *B. canis*.

| Drug | Recommended dose | Frequency | Comments |
|-------------------------|----------------------|---------------------------|--|
| Imidocarb dipropionate | 5 mg/kg s.c. or i.m. | Two at 14-day interval | Pain at injection site |
| Diminazene (di)acetate | 3.5 mg/kg i.m. | Single | Low therapeutic index |
| Phenamidine isethionate | 15 mg/kg s.c. | Single or repeat 24 hours | Vomiting and CNS signs common side effects |
| Trypan blue | 10 mg/kg i.v. | | 1% solution, tissue irritant |

Table 12.14 Babesicides for use in dogs against *B. gibsoni*.

| Drug | Recommended dose | Frequency | Comments |
|-------------------------|------------------|---------------------------|--|
| Diminazene (di)acetate | 3.5 mg/kg i.m. | Single | Low therapeutic index |
| Phenamidine isethionate | 15 mg/kg s.c. | Single or repeat 24 hours | Vomiting and CNS signs common side effects |
| Parvaquone | 20 mg/kg s.c. | Single | |
| Clindamycin | 25 mg/kg | Twice daily | |

Description: Small piroplasms, with the majority of merozoites present in erythrocytes, round, irregularly round and 1.5–2 µm in diameter; some are elongate, 2–3 µm long and may form cruciform meronts.

Host: Cat

Geographical distribution: Africa

Pathogenesis: Infection usually manifests as an afebrile, chronic, low-grade disease.

Clinical signs: Affected animals show anorexia, depression, anaemia, emaciation, constipation and jaundice.

Diagnosis: Examination of blood films, stained with Romanowsky stains such as Giemsa, will reveal the parasites in the red cells. Species identification between large and small *Babesia* is essential with regard to choice of therapeutic drugs. Concurrent infection with other haemoparasites such as *Mycoplasma (Haemobartonella)* can be common in endemic areas and complicates the diagnosis.

Pathology: There is splenomegaly and jaundice, and complications are wide-ranging and include hepatopathy, renal failure, pulmonary oedema and immune-mediated haemolytic anaemia often associated with feline immunodeficiency disease, FeLV or feline infectious anaemia (*Mycoplasma*).

Epidemiology: Natural hosts are wild cats such as the lion and leopard. The highest prevalence is in young adult cats (<3 years old) during the spring and summer in endemic regions. The vectors are unknown, although *Haemaphysalis leachi* has been incriminated in South Africa.

Treatment: The antimalarial drug primaquine phosphate 0.5 mg/kg orally is the drug of choice for treating *B. felis* infections. Although it reduces the parasitaemia it does not sterilise the infection. Accurate dosing is required in cats to avoid toxicity, although vomiting is a common side effect at this dose rate.

Control: Reducing tick exposure is the best way to prevent infection, although this is rarely achievable in endemic areas. Care must be taken in cats with the use of acaricides due to their increased susceptibility to many compounds.

Theileria annae

Synonym: *Babesia annae*

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Theileriidae

Description: Merozoites are small, usually singular, 1 by 2.5 µm.

Hosts: Dog, fox

Geographical distribution: Parts of Europe (Spain)

Pathogenesis: Reported infections cause anaemia.

Cytauxzoon felis

Synonym: *Theileria felis*

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Theileriidae

Description: The single signet-ring-shaped forms present within erythrocytes are 1–1.2 µm in diameter. Bipolar oval forms, tetrads and dark-staining ‘dots’ may also be seen.

Hosts: Cat, bobcat (*Lynx rufus*)

Geographical distribution: USA

Pathogenesis: Infection of domestic cats with the merogenous stage typically results in a rapidly progressive systemic disease with a high mortality rate. In natural infections with *C. felis* there is an apparent variation in pathogenicity that may be associated with geographical location. During the merogenous phase there is mechanical obstruction to blood flow through various organs, notably the lungs, resulting in a shock-like state. Intravascular and extravascular haemolysis occurs because of erythrocyte invasion by merozoites.

Clinical signs: Soon after infection, affected cats develop non-specific signs, such as anorexia, lymphadenopathy, fever and lethargy, but the course of the disease is usually rapid, with the onset of a severe clinical syndrome characterised by dehydration, pallor, dyspnoea, icterus, recumbency and death. Usually, by the time the cat is presented, it is severely ill. Most cats die within 9–15 days following infection by virulent strains, regardless of treatment.

Diagnosis: Diagnosis is made by the identification of erythrocytic piroplasms in blood smears stained with Wright’s stain or Giemsa. Parasitaemias are typically low (1–4%) although in some acute infections as many as 25% of the red cells may be infected. *C. felis* is a small piroplasm that must be differentiated from *Babesia felis*, which is very similar in size and appearance under light microscopy, but differs in geographical location. Dark-staining ‘dot’ forms may be mistaken for a more common and widespread parasite of cats, *Mycoplasma (Haemobartonella)* spp., the cause of feline infectious anaemia. Tissue meronts can be demonstrated in impression smears from bone marrow, spleen or lymph nodes, where they are typically numerous. There is currently no serological assay commercially available.

Pathology: Affected animals are markedly dehydrated, with generalised pallor, jaundice and numerous petechiae and ecchymoses of the epicardium and serosal membranes of the abdominal organs, as well as the visceral pleura of the lungs and mucosa of the urinary bladder. Pulmonary vessels are enlarged and tortuous as a result of vascular occlusion by the tissue stages. The lymph nodes are enlarged, congested, or haemorrhagic and oedematous and the spleen is markedly enlarged. Extra-erythrocytic forms are found within phagocytes in the spleen, lymph nodes, lungs, liver, kidneys and sometimes veins of the heart, urinary bladder and bone marrow and contain hundreds of merozoites or indistinct Koch bodies.

Epidemiology: This species has been found in the erythrocytes and tissues of domestic cats in the USA. It is suspected that *Dermacentor variabilis* is the principal vector. The natural hosts are the North American wild cat species, such as the bobcat, and it is thought that transmission to domestic cats represents inadvertent infection of a dead-end host. The highest incidence of infection occurs during early summer through to autumn when ticks are most active.

Treatment: Once diagnosed, the prognosis is poor and treatment often unsuccessful. Treatment with diminazene aceturate or imidocarb dipropionate, both at 2 mg/kg i.m., may be used but may result in transient worsening of the condition. Supportive fluid therapy or blood transfusion may also be beneficial.

Control: Reducing tick exposure is the best way to prevent infection although this is rarely achievable in endemic areas. Care must be taken in cats with the use of acaricides due to their increased susceptibility to many compounds.

Hepatozoon spp.

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Hepatozoidae

Description: Gamonts are found in the cytoplasm of neutrophils and have an ellipsoidal shape, and round or pleomorphic nucleus.

Host: Cat

Geographical distribution: France, Israel, India, South Africa

Pathogenesis: Feline hepatozoonosis is characterised by skeletal and myocardial muscle involvement and is commonly associated with immunosuppressive viral disease caused by FIV and FeLV. Gamonts are found in peripheral blood neutrophils, although the level of parasitaemia is usually low with less than 1% of neutrophils containing gamonts.

Clinical signs: Infected cats have fever, and may show gait abnormalities, muscular weakness and paresis.

Diagnosis: Diagnosis is based on the detection of the parasite in blood smears.

Epidemiology: The epidemiology of the disease and the vector(s) are unknown.

Treatment and control: Oral administration of doxycycline 5 mg/kg for 10 days has been used to eliminate gamonts from the blood of domestic cats.

Notes: Hepatozoonosis is a rare infection in cats and the species involved have not been identified.

Anaplasma phagocytophilum

Synonyms: *Anaplasma phagocytophila*, *Ehrlichia phagocytophila*, *Cytoecetes phagocytophila*, *Anaplasma platys*, *Ehrlichia platys*

Common names: Tick-borne fever, pasture fever, canine granulocytic ehrlichiosis, human granulocytic ehrlichiosis, equine granulocytic ehrlichiosis, canine infectious thrombocytopaenia

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: Blood smears stained with Giemsa or Wright's stain reveal one or more loose aggregates (morulae or inclusion bodies, 1.5–5 µm in diameter) of blue–grey to dark-blue coccoid, coccobacillary or pleomorphic organisms within the cytoplasm of neutrophils.

Hosts: Sheep, cattle, dog, horse, deer, rodents, human

Geographical distribution: Probably worldwide; Europe (UK, Norway, Finland, Netherlands and Austria), USA, South America, Australia

Pathogenesis: Organisms enter the dermis via a tick bite and are then spread via the blood and/or the lymph and localise in mature granulocytes, mainly in neutrophils but also in eosinophils, of the peripheral blood. In dogs, severe pulmonary inflammation, alveolar damage and vasculitis of the extremities in the absence of bacterial organisms suggest an immunopathological course of events, such as cytokine-mediated stimulation of host macrophages and non-specific mononuclear phagocyte activity. The infection may also induce an overactive inflammatory response, such as a septic shock-like syndrome, or diffuse alveolar damage leading to respiratory distress syndrome. Phagocytic dysfunction of infected neutrophils may result in defective host defence and subsequent secondary infections have been reported.

Both animals and humans can be co-infected with various *Anaplasma*, *Ehrlichia*, *Borrelia*, *Bartonella*, *Rickettsia*, *Babesia* and arboviral species. Infection with any of these organisms causes a wide range of clinical and pathological abnormalities, ranging in severity from asymptomatic infection to death. The risk of acquiring one or more tick-borne infections may be dependent on the prevalence of multi-infected vectors. For example, *A. phagocytophilum* and *Borrelia burgdorferi* share both reservoir hosts and vectors, and in geographical areas where tick-borne fever is endemic, borreliosis is also prevalent.

Clinical signs: In dogs, the spectrum of clinical manifestations caused by *A. phagocytophilum* is wide but most commonly presents as an acute febrile syndrome. The incubation period may vary from 4 to 14 days, depending on the immune status of the infected individual and the bacterial strain involved. Infected dogs usually present with a history of lethargy and anorexia. Clinical examination commonly reveals fever, reluctance to move and, occasionally, splenomegaly. Less commonly, animals may show lameness, diarrhoea or nervous signs such as seizures. Systemic manifestations may include haemorrhage, shock and multiorgan failure.

Diagnosis: *Anaplasma phagocytophilum* should be considered when an animal presents with an acute febrile illness in an endemic geographic area. Stained blood smears should be examined and with Wright's stain morulae typically appear as dark-blue irregularly stained densities in the cytoplasm of neutrophils. The colour of the morulae is usually darker than that of the cell nucleus. Morulae are often sparse and difficult to detect and a negative blood smear cannot rule out *A. phagocytophilum* infection. Specific diagnostic tests include IFAT, immunoblot analyses, ELISA and PCR analyses. The most widely accepted diagnostic criterion is a fourfold change in titre by IFAT. However, cross-reactivity may occur with other members of the genera *Anaplasma* and *Ehrlichia*. Thrombocytopaenia can be a haematological finding although leucopaenia has also been reported in rare cases.

Pathology: The disease is characterised by haematological changes typified by thrombocytopaenia and leucopaenia. The leucopaenia is

a result of early lymphopaenia later accompanied by neutropaenia. Thrombocytopaenia is one of the most consistent haematological abnormalities in infected dogs. It may be moderate to severe and persists for a few days before returning to normal. Biochemical abnormalities may include mildly elevated serum alkaline phosphatase and alanine aminotransferase activities.

Epidemiology: Rodents as well as domestic and wild ruminants (sheep and deer) have been reported as reservoir hosts of *A. phagocytophilum* in Europe. The predominant reservoir host varies depending on the local natural and agricultural landscape. The vector of *A. phagocytophilum* in Europe is the common sheep tick *Ixodes ricinus* (Table 12.15). The organisms spend part of their normal life cycle within the tick and are transmitted trans-stadially. As the tick vector feeds on a wide range of vertebrate animals, transmission of the infectious agent may take place to multiple host species.

Treatment: Doxycycline 5–10 mg/kg for 3 weeks appears to be the most effective regimen for treating infections in dogs and cats. Severe disease may require treatment for longer periods. The most common side effects of doxycycline treatment are nausea and vomiting, which are avoided by administering the drug with food.

Control: In dogs and cats, infections can be prevented to some extent by avoiding tick-infested areas. Careful daily inspection for, and removal of, ticks is recommended in combination with the application of residual acaricidal products. Spray, spot-on liquid or collar formulations are available with residual efficacy of 1 month or more depending on the product.

Notes: The newly reclassified *Anaplasma phagocytophilum* combo nov. (formerly known as three separate ehrlichiae *E. phagocytophila*, *E. equi* and *Anaplasma platys* [formerly known as *E. platys*]) causes canine, equine and human granulocytic ehrlichiosis.

Ehrlichia canis

Common names: Canine monocytic ehrlichiosis, tropical canine pancytopenia

Predilection site: Blood

Table 12.15 Tick-borne *Rickettsia* of dogs.

| Disease agent | Disease | Primary tick vectors | Distribution |
|--|--|--|------------------------------------|
| <i>Ehrlichia canis</i> | Canine monocytic ehrlichiosis | <i>Rhipicephalus sanguineus</i> | Worldwide; tropical/temperate |
| <i>Ehrlichia chaffensis</i> | | <i>Amblyomma americanum</i> | Worldwide |
| <i>Ehrlichia ewingii</i> | Canine granulocytic ehrlichiosis | <i>Amblyomma americanum</i> | Southeastern and south central USA |
| <i>Anaplasma phagocytophilum</i> (including <i>A. platys</i>) | | <i>Ixodes</i> spp. <i>Rhipicephalus sanguineus</i> | Worldwide |
| <i>Rickettsia rickettsii</i> | Rocky Mountain spotted fever | <i>Dermacentor variabilis</i> <i>Dermacentor andersoni</i> | North and South America |
| <i>Rickettsia conorii</i> | Boutonneuse fever Mediterranean fever Indian tick typhus East African tick typhus | <i>Rhipicephalus</i> spp. <i>Amblyomma</i> spp. <i>Hyalomma</i> spp. | Europe Asia, Africa |

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: *Ehrlichia canis* is a small, pleomorphic, Gram-negative, coccoid, obligatory intracellular bacterium that parasitises circulating monocytes, intracytoplasmically in clusters (morulae). The earliest stages are small elementary bodies 0.2–0.4 µm in diameter, followed by slightly larger initial bodies 0.5–4 µm in diameter, and finally even larger inclusion bodies 4–6 µm in diameter. The organisms stain blue with Romanowsky stain, light red with Macchiavello stain and brown–black by silver stain.

Host: Dog

Geographical distribution: Asia, Europe, Africa, Australia and America

Pathogenesis: Following infection, ehrlichiae organisms enter the bloodstream and lymphatics and localise in macrophages, mainly in the spleen and liver, where they replicate by binary fission. From there, infected macrophages disseminate the infection to other organ systems. The incubation period is 8–20 days and is followed consecutively by an acute, a subclinical and a chronic phase. The acute phase may last 2–4 weeks, and if not treated may enter the subclinical phase of the disease. Dogs in this phase may remain persistent carriers of *E. canis* for months or years. The spleen plays a major role in the pathogenesis of the disease and persistence of infection appears to be within splenic macrophages. Some persistently infected dogs may recover spontaneously, but others subsequently develop the chronic severe form of the disease. Not all dogs develop the chronic phase, and factors leading to the development of this phase remain unclear. The prognosis at this stage is grave, and death may occur as a consequence of haemorrhage and/or secondary infection. Immunological mechanisms appear to be involved in the pathogenesis of the disease, through the production of antibodies that bind to erythrocyte membranes and of platelet-bound antibodies which appear to play a role in the pathogenesis of thrombocytopaenia. Other mechanisms involved in the development of the thrombocytopaenia include increased platelet destruction and shortened platelet half-life during the acute phase and decreased production in the chronic phase. Meningitis and meningoencephalitis are associated with extensive lymphoplasmacytic and monocytic infiltration, perivascular cuffing and gliosis. On rare occasions morulae may be detected in the cerebrospinal fluid of dogs with neurological signs. The finding of circulating immune complexes in sera of naturally infected dogs suggests that some of the pathological and clinical manifestations are mediated by immune complexes.

Clinical signs: *Ehrlichia canis* infects all breeds of dogs; however, the German shepherd appears to be more susceptible to clinical disease and more severely affected than other breeds, with a higher mortality rate. There is no age predilection, and both sexes are equally affected. The disease is manifested by a wide variety of clinical signs. During the acute phase, clinical signs range from mild and non-specific to severe and life-threatening. Common non-specific signs in this phase include depression, lethargy, anorexia, pyrexia, tachypnoea and weight loss. Specific clinical signs include

lymphadenomegaly, splenomegaly, petechiation and ecchymoses of the skin and mucous membranes, and occasional epistaxis. Less commonly there is vomiting, and serous or purulent oculonasal discharge and dyspnoea. In the chronic severe form of the disease, clinical signs may be similar to those seen in the acute disease but more severe. There may be pallor of the mucous membranes and emaciation, and peripheral oedema, especially of the hindlimbs and scrotum, may also be seen. Entire bitches may show prolonged bleeding during oestrus, infertility, abortion and neonatal death. Secondary bacterial and protozoal infections may cause interstitial pneumonia and renal failure.

Ocular signs have been reported to occur during the acute and chronic phases and may manifest as conjunctivitis, petechiae and ecchymoses of the conjunctiva and iris, corneal oedema and panuveitis. Subretinal haemorrhage and retinal detachment resulting in blindness may occur due to a monoclonal gammopathy and hyperviscosity. Neurological signs include ataxia, seizures, paresis, hyperaesthesia and cranial nerve dysfunction, and may be attributed to meningitis or meningoencephalitis, which are more commonly seen during the acute phase.

Systemic manifestations may include haemorrhage, shock and multiorgan failure.

Diagnosis: Diagnosis of *E. canis* infection is based on history, clinical presentation and clinical pathological findings supported by serology. Residence in or travel to known endemic areas and a history of tick infestation should increase the suspicion of infection.

In general, *Ehrlichia* can be distinguished by the type of cell they invade. As the name of the disease it causes implies, *E. canis* invades mononuclear cells. Intracytoplasmic *E. canis* morulae may be visualised in monocytes during the acute phase of the disease in some cases. Examination of the buffy coat enhances the chance of visualising morulae in smears. During the acute phase there is an increase in the mean platelet volume, mild leucopaenia and anaemia, and megaplatelets appear in the blood smear reflecting active thrombopoiesis. Monocytosis, and reactive monocytes and large granular lymphocytes are also seen. During the subclinical phase a mild thrombocytopenia is a commonly found disease, with severe pancytopenia as a result of a suppressed hypocellular bone marrow.

On blood biochemistry there is hypoalbuminaemia and hyperglobulinaemia, the latter mainly due to hypergammaglobulinaemia, which is usually polyclonal, as determined by serum protein electrophoresis. On rare occasions, monoclonal gammopathy may be noticed and may result in a hyperviscosity syndrome. Pancytopenic dogs manifest significantly lower concentrations of total protein, total globulin and gamma-globulin concentrations compared with non-pancytopenic dogs. Mild transient increase in serum alanine aminotransferase and alkaline phosphatase may also be present. Anti-platelet antibody test as well as Coombs' test may be positive in infected dogs.

IFAT is the most widely used serological assay for the diagnosis of canine ehrlichiosis, and titres at a dilution equal to or greater than 1 : 40 are considered evidence of exposure. Two consecutive tests are recommended, 1–2 weeks apart, with a fourfold increase in antibody titre indicative of active infection. In areas endemic for other *Ehrlichia* species, serological cross-reactivity may complicate the diagnosis. ELISAs for *E. canis* antibodies have been developed and several commercial dot-ELISA antibody tests have been developed for rapid in-clinic use. PCR assays using specific primers for *E. canis* have also been developed. Concurrent infections with other

tick-borne pathogens, such as *Babesia* spp. and *Hepatozoon canis*, are common in endemic areas and it is therefore important to examine blood smears of infected dogs microscopically and to consider multiple serological or PCR screening for co-infecting organisms.

Pathology: Once present in tissues, *E. canis* organisms continue to invade, persist and replicate in cells. Circulating infected cells may induce vasculitis and subsequent intravascular coagulation, which, in combination with an altered cell-mediated immunity, result in the destruction of platelets. Similar destruction of leucocytes and erythrocytes in combination with decreased erythrocyte production may cause clinical leucopaenia and anaemia, respectively. During the subclinical phase, thrombocytopenia, leucopaenia and anaemia may continue. Hyperglobulinaemia may be observed in the chronic stages, which is unrelated to serum antibody levels. Bone marrow may be impaired during the chronic phase, although the mechanisms for suppression are not completely understood.

Epidemiology: *Ehrlichia canis* is transmitted by the brown dog-tick, *Rhipicephalus sanguineus*. Transmission has also been shown to occur experimentally with the American dog-tick, *Dermacentor variabilis*. Transmission in the tick occurs trans-stadially, but not transovarially. Larvae and nymphs become infected while feeding on rickettsaemic dogs and transmit the infection to the host after moulting to nymphs and adults, respectively. Adult ticks have been shown to transmit infection 155 days after becoming infected. This phenomenon allows ticks to overwinter and infect hosts in the following spring. The occurrence and geographical distribution of *E. canis* is related to the distribution and biology of its tick vector. *Rhipicephalus sanguineus* ticks are abundant during the warm season, and disease in dogs is seen most commonly during the summer months. Dogs living in endemic regions and those travelling to endemic areas should be considered at risk of infection.

Treatment: Doxycycline 10 mg/kg once daily by mouth (or 5 mg/kg twice daily), for a minimum of 3 weeks, is the treatment of choice for acute infections, and most acute cases respond and show clinical improvement within 24–72 hours. Dogs in the subclinical phase may need prolonged treatment, while dogs suffering from the chronic severe form of the disease are usually unresponsive to treatment. Other drugs with known efficacy against *E. canis* include tetracycline hydrochloride (22 mg/kg), oxytetracycline (25 mg/kg) and chloramphenicol (50 mg/kg) all given at 8-hourly intervals. Despite treatment, antibody titres may persist for months and even for years. Their persistence may represent an aberrant immune response, or treatment failure, but progressive decrease in gamma-globulin concentrations is associated with elimination of the rickettsia. *Ehrlichia canis* antibodies do not provide protection against rechallenge, and seropositive dogs remain susceptible.

Control: No effective anti-*E. canis* vaccine has been developed and tick control remains the most effective preventive measure against infection. Breaking the life cycle of the tick vector at the level of the canine host will eliminate the source of numerous pathogenic agents, in addition to ehrlichiae, that infect dogs and may decrease the risk of transmission to humans for those tick vectors with broad host ranges. Common acaricides such as amitraz, fipronil and pyrethrin, when used according to the manufacturer's instructions, are effective. By targeting the vector, the life cycle and consequently transmission of ehrlichiae will be interrupted. In endemic areas, low-dose oxytetracycline treatment (6.6 mg/kg) once daily has been suggested as an additional prophylactic measure.

Ehrlichia chaffensis

Common name: Canine monocytic ehrlichiosis

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: *Ehrlichia chaffensis* is a small, pleomorphic, Gram-negative, coccoid, obligatory intracellular bacterium that parasitises circulating monocytes and macrophages, intracytoplasmically in clusters (morulae).

Hosts: Dog, human, deer

Geographical distribution: States of southern USA

Pathogenesis and clinical signs: Experimental infections in dogs have shown fever only. The clinical significance of natural canine infection has yet to be determined.

Diagnosis: The IFAT detects exposure to the rickettsia, but it cannot differentiate between antibodies to other canine ehrlichiae. Species identification is by western immunoblot analysis and by PCR using species-specific primers.

Epidemiology: *Ehrlichia chaffensis* is transmitted by *Amblyomma americanum* (lone star tick) and to a lesser extent by *Dermacentor variabilis*. Persistently infected white-tailed deer (*Odocoileus virginianus*), and possibly canids, serve as reservoirs.

Treatment and control: As for *E. canis*, although treatment is not usually required.

Ehrlichia ewingii

Common name: Canine granulocytic ehrlichiosis

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: *Ehrlichia ewingii* is a small, pleomorphic, Gram-negative, coccoid, obligatory intracellular bacterium that parasitises circulating neutrophils and eosinophils, intracytoplasmically in clusters (morulae).

Host: Dog

Geographical distribution: Southeast and south central USA

Pathogenesis: Following infection, ehrlichiae enter the bloodstream and lymphatics and localise in neutrophils. The pathogenesis of polyarthritis, observed more often with infection by granulocytic ehrlichiae, arises from haemarthrosis and immune complex deposition into the joints.

Clinical signs: The disease is usually an acute mild disease that may lead to polyarthritis in chronically infected dogs. Lameness, joint swelling, stiff gait and fever are common clinical signs. Haematological changes are mild and include thrombocytopenia and anaemia.

Diagnosis: Diagnosis of *E. ewingii* infection is based on history, clinical presentation and clinical pathological findings supported by serology. Residing in, or travel to, known endemic areas and a history of tick infestation should increase the suspicion of infection. Visualisation of morulae in the respective cell types provides a definitive diagnosis and allows differentiation between the monocytic and granulocytic ehrlichiae. Intracytoplasmic *E. ewingii* morulae may be seen within neutrophils.

The IFAT is the most widely used serological assay for the diagnosis of canine ehrlichiosis. However, as *E. ewingii* has not yet been cultured *in vitro*, antigen is not readily available for IFAT. In areas endemic for other *Ehrlichia* species, serological cross-reactivity with the monocytic *Ehrlichia* spp. may complicate the diagnosis. Anti-*E. ewingii* antibodies strongly cross-react with *E. canis* and *E. chaffensis*, and do not (or weakly) react with *A. phagocytophilum*. Western immunoblot and species-specific PCR assays should be used to confirm the ehrlichial species. Species determination is important, as *A. phagocytophilum* is also associated with intra-neutrophilic morula formation and similar clinical signs in dogs.

Pathology: After entering the canine host through the bite of the tick vector, ehrlichial organisms travel through the circulation, invade cells and disseminate to various tissues. Once in tissues, they continue to invade, persist and replicate in cells. Polyarthritis may arise from haemarthrosis and immune complex deposition into the joints and is often accompanied by neutrophilic inflammation.

Epidemiology: Ehrlichiosis caused by *E. ewingii* has been diagnosed in the USA only. It occurs mainly in the spring and early summer. The main tick vector is *Amblyomma americanum* but the organism has been identified in a number of other ticks, including *Rhipicephalus sanguineus*, *Dermacentor variabilis*, *Ixodes scapularis* and *I. pacificus*.

Treatment: Tetracyclines, especially doxycycline, elicit rapid clinical improvement.

Control: Tick control is the most effective preventive measure against infection. By targeting the vector, the life cycle and consequently transmission of ehrlichiae will be interrupted. Common acaricides such as amitraz, fipronil and pyrethrins, when used according to the manufacturer's instructions, are effective in controlling ticks.

Notes: *Ehrlichia ewingii* and the newly reclassified *Anaplasma phagocytophilum* combo nov. cause canine and human granulocytic ehrlichiosis. *Ehrlichia ewingii* has been implicated as the cause of human infections in the USA, particularly in immunocompromised people. The role of the dog as a zoonotic reservoir for *E. ewingii* infection is unknown.

Rickettsia rickettsii

Common name: Rocky Mountain spotted fever

Predilection site: Blood vessels

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Rickettsiaceae

Description: Small, pleomorphic, Gram-negative, coccoid, obligatory intracellular organisms infecting endothelial cells of smaller blood vessels.

Hosts: Dog, human

Geographical distribution: USA, Canada, Central America

Pathogenesis: Following infection the organisms enter the bloodstream and infect endothelial cells, causing widespread vasculitis leading to activation of the coagulation and fibrinolytic pathways. Thrombocytopenia occurs through coagulatory and immune-mediated mechanisms. In chronic untreated cases, organs such as the skin, brain, heart and kidneys may develop multiple foci of necrosis and vascular injury leads to leakage of intravascular fluids and oedema. Fluid accumulation in tissues such as the CNS can cause significant brain oedema, resulting in progressive mental and cardiorespiratory depression.

Clinical signs: Infected dogs usually develop fever within several days after tick exposure. This is usually accompanied by signs of lethargy, mental dullness, inappetence, arthralgia and myalgia, manifest as difficulty in rising and eventual reluctance to walk. Lymphadenomegaly of all peripheral lymph nodes is apparent, and subcutaneous oedema and dermal necrosis may develop in severely affected animals. Petechial haemorrhages may occur rarely on the mucous membranes, and more commonly in the ocular fundus. Neurological signs may appear due to meningitis and can include hyperaesthesia, seizures, vestibular dysfunction and a variety of manifestations depending on the lesion localisation. Recovery is rapid and complete in those animals receiving treatment early, before the onset of organ damage or neurological complications. Once the neurological signs have developed, recovery is delayed, or signs may be permanent.

Diagnosis: Clinical laboratory findings are non-specific for a generalised acute-phase inflammatory reaction. There is usually a leucopenia in the acute stages followed by a moderate leucocytosis. A left shift and toxic granulation of neutrophils may be observed in animals with the most severe tissue necrosis. Thrombocytopenia is one of the most consistent laboratory findings. Serum biochemical abnormalities include hypoalbuminaemia, elevated serum alkaline phosphatase activity, and variable hyponatraemia and hyperbilirubinaemia. Conduction disturbances related to myocarditis may be seen on electrocardiography and a diffuse increase in pulmonary interstitial density on radiography. A micro-immunofluorescence (Micro-IF) test is used to determine specific antibodies. Titres above 1 : 1024 generally indicate recent exposure. PCR-specific primers have been used to identify organisms in blood or tissue specimens. Rickettsial isolation involves risk and can only be done in secure biocontainment facilities.

Pathology: On postmortem, there are usually widespread petechial and ecchymotic haemorrhages, lymphadenomegaly and splenomegaly. Microscopically, there is a widespread necrotising vasculitis in many organs.

Epidemiology: Two tick species, *Dermacentor andersoni* (wood tick) and *D. variabilis* (dog tick), both three-host ticks, appear to be mainly involved in the transmission of *R. rickettsii*. Only a small

proportion of ticks may be infected in the overall population of a given area. In addition to the low prevalence of infection, infected ticks are not immediately infectious but become so following tick attachment and blood feeding for periods of 5–20 hours. Dogs usually develop illness during the warmer months of the year when questing ticks are active. This seasonality is less noticeable at lower latitudes.

Treatment: Left untreated, the disease is highly fatal and treatment should be instituted whenever the disease is suspected. Tetracyclines are the antibiotics of choice and should be administered for at least 7 days, but are only effective if they are given prior to the onset of tissue necrosis or organ failure. Recovery is usually associated with protective immunity.

Control: Prevention can be achieved by tick control and periodic treatment with systemic or topically applied acaricides.

Notes: Rocky Mountain spotted fever is an important zoonotic disease because of its high prevalence and potentially fatal outcome if diagnosis is delayed or missed. Early signs in humans may be vague and misdiagnosis can occur until a rash develops later in the course of disease.

Rickettsia conorii

Common names: Boutonneuse fever, Mediterranean spotted fever, Indian tick typhus, East African tick typhus

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Rickettsiaceae

Description: Small, pleomorphic, Gram-negative, coccoid, obligatory intracellular organisms infecting endothelial cells of smaller blood vessels.

Hosts: Rodents, dog, cattle, sheep, goat, human

Geographical distribution: Southern Europe, Africa, India and the Oriental region

Pathogenesis: Infections appear to be non-pathogenic.

Diagnosis: The rickettsiae can be demonstrated by staining blood or organ smears with Giemsa or may be detected serologically.

Epidemiology: The vector of Mediterranean boutonneuse fever is *Rhipicephalus sanguineus*. Apart from dogs, sheep and cattle, other small free-living mammals, such as rats, mice and shrews, are believed to play an important role in the cycle of infection within tick vectors.

Treatment and control: Not usually required although if infection is suspected, tetracyclines are usually effective.

Rickettsia felis

Predilection site: Blood vessels

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Rickettsiaceae

Description: Small, pleomorphic, Gram-negative, coccoid, obligatory intracellular organisms infecting endothelial cells of smaller blood vessels.

Hosts: Cat, dog, human

Geographical distribution: North and South America, Europe

Pathogenesis and clinical signs: The pathogenesis of natural infections in dogs and cats is unknown. Cats infected with *R. felis* through exposure to infected fleas develop a subclinical infection.

Epidemiology: In endemic areas of the USA, opossums are major reservoirs for *R. felis*. Infection to dogs and cats is transmitted by the cat flea, *Ctenocephalides felis*.

Treatment and control: Treatment with tetracyclines is likely to be effective but seldom indicated. Prevention can be achieved by flea control and periodic treatment with systemic or topically applied insecticides.

Notes: *Rickettsia felis* causes flea-transmitted human typhus along with *R. typhus*; the latter is transmitted by rodent fleas.

Haemobartonella felis

Synonyms: *Mycoplasma haemofelis*, *Candidatus Mycoplasma turicensis*, *Mycoplasma haemominutum*

Predilection site: Blood

Kingdom: Bacteria

Phylum: Firmicutes

Order: Mycoplasmatales

Family: Mycoplasmataceae

Description: Small, pleomorphic, Gram-negative, coccoid, obligatory intracellular organisms infecting erythrocytes.

Host: Cat

Geographical distribution: Northern and southern Europe

Pathogenesis: Haemoplasmas induce anaemia by haemolysis and sequestration. The disease may be acute or chronic with periodic recrudescence of clinical signs. Recovered cats may remain carriers. Infection with *Candidatus M. haemominutum* does not often result in clinical signs but a fall in packed cell volume does occur.

Clinical signs: In the acute form, there is intermittent fever with a progressive anaemia.

Diagnosis: The organisms can be detected in blood smears stained with Romanowsky stain.

Pathology: There are no specific or pathognomonic pathological findings, although cats with concurrent FeLV infection develop more pronounced lesions. Tissues are usually pale and on occasions jaundiced. The liver is often pale and jaundiced.

Splenomegaly and lymph node enlargement have been reported. Histology of the liver includes centrilobular congestion and degeneration, and in cats with concurrent FeLV there may be haemosiderosis. In the spleen there is congestion, extramedullary haemopoiesis, follicular hyperplasia, erythrophagocytosis and haemosiderosis.

Epidemiology: Transmission of the disease probably depends on arthropods including lice, fleas, ticks and biting flies and, at least in the case of *H. felis*, by ingestion of blood during fighting. Infection is most common in young cats.

Treatment and control: Treatment with tetracyclines is effective. Control blood-sucking arthropods with insecticides and instigate prompt treatment following cat fights.

Notes: The taxonomy of this species is subject to much debate and there is a proposal to reclassify it into the bacterial genus *Mycoplasma* (class Mollicutes) based on 16S rRNA gene sequences and phylogenetic analysis. DNA studies have additionally demonstrated the existence of two distinct species of *H. felis*: *Mycoplasma haemofelis* (large species) and *Candidatus Mycoplasma haemominutum* (small species). A third species *Candidatus Mycoplasma turicensis* has also been reported.

Parasites of the nervous system

EYES

Thelazia callipaeda

Common name: Eye worm

Predilection site: Eye, conjunctival sac and lacrimal duct

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Small, thin, white worms 1.0–1.7 cm long; males are 7–11.5 mm and females 7–17 mm.

Description, microscopic: In the male the left spicule is much longer than the right. In the female the vulva is in the oesophageal region. When laid the eggs contain a fully developed larva.

Final hosts: Dog, cat, human, primates and occasionally sheep and deer

Intermediate hosts: Muscid flies, particularly *Fannia* spp. and drosophilid fruit flies of the genera *Amiota* and *Phortica*

Geographical distribution: Far East

Pathogenesis: Lesions are caused by the serrated cuticle of the worm and most damage results from movement by the active young adults, causing lacrimation followed by conjunctivitis. Infection may predispose the host to secondary bacterial infection.

Clinical signs: Conjunctivitis, excessive lacrimation

Diagnosis: This is based on observation of the parasites in the conjunctival sac or on the conjunctiva following local anaesthesia, or finding larvae in the lacrimal secretion (Fig. 12.24).

Fig. 12.24 *Thelazia* in the eye of an infected dog.

Pathology: Invasion of the lacrimal gland and ducts may cause inflammation leading to occlusion and reduced tear production. Mechanical irritation of the conjunctiva produces inflammation, while damage to the cornea leads to opacity, keratitis and corneal ulceration.

Epidemiology: *Thelazia* infections occur seasonally and are linked to periods of maximum fly activity.

Treatment: Surgical removal with forceps following the application of an ocular local anaesthetic. In cases of secondary bacterial infection the use of antibiotic eye preparations may be indicated. Ivermectin 0.2 mg/kg s.c. has been reported to be effective, as has direct instillation of 1% moxidectin.

Control: Prevention is difficult because of the ubiquitous nature of the fly vectors.

Thelazia californiensis

Common name: Eye worm

Predilection site: Eye, conjunctival sac and lacrimal duct

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Small thin white worms 1.0–1.5 cm long.

Description, microscopic: A mouth capsule is present and the cuticle has prominent striations at the anterior end.

Final hosts: Dog, cat

Intermediate hosts: Muscid flies

Geographical distribution: North America

All other details as for *T. callipaeda*.

CENTRAL NERVOUS SYSTEM

Taenia solium

Synonym: *Cysticercus cellulosae*

Common name: Human pork tapeworm

Predilection site: Small intestine (final host); muscle (intermediate host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: The adult tapeworm is 3–5 m long with a scolex, typically taeniid, having a rostellum with four suckers and armed with two concentric rows of 22–32 hooks. The uterus of the gravid segment has 7–13 lateral branches. Adults can survive in humans for many years.

Description, microscopic: Cysts are milky white and have a scolex bearing a rostellum and hooks similar to the adult.

Final host: Human

Intermediate hosts: Pig, wild boar, rarely dog and human

Pathogenesis: Dogs that become infected with the metacystode stage can also show signs of cerebral cysticercosis with convulsions.

Encephalitozoon cuniculi

Synonym: *Nosema cuniculi*

Predilection site: Blood

Kingdom: Fungii

Phylum: Microsporidia

Order: Microsporida

Family: Enterocytozoonidae

Description: Microsporidia are obligate, intracellular, spore-forming protozoa. Trophozoites are 2–2.5 by 0.8–1.2 µm in tissue sections or 4 by 2.5 µm in smears. Spores are about 2 µm long and contain a spirally coiled polar filament with four to five coils.

Hosts: Rabbit, dog, fox (red and silver, *Vulpes vulpes*; blue, *Alopex lagopus*), cat, mouse, rat, human

Geographical distribution: Worldwide

Pathogenesis: The parasite develops within parasitophorous vacuoles in macrophages and other cells, especially vascular endothelial cells.

Clinical signs: Infection in dogs is usually asymptomatic, but there may be loss of condition, posterior weakness, incoordination, apathy and epileptiform seizures.

Diagnosis: Diagnosis in the live animal is difficult and is usually based on identifying the lesions on histopathology and observation of the organisms in Giemsa, Gram or Goodpasture-carbol fuchsin stains. A serum ELISA test is available.

Pathology: In the dog, there has been reported non-suppurative nephritis, encephalitis and vasculitis.

Epidemiology: Not reported in dogs, although in other hosts transmission via urine from infected animals has been described.

Treatment and control: Not reported in dogs.

Notes: Three strains of *Encephalitozoon* have been identified: strain I ('rabbit strain'); strain II ('rodent strain'); strain III ('dog strain'). Each of the three strains has been reported in humans and infections in dogs may therefore pose a potential zoonotic risk.

Toxoplasma gondii

For more details see Parasites of the locomotory system.

Neospora caninum

Synonym: *Histoplasma gondii*

Predilection site: Blood

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: Unsporulated oocysts in dogs are reported to be 11.7 by 11.3 μm (range 10.6–12.4 \times 10.6–12.0 μm) in size. Tachyzoites measure 6 by 2 μm and are usually located in the cytoplasm of cells. Tissue cysts are oval, 107 μm long, and have a thick wall (up to 4 μm) and are found only in neural tissue.

Final hosts: Dog, coyote, wolf, dingo

Intermediate hosts: Cattle, sheep, goat, deer, horse, dog, fox, chicken, wild birds

Geographical distribution: Worldwide

Pathogenesis: Neosporosis occurs most severely in transplacentally infected puppies and is characterised by a progressive ascending paralysis, particularly of the hindlimbs. Polymyositis and hepatitis may also occur. Clinical signs are first noticed at 1–6 months of age but can be seen in adults and older dogs. Sudden death due to myocarditis has been reported.

Clinical signs: Fatal, ascending hindleg paralysis

Diagnosis: History of neurological signs, muscle weakness with a progressive ascending paralysis. An IFAT is available; titres of 1 : 50 or greater are considered positive. A cerebrospinal fluid PCR can be used in diagnosing active CNS infection.

Pathology: Lesions are most commonly seen in the brain, spinal cord, nerve roots and skeletal muscles, but any organ may be involved including the skin. In the brain, the grey matter is most severely affected, while the submeningeal white matter tends to be most severely affected in the spinal cord. Tachyzoite proliferation is associated with focal malacia, suppuration and granulomatous reaction. Chronic lesions are characterised by lymphoplasmacytic perivascular infiltrations and gliosis. A marked fibrosis may develop, particularly in submeningeal areas of the cerebral and cerebellar cortex. Parasitised muscle fibres undergo rapid necrosis, and there are massive infiltrations of macrophages, lymphocytes and plasma cells. Tissue cysts are scarce and usually found only in the CNS.

Epidemiology: The dog and other canids are the final host, and can also act as intermediate hosts in prenatal infections. In naturally infected dogs, the main route of transmission is thought to be transplacental, with chronically infected bitches developing a parasitaemia during gestation that leads to successive litters becoming infected. Infected pups may either show clinical signs or carry infection subclinically leading to disease later in life following immunosuppressive illness or administration of immunosuppressive drugs.

Treatment: If canine neosporosis is diagnosed early, treatment with trimethoprim, sulphadiazine, pyrimethamine and clindamycin might be useful. Decoquinatate has been shown to kill *N. caninum* tachyzoites in cultures.

Control: Dogs should not be allowed to eat aborted fetuses or fetal membranes, and their faeces should be prevented from contaminating bovine feedstuffs.

Parasites of the reproductive/urogenital system

Capillaria plica

Synonym: *Pearsonema plica*

Common name: Bladder hairworm

Predilection site: Urinary bladder, and occasionally the pelvis of the kidney

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: Fine, whitish, filamentous worms 1–6 cm long; males measure 13–30 mm and females 30–60 mm.

Description, microscopic: The males have a long thin single spicule and often possess a primitive bursa-like structure. The medium-sized ovoid eggs are barrel-shaped, and have thick yellowish shells that are slightly striated with protruding transparent flattened bipolar plugs. They measure 63–68 by 24–27 μm and the almost colourless contents are granular and unsegmented. The egg is only observed in urine.

Final hosts: Fox, dog, wolf and more rarely cat

Intermediate hosts: Earthworms

Geographical distribution: Many parts of the world

Pathogenesis: It is rarely of pathogenic significance, but can occasionally induce cystitis where secondary bacterial infection occurs.

Clinical signs: Infections are usually asymptomatic. Cystitis and difficulty in urinating have been observed.

Diagnosis: Diagnosis is based on finding the typical *Capillaria* eggs in urine.

Pathology: Most infections are harmless; the anterior end of the worm embedded in the surface epithelium provokes a light cellular reaction in the lamina propria.

Epidemiology: The route of transmission is via the ingestion of infective larvae present in earthworms.

Treatment: Successful treatment with fenbendazole 50 mg/kg orally daily for 3 days has been reported.

Control: Care should be taken to ensure that runs are clean, dry and free-draining.

Capillaria feliscati

Synonym: *Pearsonema feliscati*

Common name: Bladder hairworm

Predilection site: Urinary bladder

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: Adult worms are small thread-like parasites; adult females measure 30–60 mm, males 13–30 mm long.

Description, microscopic: Eggs are oval and colourless with a thick capsule and typical bipolar plugs, and measure 50–68 by 22–32 μm .

Final host: Cat

Intermediate hosts: Earthworms

Geographical distribution: Many parts of the world

Pathology: *Capillaria feliscati* lie free on the surface of the bladder mucosa.

Dioctophyma renale

Synonyms: *Dictophyme renale*, *Eustrongylus gigas*

Common name: Giant kidney worm

Predilection site: Kidney parenchyma, abdominal cavity

Phylum: Nematoda

Class: Secernentea

Superfamily: Dioctophymatoidea

Description, gross: *Dioctophyma* is the largest parasitic nematode of domestic animals, the female measuring more than 60 cm in length, with a diameter of around 1.0 cm. The male is about 35–40 cm long. The worms are deep red–purple in colour. Their size and predilection site are sufficient for identification.

Description, microscopic: Male worm have only one spicule and possess a bell-shaped copulatory bursa. The eggs are lemon-shaped, yellowish-brown, with a thick pitted shell and slightly protruding bipolar plugs. They measure about 71–84 by 46–52 μm and the granular contents are unsegmented when passed. The eggs are observed in the urine.

Final hosts: Dog, fox, mink, ferret, otter, pine marten, polecat, mink; sporadically reported in the cat, pig, horse, cattle and human

Intermediate hosts: Aquatic oligochaetes (annelids), e.g. *Lumbriculus variegatus*

Geographical distribution: Temperate and sub-arctic areas; North and South America, Asia. It occurs sporadically in Europe, but has

not been recorded in Britain. Its main endemic area is the northern part of North America, chiefly Canada.

Pathogenesis: The final effect of infection is destruction of the kidney. Usually only one kidney is affected, the right being more often involved than the left. The parenchyma is destroyed leaving only the capsule as a distended sac containing the worms; though there may be three or four worms in a kidney, occasionally there is only one. Rarely, the worms may occur in the abdominal cavity, either free or encapsulated, and in the subcutaneous connective tissue.

Clinical signs: The main signs are dysuria with some haematuria, especially at the end of micturition; in a few cases there is lumbar pain. However, most cases are completely asymptomatic, even when one kidney has been completely destroyed. Worms in the abdominal cavity can cause a chronic peritonitis.

Diagnosis: The eggs are quite characteristic, being ovoid and yellowy-brown with pitted shells, and their occurrence in the urine, singly or in clumps or chains, is diagnostic.

Pathology: Adult worms in the renal pelvis are very destructive, causing initially haemorrhagic pyelitis which becomes suppurative, and the parenchyma is eventually destroyed until only the tunic contains the worm and exudate. In the abdominal cavity, the worm often entwines a lobe of the liver and may cause erosion of the hepatic capsule, leading to haemorrhage or infarction and rupture.

Epidemiology: As in many of the parasitic infections of domestic carnivores there is a large reservoir in wild animals from which the intermediate and paratenic hosts are infected. Ranch mink probably acquire infection from their fish diet, and domestic dogs by casual ingestion of infected annelids, frogs or fish.

Treatment: This is rarely called for, although surgery may be attempted in confirmed cases.

Control: Elimination of raw fish from the diet.

Notes: *Dioctophyma* (red scourge) infection in humans has been mainly recorded in North America, but other cases have occurred throughout the world. Annelid intermediate hosts in the drinking water are infective and uncooked frogs and fish act as paratenic hosts. The adult worms are found in a thick-walled cyst in the kidney (usually the right) and may cause loin pain and haematuria.

Parasites of the locomotory system

Trichinella spiralis

For more details see Chapter 11.

Toxoplasma gondii

Predilection site: Muscle, lung, liver, reproductive system, CNS

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystidae

Description: Oocysts in the faeces of cats are unsporulated when passed, spherical and measure 13 by 12 μm (Fig. 12.25). When

Fig. 12.25 Oocysts of *Toxoplasma gondii*.

sporulated, which takes 1–5 days, the oocysts are subspherical and measure 11–14 by 9–11 μm (mean $12.5 \times 10 \mu\text{m}$), and contain two ellipsoid sporocysts ($8.5 \times 6 \mu\text{m}$), each with four sporozoites, without a Stieda body and with a residuum.

Final hosts: Cat, other felids

Intermediate hosts: Any mammal, including human, or birds. Note that the final host, the cat, may also be an intermediate host and harbour extra-intestinal stages.

Geographical distribution: Worldwide

Pathogenesis: Most *Toxoplasma* infections in animals are light and consequently asymptomatic.

Clinical signs:

- Cats. Despite the fact that cats are frequently infected, clinical disease is rare, although enteritis, enlarged mesenteric lymph nodes, pneumonia, degenerative changes in the CNS and encephalitis have been recorded in experimental infections. Congenital transmission, although uncommon, has occurred following activation of bradyzoite cysts during pregnancy.
- Dogs. The onset of illness is marked by fever with lassitude, anorexia and diarrhoea. Pneumonia and neurological manifestations are common. Infection may occur in conjunction with distemper and has also been incriminated in distemper vaccination breakdowns. At necropsy, bradyzoite cysts can be demonstrated in cells in the brain and the respiratory tract; the associated lymph nodes are enlarged.

Diagnosis: Diagnosis is usually based on serological testing by latex agglutination test or ELISA.

Pathology: At necropsy, bradyzoite cysts can be demonstrated in cells in the brain and the respiratory tract; the associated lymph nodes are enlarged.

Epidemiology: Most cats become infected by ingesting *Toxoplasma*-infected animals, usually rodents, whose tissues contain tachyzoites or bradyzoites. Direct transmission of oocysts between cats can also occur. The ingestion of mature bradyzoites is the most important route and results in the shedding of higher numbers of oocysts than when infection is acquired from other stages. Following infection, the cyst wall is digested in the cat's stomach, and in the intestinal epithelium the liberated bradyzoites initiate a cycle of merogonous and gametogonous development culminating in the production of

oocysts in 3–10 days. Oocysts are shed for only 1–2 weeks. During this cycle in the intestinal mucosa, the organisms may invade the extra-intestinal organs where the development of tachyzoites and bradyzoites proceeds as in intermediate hosts.

Dogs are infected by the ingestion of undercooked meat containing *Toxoplasma* cysts.

The cat plays a central role in the epidemiology of toxoplasmosis and the disease is virtually absent from areas where cats do not occur. Epidemiological investigations in the USA and elsewhere indicate that 60% of cats are serologically positive to *Toxoplasma* antigen, the majority acquiring infection by predation. As might be expected infections are more prevalent in stray cats. Congenital infection is rare. Following infection, cats shed oocysts for only 1–2 weeks, after which they are resistant to reinfection. However, a proportion remain as carriers, perhaps due to the persistence of some meronts, and reactivation of infection with shedding of oocysts may occur in association with intercurrent disease, during the periparturient period in queens or following corticosteroid therapy. However, the oocysts appear to be very resistant and this compensates for the comparatively short period of oocyst excretion.

Treatment and control: Not indicated

Hepatozoon americanum

Common name: Canine hepatozoonosis

Predilection site: Blood, muscle

Phylum: Apicomplexa

Class: Aconoidasida

Family: Hepatozoidae

Description: Gamonts present within neutrophils are ellipsoidal in shape, 8.8 by 3.9 μm , with a central compact nucleus and enveloped in a thick membrane. The cytoplasm stains pale blue and the nucleus dark reddish with Giemsa stain. Muscle cysts are round to oval, 250–500 μm in diameter, with the outer portion composed of concentric layers of fine pale-staining lamellar membranes giving the cyst an 'onion skin' structure.

Host: Dog

Geographical distribution: Southeast USA

Pathogenesis: The earliest lesions occur in skeletal muscle with the formation of characteristic 'onion-skin' cysts comprising meronts and mucopolysaccharide lamellar membranes laid down by the host cells. Clinical signs in infected dogs result from the pyogranulomatous inflammatory response that occurs after the encysted mature meront ruptures, releasing merozoites into the surrounding tissue. Some cysts undergo merogony very rapidly while others appear to enter dormancy. Prolonged infection may occur from a single infecting episode perpetuated by repeated merogonic cycles. Infected dogs commonly develop osteoproliferative lesions, most frequently on the diaphysis of long bones. Pain results from both the pyogranulomatous inflammation in skeletal muscle and the osteoproliferative lesions. Prolonged infection may persist, perpetuated by prolonged merogony cycles. Muscle atrophy becomes apparent with chronic disease and can result in secondary weakness.

Clinical signs: Dogs infected with *H. americanum* are often presented with fever, generalised pain or hyperaesthesia, muscle atrophy,

weakness, depression, reluctance to rise and mucopurulent ocular discharge. Muscle atrophy becomes apparent with chronic disease and can result in secondary weakness. Most dogs maintain a relatively normal appetite, but weight loss is common due to muscle atrophy and chronic cachexia. Mucopurulent ocular discharge is common and is sometimes associated with decreased tear production. Less frequently, clinical signs include polyuria and polydipsia, abnormal lung sounds or cough, pale mucous membranes and lymphadenomegaly.

Diagnosis: Diagnosis based on the identification of gamonts in blood smears is unreliable because of the low numbers present in circulating blood. Blood samples should be examined rapidly using buffy coat smears. Muscle biopsy of the biceps or epaxial muscles is the most consistent method of identification of the characteristic cysts with pyogranuloma formation and the presence of parasites. An ELISA for *H. americanum* has been reported. Infected dogs have a marked neutrophilia, a mild to moderate normocytic normochromic non-regenerative anaemia and thrombocytosis.

Pathology: On postmortem, chronically infected dogs show cachexia and muscle atrophy, and osteoproliferative lesions may be apparent on bone surfaces. Grossly, pyogranulomas may appear as multiple foci, 1–2 mm in diameter, diffusely scattered predominantly in skeletal and cardiac muscle; they may also be found sporadically in other tissues including adipose tissue, lymph node, intestinal smooth muscle, spleen, skin, kidney, salivary gland, liver, pancreas and lung. Vascular changes in various organs include fibrinoid degeneration of vessel walls, mineralisation and proliferation of vascular intima, and pyogranulomatous vasculitis. Renal lesions are frequently present and include focal pyogranulomatous inflammation with mild glomerulonephritis, lymphoplasmacytic interstitial nephritis, mesangioproliferative glomerulonephritis and occasionally amyloidosis. Amyloid deposits may also be found in spleen, lymph nodes, small intestine and liver. Occasional findings include pulmonary congestion, splenic coagulative necrosis, lymphadenopathy and congestion of the gastric mucosa.

Epidemiology: The main vector of *H. americanum* is the Gulf Coast tick, *Amblyomma maculatum*, which is found in southern North America, Central America and the northern parts of South America. Infection is transmitted trans-stadially from nymph to adult stages of the tick vectors. Larval *A. maculatum* can also become infected and transmit *H. americanum* as newly moulted nymphs or adults. Infection appears to be mainly from ingestion of infected ticks. Vertical transmission has been reported.

Treatment: There is no effective treatment capable of eliminating all stages. Clinical remission can be obtained rapidly using a combination of trimethoprim–sulphadiazine (15 mg/kg twice daily), clindamycin (10 mg/kg three times daily) and pyrimethamine (0.25 mg/kg daily) over a period of 14 days. Palliative therapy with non-steroidal anti-inflammatory drugs (NSAIDs) may also be required to reduce fever and pain.

Control: As for *H. canis*

Parasites of the integument

Rhabditis strongyloides

Synonym: *Pelodera strongyloides*

Predilection site: Subcutaneous tissue, skin

Phylum: Nematoda

Class: Secernentea

Superfamily: Rhabditoidea

Description, gross: Very small worms, 1.0–2.8 mm in length with a rhabditiform oesophagus.

Description, microscopic: Larvae are approximately 600 µm in length.

Hosts: Dog, cattle, horse

Geographical distribution: Presumed worldwide

Pathogenesis: Worms invade the hair follicles causing an intense pruritus. Lesions, usually confined to areas of the body in contact with the ground, show hair loss, erythema and pustule formation if infected with bacteria. The intense itching is probably induced by an allergic reaction to the parasite.

Clinical signs: Pruritus, erythema and pustule formation

Diagnosis: The very small worms, 1.0–2.8 mm in length with a rhabditiform oesophagus, may be recovered from skin scrapings.

Pathology: The worms invade the follicles, attracting large numbers of eosinophils. An acute dermatitis develops, commonly with suppurative folliculitis due to secondary bacterial infection.

Epidemiology: These worms are saprophytic, living in warm moist soil rich in organic matter, and significant infections probably require the host's skin to be continually moist and dirty. Cases have been most frequently reported in dogs housed in kennels with damp hay or straw bedding.

Treatment: Treatment is symptomatic.

Control: The condition can be prevented by housing animals on clean dry bedding.

Acanthocheilonema reconditum

Synonym: *Dipetalonema reconditum*

Predilection site: Subcutaneous tissues, kidney and body cavity

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Male worms measure on average 1.5 cm and females about 2.5 cm.

Description, microscopic: The male spicules are unequal. The un-sheathed microfilariae are less than 300 µm in length and have a blunt head, and hooked posterior end with button-hook tails.

Final hosts: Dog and various canids

Intermediate hosts: Fleas (*Ctenocephalides canis*, *Ctenocephalides felis*, *Pulex irritans*), ticks (*Rhipicephalus sanguineus*), lice (*Heterodoxus spiniger*, *Linognathus setosus*) and mosquitoes

Geographical distribution: Africa, USA, Europe

Pathogenesis: The worms are not usually considered pathogenic.

Clinical signs: No associated clinical signs.

Diagnosis: *Acanthocheilonema reconditum* often occurs in the same endemic area as *Dirofilaria immitis* and the presence of its microfilariae may lead to misdiagnosis on blood examination. The identification of the microfilariae in the blood (samples ideally taken in the early evening) is aided by concentrating the parasites following lysis, filtration and then staining with methylene blue or May–Grunwald Giemsa. Commercial kits are available for this technique. Alternatively one part of blood and nine parts of formalin are centrifuged and the sediment mixed with a blue stain and examined as a microscopic smear. The microfilariae have to be differentiated from those of *D. immitis*, which are more than 300 µm in length and have a tapered head and a straight tail; those of *A. reconditum* are less than 300 µm in length and have a blunt head and a hooked posterior end. More precise differentiation may be achieved by using histochemical stains for acid phosphatase activity. *Dirofilaria immitis* shows distinct red acid-phosphate positive spots at the excretory pore and anus, while *A. reconditum* stains pink overall. Differential diagnosis may be achieved through the application of PCR-based recombinant DNA technology.

Pathology: No associated pathology. The presence of adult worms may occasionally cause subcutaneous abscessation and ulceration.

Epidemiology: Infection is presumably common in areas where the parasite and intermediate hosts coexist.

Treatment: Drug therapy is not usually indicated.

Control: Preventive measures include control of the intermediate hosts.

Acanthocheilonema grassi

Synonyms: *Dipetalonema grassi*, *Cercopithifilaria grassi*

Common name: Subcutaneous filarioidosis

Predilection site: Subcutaneous tissue

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: The adult worms are small, the females measuring about 2.5 cm in length.

Description, microscopic: Microfilariae are large, 570 µm in length, with a hook-shaped tail.

Final host: Dog

Intermediate hosts: Ticks and fleas

Geographical distribution: Southern Europe, Africa

Pathogenesis: *Acanthocheilonema grassi* inhabits the thoracic cavity and subcutaneous tissues. It is considered to be of low pathogenicity.

Clinical signs: Infection with this parasite is usually asymptomatic.

Diagnosis: Identification of the microfilariae in the blood (samples ideally taken in the early evening) is aided by concentrating the parasites following lysis, filtration and then staining with methylene blue or May–Grunwald Giemsa. Alternatively, one part of blood and nine parts of formalin are centrifuged and the sediment mixed

with a blue stain and examined as a microscopic smear. The microfilariae are large with a hook-shaped tail.

Pathology: No pathology is associated with the infection.

Epidemiology: Infection is presumably common in areas where the parasite and intermediate hosts coexist.

Treatment and control: Not required

Acanthocheilonema dracunculoides

Synonym: *Dipetalonema dracunculoides*

Predilection site: Peritoneum

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: The adult worms are small; male worms are 2.4–3 cm, females 3.2–6 cm in length.

Description, microscopic: Males have broad unequal spicules. Microfilariae are not sheathed, about 300 µm in length, with a short blunt tail.

Final hosts: Dog, hyena

Intermediate hosts: Ticks and fleas

Geographical distribution: Africa (Kenya) and parts of India

Pathogenesis and clinical signs: Not considered pathogenic.

All other details are essentially as for *D. reconditum*.

Dirofilaria repens

Synonym: *Noctiella repens*

Common name: Cutaneous dirofilariosis

Predilection site: Subcutaneous, intermuscular tissues

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: The adults are long slender worms measuring around 5 cm up to 15 cm in length. Males are 5–7 cm and females 13–17 cm.

Description, microscopic: Microfilariae measure 360 by 12 µm.

Final hosts: Dog, cat, fox, bear, occasionally human

Intermediate hosts: Mosquitoes of the genera *Aedes*, *Mansonia*, *Anopheles*, *Culex*

Geographical distribution: Mediterranean basin (Italy, Spain, Greece, France, former Yugoslavia), Middle East, sub-Saharan Africa, Asia, USA and Canada

Pathogenesis: The adults are found in nodules in subcutaneous and intermuscular tissues and the microfilariae in the blood and lymph. *Dirofilaria repens* is responsible for cutaneous dirofilariosis, causing

mild skin lesions and localised itching. It is of little pathogenic significance in dogs.

In humans, infection is usually asymptomatic. Subcutaneous nodules are found in the breasts, arms, legs, scrotum, eyelid, conjunctivae, penis and testes.

Clinical signs: Itching, mild skin lesions, subcutaneous nodules

Diagnosis: As the microfilariae of *D. repens* and *D. immitis* are morphologically similar, techniques such as isoenzyme characterisation and recombinant DNA application are required to distinguish these species.

Pathology: The presence of the adult parasites causes a local inflammatory reaction with accumulations of eosinophils and mononuclear cells.

Epidemiology: Infection is by biting mosquitoes and transmission is generally confined to warmer months when mosquitoes are active.

Treatment: Treatment is achieved by the surgical removal of the parasites from skin lesions.

Control: Mosquito control is difficult and therefore prophylaxis is based almost entirely on preventive medication with avermectins or milbemycins as used for *D. immitis*.

Dracunculus medinensis

Common names: Guinea worm, Medina worm

Predilection site: Subcutaneous connective tissue

Phylum: Nematoda

Class: Secernentea

Family: Dracunculidae

Description, gross: Males measure about 2–3 cm and females up to around 100 cm in length.

Description, microscopic: The female worm has no vulva.

Final host: Human and occasionally cattle, horse, dog, cat and other mammals

Intermediate hosts: Copepod crustaceans (*Cyclops* spp.)

Geographical distribution: Africa, Middle East and parts of Asia

Pathogenesis: Following initial infection there are virtually no signs of disease until the gravid adult female emerges in the subcutaneous tissues of the extremities. Pathogenesis is associated with cutaneous ulcer formation.

Clinical signs: The migration of the worm to the surface of the skin may induce pruritis and urticaria and a blister on an extremity.

Diagnosis: Symptoms of dracunculosis are pathognomonic.

Pathology: Secondary bacterial infection of the ulcer lesion or degeneration of worms can cause marked abscessation.

Treatment: The worm may be gradually removed through the lesion by winding it round a small stick at a rate of about 2 cm each day; alternatively it may be surgically excised. Treatment with thiazolidazole or niridazole, administered over several days, might be

effective. Ivermectin or albendazole may be useful but efficacy data are lacking.

Control: This is best achieved through the provision of clean drinking water or water that has been adequately sieved to remove any copepods.

Dracunculus insignis

Common name: North American Guinea worm

Predilection site: Subcutaneous connective tissue

Phylum: Nematoda

Class: Secernentea

Family: Dracunculidae

Final hosts: Raccoons and other carnivores, including dog and cat

Intermediate hosts: Copepod crustaceans (*Cyclops* spp.)

Geographical distribution: North America

Notes: Other aspects are essentially similar to *D. medinensis*.

Cutaneous leishmaniosis

Several species of *Leishmania* are responsible for cutaneous leishmaniosis, characterised by a moist ulcerative lesion at the site of insect bites that may become large and granulomatous.

Leishmania infantum

For more details see Parasites of the liver.

Leishmania tropica

Synonym: *Leishmania tropica* complex

Common names: Cutaneous leishmaniosis, 'dry' oriental sore, Jericho boil

Predilection site: Skin

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Description: *Leishmania* amastigotes are small, round or oval bodies, 1.5–3.0 by 2.5–6.5 μm , located within macrophages and possessing a large nucleus and rod-shaped kinetoplast associated with a rudimentary flagellum, which does not extend beyond the cell margin.

Hosts: Human, dog, rock hyrax (*Procapra capensis*)

Geographical distribution: In the dog, *L. tropica* occurs in central and southwest Asia and equatorial and southern Africa, Kenya and Namibia.

Pathogenesis: *Leishmania tropica* causes cutaneous leishmaniosis or 'oriental sore', the lesions developing at the site of the insect bite.

Gradually the lesion enlarges, remaining red but without heat or pain. Resolution involves immigration of leucocytes, which isolate the infected area leading to necrosis and granuloma formation. Macrophages infected with *Leishmania* organisms are eventually destroyed, and the animal recovers and is immune to reinfection.

Clinical signs: It may take many months or even years for infected dogs to develop clinical signs, so that the disease may only become apparent long after dogs have left endemic areas. Lesions are confined to shallow skin ulcers often on the lip or eyelid, from which recovery is often spontaneous.

Diagnosis: See *Leishmania donovani infantum*

Pathology: The basic lesions are foci of activated proliferating macrophages infected with *Leishmania* organisms. In some cases, these are ultimately surrounded by plasma cells and lymphocytes leading to necrosis and granuloma formation.

Epidemiology: The disease is urban in distribution and dogs are commonly infected. Transmission is by sandflies of the genus *Phlebotomus* (*P. sergenti*, *P. guggisbergi*), particularly in cities and rocky areas in semi-arid areas.

Treatment and control: See *Leishmania donovani infantum*.

Other *Leishmania* species reported in dogs include:

- *Leishmania aethiopica* found in the Highlands of Ethiopia and Kenya.
- *Leishmania major* in North Africa, southwest Asia (Algeria to Saudi Arabia) and central Asia (Iran to Uzbekistan), West Africa.
- *Leishmania peruviana* found on the mountain slopes of the western Andes in Peru and Bolivia.

ECTOPARASITES

LICE

Heavy louse infestation is known as pediculosis. Blood-sucking lice have been implicated in the transmission of disease such as anaplasmosis. However, lice are predominantly of importance because of the direct damage they cause, by either blood-feeding or chewing the skin or hair. Clinical importance is therefore usually a function of their density. Transmission of lice is usually by direct physical contact.

Description: Lice have a segmented body divided into a head, thorax and abdomen. They have three pairs of jointed legs and a pair of short antennae. All lice are dorsoventrally flattened and wingless. The sensory organs are poorly developed; the eyes are vestigial or absent.

Clinical signs: The most notable sign of louse infestation is a scruffy, dry hair or coat. Restlessness, rubbing and damage to the coat suggest that lice are present, and when the hair is parted the parasites will be found.

Diagnosis: The lice and their eggs may be seen within the hair and on the skin when the coat is parted. The lice may be removed and identified under a light microscope.

Pathology: Heavy infestations cause intense pruritus, associated with papulocrustous dermatitis or with patchy alopecia.

Treatment: Lice are killed by most organophosphates (e.g. chlorpyrifos, malathion or diazinon), amitraz, pyrethroids (e.g. permethrin)

and carbamates (e.g. carbaryl). Organophosphates and permethrin should not be used in cats; amitraz should be used only with care at half the dose applied to dogs. The more recent products imidacloprid, fipronil and the macrocyclic lactone selamectin may also be particularly effective with high safety margins. However, since the eggs are relatively resistant to most insecticides, repeat treatments 14 days apart may be recommended for some products in order to kill newly hatched lice.

Control: Since lice spend their entire life on the host animal, control is readily achieved through the use of topical insecticides on all in-contact animals. Lice can be spread on dirty, shared grooming equipment so appropriate hygiene is essential.

Felicola subrostratus

Synonym: *Felicola subrostrata*

Common name: Cat biting louse

Predilection site: Skin, face, pinnae, back

Class: Insecta

Order: Phthiraptera

Suborder: Ischnocera

Family: Trichodectidae

Description: This louse is beige or yellow in colour, with transverse brown bands. Adults are an average of 1–1.5 mm in length. The shape of the head is very characteristic, being triangular and pointed anteriorly (see Fig. 3.67). Ventrally there is a median longitudinal groove on the head, which fits around the individual hairs of the host. The antennae have three segments, are fully exposed and are similar in both sexes. The legs are small, slender and end in single claws. The abdomen has only three pairs of spiracles and is smooth with few setae.

Host: Cat

Geographical distribution: Worldwide

Pathogenesis: This is a chewing louse and is the only species of louse that commonly occurs on cats. Pediculosis is now rare and generally is seen only in elderly or chronically ill animals. It is more problematic in long-haired breeds and pathogenic populations may develop under thickly matted or neglected fur. Infestations most commonly occur on the face, back and pinnae, causing a dull ruffled coat, scaling, crusts and alopecia.

Epidemiology: Generally, infestation occurs via close bodily contact. This species of louse is highly host-specific. Infestations may be common in catteries, where asymptomatic carriers may act as reservoirs. Kittens may be particularly susceptible to infestation.

Heterodoxus spiniger

Predilection site: Skin

Class: Insecta

Order: Phthiraptera

Suborder: Amblycera

Family: Boopidae

Description: *Heterodoxus spiniger* is a large, slender, yellowish-coloured louse. Adults are about 5 mm in length, with a dense covering of thick, medium and long setae (see Fig. 3.60). It can easily be distinguished from other lice infesting domestic mammals since the tarsi end in two claws, as opposed to one in the Anoplura and Trichodectidae.

Hosts: Dog and other carnivores

Geographical distribution: Confined to tropical and subtropical regions between latitudes 40° N and 40° S

Pathogenesis: Lice infestations often accompany manifestations of poor health such as internal parasitism, infectious disease, malnutrition and poor sanitation.

Epidemiology: Infection occurs after direct contact with an infested host animal. Cross-contamination between different host species is possible if the animals have physical contact.

Notes: It is thought that *H. spiniger* evolved in Australasia as a louse of marsupials that subsequently switched to dingo hosts, and now parasitises a number of canids and other carnivores. *Heterodoxus spiniger* can be found anywhere on the body of the host.

Linognathus setosus

Common name: Dog sucking louse

Predilection site: Skin of head and neck areas

Class: Insecta

Order: Phthiraptera

Suborder: Anoplura

Family: Linognathidae

Description: This species of louse is up to 2 mm long when fully fed, with a long pointed head. It does not have eyes or ocular points. The second and third pairs of legs are larger than the first pair and end in stout claws. The thoracic sternal plate is absent or if present is weakly developed. Paratergal plates are absent from the abdomen.

Hosts: Dog and other canids

Geographical distribution: Worldwide

Pathogenesis: *Linognathus setosus* is a common and widespread parasite of dogs, particularly the long ears of breeds such as the spaniel, basset and Afghan hounds. It may cause anaemia and is usually of greater pathogenic significance in younger animals. *Linognathus setosus* is primarily found in the head and neck areas and is especially common under the collar.

Linognathus setosus has been shown to harbour immature stages of the filarial nematode *Acanthocheilonema reconditum*, which parasitises dogs. However, it is unknown whether the lice act as efficient vectors of these parasites.

Epidemiology: Generally, for the transfer of louse infestation, close bodily contact is necessary. Lice dropped or pulled from the host die in a few days, but eggs that have fallen from the host may continue to hatch over 2–3 weeks in warm weather. Therefore, bedding used by infested hosts should be disinfected.

Trichodectes canis

Common name: Dog biting louse

Predilection site: Skin, head, neck and tail regions

Class: Insecta

Order: Phthiraptera

Suborder: Ischnocera

Family: Trichodectidae

Description: *Trichodectes canis* is a small, broad, yellowish-coloured louse. It is 1–2 mm in length, with dark markings. The head is broader than long and the antennae are three-segmented, short and exposed (see Fig. 3.68). The legs are stout and their tarsi bear single claws, with which they tightly grasp the hair of their host. The abdomen has six pairs of spiracles on segments 2–6 and many rows of large thick setae.

Hosts: Dog, wild canids

Geographical distribution: Worldwide

Pathogenesis: *Trichodectes canis* can be a harmful ectoparasite of dogs, particularly in puppies and old or debilitated dogs. It is most commonly found on the head, neck and tail attached to the base of hairs. It feeds on tissue debris. It is a highly active species and infestation produces intense irritation around predilection sites. Lice often congregate around body orifices or wounds seeking moisture. Intense pruritus, scratching, biting, sleeplessness, nervousness and a matted coat are all typical of *T. canis* infestation. Skin damage caused by scratching results in inflammation, excoriation, alopecia and secondary bacterial involvement.

Trichodectes canis is important as a vector of the tapeworm *Dipylidium caninum*. Lice become infected when they ingest *D. caninum* eggs from dried host faeces. The tapeworm develops into a cysticercoid stage within the louse, where it remains quiescent until the louse is ingested by a dog during grooming. In the gut of the dog the cysticercoid is liberated and develops into an adult tapeworm.

MITES

Infestation by mites is called acariasis and can result in severe dermatitis, known as mange, which may cause significant welfare problems and economic losses.

All mites are small, usually less than 1 mm in length. The body shows no segmentation, although it can have various sutures and grooves. Adult and nymphal mites have four pairs of legs; larvae have only three pairs. The body is usually soft but may carry a number of hardened plates. Eyes are usually absent and hence most mites are blind. Hairs, or setae, many of which are sensory in function, cover the body of many species of mite. The mouthparts are highly specialised, consisting of a pair of chelicerae, which may be used for tearing, grasping or piercing.

Cheyletiella blakei

Predilection site: Face, but may occur all over the body

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Cheyletidae

Description: Adults are about 400 µm in length and ovoid. They have blade-like chelicerae that are used for piercing their host, and short strong opposable palps with curved palpal claws. The palpal femur possesses a long serrated dorsal seta. The body tends to be slightly elongated with a 'waist'. The legs are short; tarsal claws are lacking and the empodium is a narrow pad with comb-like pulvilli at the ends of the legs. Adults are highly mobile and are able to move about rapidly. The solenidion, on the genu of the first pair of legs, is conical in *C. blakei* (see Fig. 3.101c). However, this feature can vary in individuals and between life-cycle stages, making identification difficult.

Host: Cat

Geographical distribution: Worldwide

Pathogenesis: The mite is not usually highly pathogenic and is more often found in young animals in good physical condition. Long-haired cats tend to be more commonly infested than short-haired cats. This parasite is readily transferred to humans even on short contact, where it causes severe irritation and intense pruritus. A positive diagnosis on a pet may be associated with a history of persistent skin rash in the owner's family. Human cases will resolve spontaneously when the animal source has been treated.

Clinical signs: *Cheyletiella blakei* most commonly infests the facial area of cats, causing mild eczema-like skin conditions and associated pruritus. It is a characteristic of the dermatitis caused by *Cheyletiella* that many skin scales are shed into the fur, giving it a powdery or mealy appearance, and the presence of moving mites among this debris has given it the common name of 'walking dandruff'.

Diagnosis: In any case of excessive scurf or dandruff in the cat, *Cheyletiella* should be considered in the differential diagnosis. On parting the coat along the back, and especially over the sacrum, scurf will be seen, and if this is combed out onto dark paper the movement of mites will be detected among the debris. Scraping is not necessary as the mites are always on the skin surface or in the coat.

Pathology: The pathology of *Cheyletiella* infestation is poorly understood. In many cases there is very little skin reaction or pruritus. In the rare severe case, heavy infestations can result in the formation of small, crusty, erythematous papules involving much of the body surface; crusts are formed, but often there is only slight hair loss.

Epidemiology: This highly contagious though mild mange can spread rapidly through catteries and kennels. Transmission is usually by direct contact with infested animals, but the adult parasite can survive for over 10 days off the host and therefore bedding and furniture can act as a source of infestation. *Cheyletiella* mites may be phoretic on cat and dog fleas (*Ctenocephalides* spp.) and may be transmitted by these ectoparasites.

Treatment: Cats can be treated with a number of topical acaricidal shampoos, such as carbamates (e.g. carbaryl) and fipronil. Selenium sulphide shampoos have also been recommended for cats. Some products with low residual activity may require three successive weekly treatments.

Control: The cats, all in-contact animals and their surroundings should be treated to control infestation rates. This is particularly important in catteries, which often serve as a source of mite infestation.

Cheyletiella yasguri

Predilection site: Back and head, but may be found all over the body

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Cheyletidae

Description: Similar in appearance to *C. blakei*, but the solenidion, on the genu of the first pair of legs, is heart-shaped in *C. yasguri* (see Fig. 3.101d). Nevertheless, this feature can vary in individuals and between life-cycle stages, making identification difficult.

Host: Dog

Pathogenesis: The mite is not highly pathogenic and is often found in young animals in good physical condition. *Cheyletiella* may be more common on short-haired breeds of dog and many individuals act as asymptomatic carriers. It is a characteristic of the dermatitis caused by *Cheyletiella* that many skin scales are shed into the hair or fur, giving it a powdery or mealy appearance (Fig. 12.26). There is very little skin reaction or pruritus. In the rare severe case, involving much of the body surface, crusts are formed but there is only slight hair loss. This parasite is readily transferred to humans even on short contact, where it causes severe irritation and intense pruritus. A positive diagnosis on a pet may be associated with a history of persistent skin rash in the owner's family. Cases will resolve spontaneously when the animal source has been treated.

Treatment: Dogs can be treated with a number of topical acaricidal shampoos, such as carbamates (e.g. carbaryl), organophosphates (e.g. phosmet, chlorpyrifos, malathion or diazinon), permethrin, amitraz and fipronil. Oral milbemycin may be effective. Some of the older products with low residual activity may require three successive weekly treatments.

All other details are as for *C. blakei*.

Fig. 12.26 Marked 'dandruff' associated with *Cheyletiella* infection.

Otodectes cynotis

Common name: Ear mite

Predilection site: External ear canal. The mite may secondarily infest other parts of the body including the head, back, tip of tail and feet.

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Psoroptidae

Description: *Otodectes* resembles *Psoroptes* and *Chorioptes* in general conformation, having an ovoid body and projecting legs (see Fig. 3.94). Like *Chorioptes*, however, it is smaller than *Psoroptes* and does not have jointed pretarsi. The sucker-like pulvillus is cup-shaped, as opposed to trumpet-shaped in *Psoroptes*. In the adult female, the first two pairs of legs carry short stalked pretarsi, while the third and fourth pairs of legs have a pair of terminal whip-like setae. The fourth pair is much reduced. The genital opening is transverse. In males all four pairs of legs carry short stalked pretarsi and pulvilli, but the posterior processes are small (Fig. 12.27).

Hosts: Cat, dog and a number of other small mammals including the ferret and red fox

Geographical distribution: Worldwide

Pathogenesis: Most animals harbour this mite, and in adult animals it has almost a commensal association with the host, signs of irritation appearing only sporadically with the transient activity of the mites. The development of clinical signs reflects the development of allergic hypersensitivity by the host to antigenic substances produced by the mites while they are feeding. This can result in responses ranging from asymptomatic to severe otitis and convulsive

Fig. 12.27 Male *Otodectes cynotis*.

Fig. 12.28 Dark waxy exudate caused by *Otodectes* infection in the dog.

seizures in different individual hosts. Young animals probably acquire the mites from their mothers during suckling.

Early in infections, there is a brownish waxy exudate in the ear canal, which becomes crusty (Fig. 12.28). The mites live deep in the crust, next to the skin. Secondary bacterial infection may result. Scratching may cause excoriation of the posterior surface of the ear pinna. The resultant violent head shaking and ear scratching are a common cause of aural haematomas. In long-standing cases a severe purulent otitis may result.

Clinical signs: In general, the ear canals become inflamed and excessively moistened with accumulations of brown-black exudates in cats and grey deposits. This is accompanied by pruritus, and intense itching that causes the host to scratch the ears, shake the head or hold it to one side and turn in circles. Signs of severe untreated cases include emaciation, spasms, self-induced trauma and convulsions, including epileptiform fits. Perforation of the tympanic membrane can result. The clinical signs may be seen in dogs at an earlier stage than in cats and foxes, which do not appear to be affected until the infestation has reached high numbers and the disease is advanced.

Diagnosis: Tentative diagnosis is based on the behaviour of the animal and the presence of dark waxy deposits and exudate in the ear canal. Confirmation depends on observing the mites either within the ear or by removing some of the deposit and exudate and placing it on a dark surface where the mites will be seen by a hand lens as whitish moving specks.

Pathology: The canal becomes full of cerumen, blood and mite faeces, giving rise to a characteristic otitis externa. Mechanical irritation may account for some of the pruritus but, in addition, the presence of IgE-like antibodies suggests that hypersensitivity also contributes to the pruritus.

Epidemiology: Transfer may occur through direct contact or from infested female hosts to their pups or kittens.

Treatment: Topical application of systemic selamectin and imidacloprid has been found to give good control in both dogs and cats. There are also many effective preparations available commercially as eardrops, including, in dogs, permethrin, thiabendazole and monosulphiram. With these preparations treatment should be repeated to kill any newly hatched mites. In cats, treatments with milbemycin and ivermectin may be used, and in both cats and dogs

fipronil eardrops may be effective. When eardrops are used the ear canal should first be thoroughly cleaned; after the eardrops have been instilled, the base of the ear should be massaged to disperse the oily preparation.

Control: Any bedding should be replaced or thoroughly disinfected. In view of the ubiquity and high infectivity of the mite, all dogs or cats in the same household, or those in close contact in kennels and catteries, should be treated at the same time as clinically affected animals. In heavy infestations concurrent whole-body treatment may also be required to kill any mites that have moved out of the ear canal.

Sarcoptes scabiei

Common name: Scabies

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Sarcoptidae

Description, adults: The adult of this species has a round, ventrally flattened, dorsally convex body (see Fig. 3.89). Adult females are 0.3–0.6 mm long and 0.25–0.4 mm wide, while males are smaller, typically up to 0.3 mm long and 0.1–0.2 mm wide. The posterior two pairs of limbs do not extend beyond the body margin. In both sexes, the pretarsi of the first two pairs of legs bear empodial claws and a sucker-like pulvillus, borne on a long stalk-like pretarsus. The sucker-like pulvilli help the mite grip the substrate as it moves. The third and fourth pairs of legs in the female and the third pair of legs in the male end in long setae and lack stalked pulvilli. The mouthparts have a rounded appearance. These mites have no eyes or stigmata. The dorsal surface of the body of *S. scabiei* is covered with transverse ridges, but also bears a central patch of triangular scales. The dorsal setae are strong and spine-like. The anus is terminal and only slightly dorsal.

Hosts: All domestic mammals and humans

Geographical distribution: Worldwide

Pathogenesis:

- Dogs. The predilection sites for the mites are thinly haired areas such as the ears (Fig. 12.29), muzzle, face and elbows but, as in other manges, severe infestations may extend over the whole body. Visually, the condition begins as erythema, with papule formation, and this is followed by scale and crust formation and alopecia (Fig. 12.30). It is a characteristic of this form of mange that there is intense pruritus, which often leads to self-inflicted trauma. After a primary infection dogs begin to scratch within a week, often before lesions are visible. In cases that are neglected for a number of months the whole skin surface may be involved, dogs becoming progressively weak and emaciated. A strong sour odour is a notable feature of this form of mange.
- Cats. Sarcoptic mange is rare in cats. In the few recorded cases, the changes have been similar to those in *Notoedres* infection, with progressive hair loss from the ears, face and neck, extending to the abdomen.

Fig. 12.29 Thickened ear edge characteristic of sarcoptic mange.

Pathology: Dogs with chronic generalised disease develop seborrhoea, severe thickening of the skin, crust build-up, peripheral lymphadenopathy and emaciation. However, the lesions associated with canine sarcoptic mange are very non-specific. Usually there is dramatic epidermal hyperplasia and a subtle, diffuse and uniform eosinophilic perivascular dermatitis. However, cases may present with no eosinophilic infiltrate and sarcoptic mange should be a differential diagnosis for any hyperplastic pruritic dermatitis.

Treatment: Treatment can be either topical or systemic. For topical treatment in dogs effective acaricides include the organochlorines gamma-hexachlorocyclohexane and bromocyclen, and the organophosphates such as phosmet and amitraz, but the availabilities of some of these compounds is limited or non-existent in some countries. Lime-sulphur is highly effective and safe for use in young animals; several dips 5 days apart are recommended. Many preparations are combined with a surfactant, which aids contact with the

Fig. 12.30 Severe sarcoptic mange in a dog.

mites by removing skin scales and softening crusts and other debris. Selamectin spot-on is effective. Other macrocyclic lactones, such as moxidectin and ivermectin, are not registered for the treatment of sarcoptic mange in dogs, but have been reported to be effective depending on the dosage and route of administration. Hair can be clipped, the crusts and dirt removed by soaking with a good anti-seborrhoeic shampoo, and an acaricidal dip applied.

In cats lime-sulphur dips at 10-day intervals have been used. Selamectin spot-on may give good control, although this is not an approved application.

Control: Based on the protected location of the parasites, the duration of the life cycle and the necessity of killing all mites, dogs should be bathed weekly with an acaricidal preparation for 4 weeks, or longer if necessary, until lesions have disappeared. Because this is a highly contagious mange, affected dogs should be isolated and it should be explained to owners that rapid cure cannot be expected. To ensure that an outbreak is contained, all dogs on the premises should be treated if possible. In severely distressed dogs, oral or parenteral corticosteroids are valuable in reducing the pruritus and so preventing further excoriation.

For more detailed descriptions see Chapter 11.

Notoedres cati

Common name: Notoedric cat mite

Predilection site: Ears

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Sarcoptidae

Description: *Notoedres* closely resembles *Sarcoptes* with a circular outline and short legs with long unjointed pedicels, but it is distinguished by its concentric 'thumb print' striations and absence of spines (see Fig. 3.90). The dorsal scales are rounded and arranged transversely. This species is also smaller than *S. scabiei*; females are about 225 µm in length and males about 150 µm, with a short square rostrum. The anal opening is distinctly dorsal and not posterior. Females have suckers on legs 1 and 2.

Hosts: Largely cat, but may occasionally infest dogs or rabbits, also wild cats, foxes, canids and civets

Geographical distribution: Worldwide

Pathogenesis: *Notoedres cati* typically burrows in the stratum corneum and the stratum germinativum, occasionally invading hair follicles and sebaceous glands, causing hyperkeratosis and thickening of the epidermis. The infection appears as dry, encrusted, scaly lesions on the edges of the ears and on the face, the skin thickened and somewhat leathery. Advanced lesions can give cats a wrinkled thickened skin with hyperkeratinisation and hyperpigmentation causing an 'old age' appearance. The associated pruritus is often intense, and there may be severe excoriation of the head and neck from scratching. In typical cases the lesions appear first on the medial edge of the ear pinna, and then spread rapidly over the ears, face, eyelids and neck. It may be spread to the feet and tail by contact when the cat grooms and sleeps.

Clinical signs: Intense pruritus, erythema, skin scaling, greyish-yellow crusts and loss of hair. Scratching, to alleviate itching, leads to excoriation of the skin, inflammation and secondary bacterial infections. If untreated, the affected animal can become severely debilitated and notoedric mange may be fatal in 4–6 months.

Diagnosis: *Notoedres cati* occur in clumps in the skin, and are usually initially found around the head and ears causing an ear canker. Transient dermatitis can occur in humans. Diagnosis may initially be based on the intense pruritus, the location of lesions and the rapid spread to involve all kittens in a litter. Confirmation is achieved by finding the mites in skin scrapings.

Pathology: Infestation is associated with erythematous dermatosis, marked epidermal hyperplasia, dermal inflammation consisting principally of mononuclear cells and regional lymphadenopathy.

Epidemiology: Notoedric mange is highly contagious and transmission from host to host is by the spread of larvae or nymphs. It occurs in local, limited outbreaks, but usually the prevalence is very low. It is rarely seen in northern Europe for example, but is more common in eastern Europe. Where it is present, it is more commonly encountered in neglected or feral animals and where cats are housed in groups.

Treatment: Skin crusts should first be softened with liquid paraffin or soap solution before applying an acaricide. Lime-sulphur dips at 10-day intervals may be used. A 1% solution of selenium sulphide is also recommended for use in cats; treatment should be given at weekly intervals for 4–6 weeks, the prognosis being good. Although not licensed for the treatment of cats, selamectin and ivermectin may prove effective against *Notoedres*, although sudden death in kittens has been reported with the use of ivermectin.

Control: All in-contact animals should be treated and bedding replaced.

Notes: This genus has somewhat similar behaviour and pathogenesis to *Sarcoptes*, but has a more restricted host range.

Demodex canis

Predilection site: Hair follicles and sebaceous glands

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Demodicidae

Description: Species of *Demodex* have an elongate tapering body, up to 0.1–0.4 mm in length, with four pairs of stumpy legs ending in small blunt claws in the adult (see Fig. 3.100). Setae are absent from the legs and body. The legs are located at the front of the body, and as such the striated opisthosoma forms at least half the body length.

Host: Dog

Geographical distribution: Worldwide

Pathogenesis: For the most part, *Demodex* mites are non-pathogenic and form a normal part of the skin fauna. Occasionally they can cause significant clinical disease, particularly in dogs, where they cause demodectic mange or demodicosis.

Fig. 12.31 Demodectic mange on the muzzle of a dog.

Early in infection there is a slight loss of hair on the face and forelimbs, followed by thickening of the skin (Fig. 12.31). The mange may progress no further than the in-contact areas; many of these localised mild infections resolve spontaneously without treatment. On the other hand, lesions may spread over the entire body, and this generalised demodicosis may take one of two forms.

- Squamous demodicosis is the less serious. It is a dry reaction, with little erythema, but widespread alopecia, desquamation and thickening of the skin. In some cases of this type only the face and paws are involved.
- Pustular or follicular demodicosis is the severe form, and follows bacterial invasion of the lesions, often by staphylococci. The skin becomes wrinkled and thickened, with many small pustules from which serum, pus and blood ooze, giving this form its common name of 'red mange' (Fig. 12.32). Affected dogs have an offensive odour. Prolonged treatment is necessary, and survivors may be severely disfigured, so early euthanasia is sometimes requested by owners and by pedigree breeders.

Fig. 12.32 Pustular demodectic mange.

The pathogenesis of *Demodex* is more complex than that of other mange mites because immune factors appear to play a large part in its occurrence and severity. It is thought that certain bitches carry a genetically controlled factor that results in immunodeficiency in their offspring, making them more susceptible to mite invasion. It has been observed that littermates from such a bitch often develop the generalised form of demodectic mange simultaneously, even though they have been reared separately. In addition, *Demodex* itself is thought to cause a cell-mediated immunodeficiency that suppresses the normal T-lymphocyte response. This defect disappears when the mites have been eradicated from the animal. Demodectic mange may erupt when dogs are given immunosuppressants for other conditions.

Clinical signs: In early infection there is a slight loss of hair on the face and forelimbs, followed by thickening of the skin. Infection may resolve spontaneously or spread over the entire body. A common notable feature of all types of demodectic mange is the absence of pruritus, but this is not universal.

Diagnosis: For confirmatory diagnosis, deep scrapings are necessary to reach the mites deep in the follicles and glands. This is best achieved by taking a fold of skin, applying a drop of liquid paraffin, and scraping until capillary blood appears. Even in normal dogs a few commensal mites may be found in the material, but the presence of a high proportion of larvae and nymphs will indicate a rapidly increasing population and hence an active infection. Skin biopsy, to detect mites in the follicles, has been used in severely affected dogs, but is rarely necessary.

Pathology: In squamous demodicosis there is little erythema, but widespread alopecia, desquamation and thickening of the skin. In severe pustular or follicular demodicosis the lesions observed are variable and may include comedones, follicular papules and casts. More severely affected patients have deep folliculitis and furunculosis with severe haemorrhagic exudation and thick crusting. Demarcation between affected areas and normal skin is abrupt. Lymphadenopathy is common. There is bacterial invasion of the lesions, often by staphylococci. Dogs with chronic generalised demodicosis have depressed cell-mediated immune responsiveness, associated with the secondary bacterial infections. In some dogs only pododemodicosis is present. Pain and pedal oedema is especially prominent in large dogs.

Epidemiology: Probably because of its location deep in the dermis, it is very difficult to transmit *Demodex* between animals unless there is prolonged contact. It is thought that most infections are acquired in the early weeks of life during suckling. This view is supported by the fact that lesions first appear on the muzzle, face, periorbital region and forelimbs.

Treatment: Of the available acaricides, the most widely used is amitraz although the organophosphate cythioate may also be applied. With their deep location in the dermis the mites are not readily accessible to most topically applied acaricides, so repeated treatment is necessary and rapid results should not be expected. In localised squamous mange recovery may be expected in 1–2 months, but in the generalised pustular form the prognosis should indicate that recovery will take at least 3 months, and should, even so, be guarded.

Treatment with oral or injectable ivermectin 250–300 µg/kg, milbemycin 2 mg/kg and moxidectin 400 µg/kg have all been used successfully for the treatment of generalised canine demodicosis. Ivermectin and moxidectin should be initiated at lower doses and

patients monitored for possible adverse effects during therapy. Where pyoderma is severe, antibiotic therapy may be necessary.

Control: In controlling the endemicity of demodicosis, it should be noted that since certain bitches are more prone than others to have susceptible offspring, it may be advisable to discard these from breeding establishments.

Notes: Species of the genus *Demodex* are believed to form a group of closely related sibling species, which are highly specific to particular hosts: *Demodex phylloides* (pig), *Demodex canis* (dog), *Demodex bovis* (cattle), *Demodex equi* (horse), *Demodex musculi* (mouse), *Demodex rattii* (rat), *Demodex caviae* (guinea pig), *Demodex cati* (cat) and *Demodex folliculorum* and *Demodex brevis* (humans). Various morphological variations may be seen on a host, these are sometimes given separate species status.

Demodex cati

Predilection site: Hair follicles and sebaceous glands

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Demodicidae

Description: Species of *Demodex* have an elongate tapering body, up to 0.1–0.4 mm in length, with four pairs of stumpy legs ending in small blunt claws in the adult. Setae are absent from the legs and body. The legs are located at the front of the body, and as such the striated opisthosoma forms at least half the body length. Short forms may be found on the cat and are referred to as *Demodex gatoi*.

Host: Cat

Geographical distribution: Worldwide

Pathogenesis: Demodicosis is rare in cats. It manifests as a localised self-limiting form confined to the eyelids and periocular region and is of the mild squamous type, with some alopecia. Feline demodicosis is usually associated with underlying debilitating

disease such as diabetes mellitus, FeLV infection and systemic lupus erythematosus.

Clinical signs: Erythema, papules and thickened skin crusts, alopecia. Generalised demodicosis is very rare, but has been reported with variable pruritus, alopecia, scaling, crusting and hyperpigmentation on the head, neck, legs and trunk.

Diagnosis: For confirmatory diagnosis, deep scrapings are necessary to reach the mites deep in the follicles and glands. This is best achieved by taking a fold of skin, applying a drop of liquid paraffin, and scraping until capillary blood appears.

Treatment: In cats, 2% lime-sulphur dips may be effective when given every 5–7 days for six dips; amitraz rinses at 0.0125–0.025% have also been used successfully. In many cases demodicosis in cats resolves spontaneously and treatment is unnecessary.

Control: Control is rarely applied.

A number of non-specific ectoparasites, particularly fleas and ticks, are also found on dogs and cats and are listed in the host-parasite checklists at the end of this chapter. More detailed descriptions of these parasites can be found in Chapter 17.

HOST-PARASITE CHECKLISTS

In the following checklists, the codes listed below apply:

Helminths

N, nematode; T, trematode; C, cestode; A, acanthocephalan.

Arthropods

F, fly; L, louse; S, flea; M, mite; Mx, maxillopod; Ti, tick; Pn, pentostomid.

Protozoa

Co, coccidia; Bs, blood sporozoa; Am, amoeba; Fl, flagellate; Ci, ciliate.

Miscellaneous 'protozoal organisms'

B, blastocyst; Mi, microsporidian; My, *Mycoplasma*; P, Pneumocystidomycete; R, *Rickettsia*.

Parasites of poultry and gamebirds

ENDOPARASITES

Parasites of the digestive system

OESOPHAGUS

Eucoleus annulata

Synonym: *Capillaria annulata*

Common name: Hairworms or threadworms

Predilection site: Oesophagus, crop

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: These are very fine filamentous worms, the narrow stichosome oesophagus occupying about one-third to half the body length. Males measure around 15–25 mm and females 37–80 mm.

Description, microscopic: The males have a long thin single spicule, with a spiny spicule sheath, and often possess a primitive bursa-like structure. This species has a cuticular swelling at the back of the head. The females contain eggs that resemble those of *Trichuris* in possessing bipolar plugs (see Fig. 4.7). The medium-sized eggs are barrel-shaped and colourless to pale brown, 60–65 by 25–28 μm , and have thick shells that are slightly striated with bipolar plugs.

Final hosts: Chicken, turkey, ducks and wild birds

Intermediate hosts: Earthworms

Geographical distribution: Worldwide

Pathogenesis: Like *Trichuris* the anterior ends of the parasite are buried in the mucosa and even light infections can produce a catarrhal inflammation and thickening of the oesophagus and crop wall. Heavy infections may cause diphtheritic inflammation and marked thickening of the wall; in such cases mortality may be high.

Clinical signs: Light infections of less than 100 worms may cause poor weight gains and lowered egg production. Heavy infections often induce inappetence and emaciation.

Diagnosis: Because of the non-specific nature of the clinical signs and the fact that, in heavy infections, these may appear before

Eucoleus eggs are present in the faeces, diagnosis depends on necropsy and careful examination of the oesophagus and crop for the presence of the worms. This may be carried out by microscopic examination of mucosal scrapings squeezed between two glass slides; alternatively, the contents should be gently washed through a fine sieve and the retained material resuspended in water and examined against a black background.

Pathology: Presence of the adult worms causes catarrhal inflammation and thickening of the oesophagus and crop wall. Heavy infections may cause diphtheritic inflammation and marked thickening of the wall.

Epidemiology: Young birds are most susceptible to *Eucoleus* infections while adults may serve as carriers. The epidemiology is largely based on the ubiquity of the earthworm intermediate host.

Treatment: Levamisole in the drinking water is highly effective as are a number of benzimidazoles given in the feed. Elevated oral doses of these anthelmintics, administered over several days, also give high efficacy.

Control: Control depends on regular anthelmintic treatment accompanied, if possible, by moving the birds to fresh ground. Scrubbing and heat treatment of affected surfaces is essential as is the provision of fresh litter in chicken houses.

Notes: The taxonomy and systematics of these parasites have been changed many times because of a difficulty in designation of particular species' features and there are many synonyms in this group. As a consequence, some species of *Capillaria* are now listed under the generic name *Eucoleus*, although they may still be universally referred to as *Capillaria*.

Eucoleus contorta

For details see section Crop.

Gongylonema ingluvicola

For details see section Crop.

Dispharynx nasuta

For details see section Proventriculus.

Echinuria uncinata

For details see section Proventriculus.

Trichomonas gallinae

Synonyms: *Cercomonas gallinae*, *Trichomonas columbae*

Common names: Canker, frounce, roup

Predilection site: Oesophagus, crop, proventriculus

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is elongate, ellipsoidal or pyriform, 5–19 by 2–9 μm , with four anterior flagella that arise from the blepharoplast (see Fig. 2.13). The undulating membrane does not reach the posterior end of the body and a free posterior flagellum is absent. An accessory filament is present. The axostyle is narrow, protrudes 2–8 μm from the body and its anterior portion is flattened into a spatulate capitulum. There is a crescent-shaped pelta anterior to the axostyle and there is no chromatic ring at its point of emergence. The parabasal body is hook-shaped and has a parabasal filament and the costa is a very fine rod running three-quarters the length of the body.

Hosts: Pigeon, turkey, chicken, raptors (hawks, falcons, eagles)

Geographical distribution: Worldwide

Pathogenesis: In the turkey and chicken, lesions most commonly occur in the crop, oesophagus and pharynx and are uncommon in the mouth.

Clinical signs: Severely affected birds lose weight, stand huddled with ruffled feathers, and may fall over when forced to move. Yellow necrotic lesions are present in the oesophagus and crop and a greenish fluid containing large numbers of trichomonads may be found in the mouth.

Diagnosis: The clinical signs are pathognomonic and can be confirmed by identifying the characteristic motile trichomonads from samples taken from lesions in the mouth or from fluid.

Pathology: The early lesions in the pharynx, oesophagus and crop are small, whitish to yellowish caseous nodules. These grow in size and may remain circumscribed and separate, or may coalesce to form thick, caseous, necrotic masses that may occlude the lumen. The circumscribed disc-shaped lesions are often described as 'yellow buttons'. The lesions in the liver, lungs and other organs are solid, yellowish, caseous nodules up to 1 cm or more in diameter.

Epidemiology: Turkeys and chickens are infected through drinking contaminated water, the source of contamination being feral pigeons and other wild birds that also use the water source. Trichomonads enter the water from the mouths, not the faeces, of the wild birds. *Trichomonas gallinae* has no cysts and is very sensitive to drying, so direct contamination is necessary.

Treatment: Nitroimidazole compounds, such as dimetridazole and metronidazole, are effective but their availability has declined in many countries through legislative changes and toxicity concerns.

Control: Control in chickens and turkeys depends on preventing access of wild pigeons to drinking water.

CROP***Gongylonema ingluvicola***

Common name: Gullet worm

Predilection site: Crop, oesophagus and occasionally proventriculus

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Long slender worm. The female worm is 32–55 mm long and the males measure around 18 mm.

Description, microscopic: Easily distinguished microscopically by the presence of longitudinal rows of round or oval cuticular bosses in the anterior region of the body. The eggs measure approximately 58 by 35 μm .

Final hosts: Chicken, turkey, partridge, pheasant, quail

Intermediate hosts: Cockroaches (*Blatella germanica*) and beetles of the species *Copris minutus*

Geographical distribution: North America, Asia, Africa, Australia and Europe

Pathogenesis: The adult parasites are moderately pathogenic, depending on the number of worms embedded in the epithelium.

Clinical signs: Light infections are often asymptomatic. Heavier infections may produce regurgitation.

Diagnosis: Usually an incidental finding on postmortem.

Pathology: Heavy infections in fowl can induce hypertrophy and cornification of the epithelium of the crop.

Trichomonas gallinae

For details see section Oesophagus.

Eucoleus contorta

Synonym: *Capillaria contorta*

Predilection site: Oesophagus, crop

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: General description as for other *Eucoleus/Capillaria* species. Males measure around 12–17 mm and females 27–38 mm.

Description, microscopic: The medium-sized lemon-shaped eggs measure about 48–60 by 21–28 μm . They have slightly barrel-shaped asymmetrical side walls with protruding transparent polar plugs (see Fig. 4.7). Eggs have a thick brown shell with a smooth surface and their granular contents are unsegmented.

Final hosts: Chicken, turkey, pheasant, partridge, duck and wild birds

Intermediate hosts: Earthworms

Geographical distribution: Worldwide

Clinical signs: Low infections are frequently asymptomatic, possibly causing some reduction in growth and lower egg production. Severely infected birds often become anaemic, weak and emaciated.

Pathology: Large numbers of worms produce an inflammation varying from catarrhal to diphtheritic.

Epidemiology: Young birds are most susceptible to *Eucoleus* infections while adults may serve as carriers. *Eucoleus contorta* is important since, having a direct life cycle, it occurs indoors in birds kept on deep litter and outdoors in free-range systems, allowing large numbers of infective eggs to accumulate.

Control: Control depends on regular anthelmintic treatment accompanied if possible by moving the birds to fresh ground. Scrubbing and heat treatment of affected surfaces is essential as is the provision of fresh litter in chicken houses.

Details of the pathogenesis, diagnosis and treatment are as for *E. annulata*.

Eucoleus annulata

For details see section Oesophagus.

PROVENTRICULUS

Several spiruroid worms are found in the oesophagus, crop and proventriculus of poultry. The life cycles of these parasites are indirect, involving a range of invertebrate hosts. Infections with these parasites are more common in free-ranging birds. Attempts to control the poultry spiruroids are unlikely to be successful because of the ready availability of the intermediate hosts.

Tetrameres americana

Synonym: *Tropisurus americana*

Common name: Globular roundworm

Predilection site: Proventriculus

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: The adults show sexual dimorphism. The males are pale, white, slender and only about 5–6 mm long. The females are bright red and almost spherical, with a diameter of about 3.5–4.5 mm (Fig. 13.1).

Description, microscopic: Males have spiny cuticles and no cordons; females have four longitudinal deep furrows on the surface. Eggs are oval, thick-shelled, 42–60 by 24–45 µm and embryonated when passed. They are transparent in appearance and have thickened poles (see Fig. 4.7).

Final hosts: Chicken, turkey, duck, goose, grouse, quail, pigeon

Intermediate hosts: Cockroaches, grasshoppers and beetles

Fig. 13.1 Adult female *Tetrameres americana*.

Geographical distribution: Commonly occurs in Africa and North America

Pathogenesis: The females in the glands of the proventriculus are blood-suckers, and can cause anaemia as well as local erosion. Heavy infections may be fatal in chicks, but this genus is usually present only in moderate numbers and is well tolerated. The migration of juvenile stages into the wall of the proventriculus can cause inflammation and thickening.

Clinical signs: Infected fowl may become anaemic and lose condition. Heavy infections, particularly in young chickens, can induce thickening of the proventriculus with oedema and in some instances this can lead to partial blockage of the lumen. Heavy infections can be fatal.

Diagnosis: At necropsy, the female *Tetrameres* appear as dark-red spots when viewed from the serosal surface of the proventriculus.

Pathology: The wall of the proventriculus may be thickened to an extent that the lumen is almost obliterated.

Epidemiology: Infection is more common in free-ranging birds.

Tetrameres fassispinga

Synonym: *Tropisurus fassispinga*

Predilection site: Proventriculus

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: See *T. americana*. Males are pale, white, slender and 5–6 mm long. The females are bright red, ovoid/spherical, with a diameter varying from around 2.5 to 6 mm.

Description, microscopic: Males have four longitudinal rows of spines along the median and lateral lines and no cordons; females have four longitudinal deep furrows on the surface. Eggs are essentially similar to those of *T. americana* and measure 48–56 by 26–30 µm.

Final hosts: Duck, goose, chicken, turkey, pigeon and wild aquatic birds

Intermediate hosts: Aquatic crustaceans such as *Daphnia* and *Gammarus*, grasshoppers, earthworms

Geographical distribution: Most parts of the world

Details of the life cycle, pathogenesis, clinical signs, diagnosis and pathology are as for *T. americana*.

Tetrameres crami

Predilection site: Proventriculus

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: See *T. americana*. Males are white, slender and about 4 mm long. The red ovoid/spherical females measure around 2 by 1.5 mm.

Final hosts: Domestic and wild duck

Intermediate hosts: Amphipods such as *Gammarus fasciatus* and *Hyalella knickerbockeri*

Geographical distribution: North America

All other details are similar to *T. americana*.

Species of *Tetrameres* found in poultry are listed in Table 13.1. Details on pathogenicity in the host species are essentially similar to those for *T. americana*.

Table 13.1 Species of *Tetrameres* found in poultry.

| Species | Hosts | Intermediate hosts | Geographical distribution |
|------------------------------|--|---|---------------------------|
| <i>Tetrameres americana</i> | Chicken, turkey, duck, goose, grouse, quail, pigeon | Cockroaches, grasshoppers and beetles | Africa and North America |
| <i>Tetrameres fissipina</i> | Ducks, goose, chicken, turkey, pigeon and wild aquatic birds | Aquatic crustaceans, grasshoppers, earthworms | Most parts of the world |
| <i>Tetrameres crami</i> | Domestic and wild duck | Amphipods | North America |
| <i>Tetrameres confusa</i> | Chicken | ? | Brazil |
| <i>Tetrameres mohtedai</i> | Chicken | ? | India |
| <i>Tetrameres pattersoni</i> | Quail | ? | ? |

Dispharynx nasuta

Common name: Spiral stomach worm

Synonyms: *Dispharynx spiralis*, *Acuaria spiralis*, *Acuaria nascuta*

Predilection site: Oesophagus, proventriculus

Phylum: Nematoda

Class: Secernentea

Superfamily: Acuarioidea

Description, gross: The body is slender and coiled, particularly the posterior of the male. Males measure up to around 8 mm long and the females 10 mm.

Description, microscopic: The cuticle is ornamented with four wavy cordons that recurve anteriorly and do not fuse. The left spicule is slender and the right spicule shorter and oval-shaped. The eggs are thick-shelled, 33–40 by 18–25 µm and embryonated when passed.

Final hosts: Chicken, turkey, pigeon, guinea fowl, grouse, pheasant and other birds

Intermediate hosts: Various isopods such as sowbugs (*Porcellio scaber*) and pillbugs (*Armadillidium vulgare*)

Geographical distribution: Asia, Africa and the Americas

Pathogenesis: Mild infections usually provoke only a slight nodular inflammatory reaction in the mucosa with excessive mucus production.

Clinical signs: Most mild infections with *Dispharynx* are inapparent. Heavily infected young birds can rapidly lose weight, become emaciated and anaemic. Deaths can be high.

Diagnosis: A tentative diagnosis is based on the presence of spiruroid eggs, which are difficult to differentiate. Species identification is usually based on morphological identification of adult worms on postmortem.

Pathology: In severe infections, deep ulcers and hypertrophy can occur in the mucosa of the proventriculus in which the anterior ends of the worms are embedded.

Echinuria uncinata

Synonym: *Acuaria uncinata*

Predilection site: Oesophagus, proventriculus, gizzard

Phylum: Nematoda

Class: Secernentea

Superfamily: Acuarioidea

Description, gross: The body is slender and males measure 8–10 mm long and the females 12–18.5 mm.

Description, microscopic: The cuticle is ornamented with four wavy cordons that are non-recurrent and which anastomose in pairs. There are four pairs of pre-cloacal papillae in two groups of two either side, and four pairs of post-cloacal papillae. The left spicule is longer than the right spicule. The small ellipsoidal eggs are thick-shelled with a smooth surface. They measure on average 37 by 20 µm and are embryonated when passed (see Fig. 4.7).

Final hosts: Duck, goose, swan and various aquatic birds

Intermediate hosts: *Daphnia* and *Gammarus*

Geographical distribution: Worldwide

Pathogenesis: The worms can cause an inflammation of the alimentary tract and the formation of caseous nodules. These nodules can be very large in the gizzard and proventriculus and interfere with the passage of food.

Clinical signs: Infected birds may become weak and emaciated and deaths have been reported.

Hystrichis tricolor

Predilection site: Proventriculus, oesophagus

Phylum: Nematoda

Class: Secernentea

Superfamily: Dioctophymatoidea

Description, gross: Adult female worms measure up to about 4 cm and males 2.5 cm in length.

Description, microscopic: The cephalic area is expanded, and possesses many regularly positioned spines. The eggs are thick-shelled, coated with tubercles and have truncated poles. They measure about 85–88 by 36–40 µm and only develop slowly in water, taking around 8–9 weeks to reach the embryonated stage.

Final hosts: Domestic and wild ducks and anatid birds

Intermediate hosts: Oligochaetes (annelids)

Geographical distribution: The extent of the distribution is not known but it occurs occasionally in Europe.

Pathogenesis: The parasite induces nodule formation (pea-sized tumours) on the wall of the proventriculus and oesophagus. Sometimes these can perforate to the pleural cavity.

Clinical signs: Low infections are usually asymptomatic but heavy burdens can induce emaciation.

Eustrongyloides papillosus

Predilection site: Oesophagus, proventriculus

Phylum: Nematoda

Class: Secernentea

Superfamily: Dioctophymatoidea

Description, gross: Females measure about 3 cm in length.

Description, microscopic: The male has a bursal cup with a fringed margin. Eggs measure on average 68 by 38 µm.

Final hosts: Duck, goose

Intermediate hosts: Aquatic oligochaetes; fish as paratenic hosts

Eustrongyloides tubifex

Synonyms: *Stongylus tubifex*, *Eustrongylus tubifex*, *Hystrichis tubifex*

Predilection site: Oesophagus, proventriculus

Phylum: Nematoda

Class: Secernentea

Superfamily: Dioctophymatoidea

Description, gross: Males measure around 3.0–3.5 cm and females 3.5–4.5 cm in length.

Description, microscopic: This worm has a small mouth and the head lacks spines. The cuticle is annulated. The male bursal cup is shaped like a trumpet and the spicule is slender and long.

Final hosts: Waterfowl

Intermediate hosts: Aquatic oligochaetes; fish as paratenic hosts

Geographical distribution: Many parts of the world

Pathogenesis: Generally considered to be of low pathogenicity and of little veterinary significance, although the parasites can induce the formation of nodules in the wall of the anterior digestive tract.

Trichomonas gallinae

For details see section Oesophagus. For treatment and control, see section Gizzard.

GIZZARD

Several species of gizzard worms are found in ducks and geese. The following applies to all species.

Pathogenesis: Adult birds may not show clinical symptoms but act as carriers. These parasites are found in the upper alimentary tract, particularly the gizzard, and may cause heavy mortality in goslings, ducklings and other young aquatic fowls. Young goslings and ducklings are particularly susceptible. The worms burrow into the mucosa of the gizzard, cause irritation and ingest blood.

Clinical signs: Young fowl may become inappetent, and show diarrhoea and anaemia. Over time the birds become emaciated, weak and, when heavily infected, fatalities can occur. Often older fowl show few clinical signs but act as reservoirs of infection.

Diagnosis: At necropsy, worms may be recovered from the mucosa of the gizzard following incubation in warm saline for 1–2 hours. *Amidostomum* spp., which possess a buccal capsule, are the main trichostrongyloids of the gizzard.

Pathology: Severe infections induce haemorrhages on the gizzard mucosa, and this may be accompanied by catarrhal inflammation. Heavy infections can cause necrosis of the horny lining of the gizzard, forming reddish-brown loose folds containing many embedded worms.

Epidemiology: The infective L₃ requires adequate moisture, such as pond margins, to survive as they are very susceptible to desiccation.

Treatment: Treatment with one of the modern benzimidazoles or levamisole, often administered in feed or drinking water, is effective.

Control: Gizzard worm infection may be prevented by ensuring that birds do not run on the same ground each year. It is important to restrict access of wild aquatic fowl to areas where geese are raised.

Amidostomum anseris

Synonym: *Amidostomum nodulosum*

Common name: Gizzard worm

Predilection site: Gizzard, occasionally proventriculus, oesophagus

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The slender adult worms, bright red in colour when fresh and up to 2.5 cm in length, are easily recognised at necropsy where they predominate in the horny lining of the gizzard. Males measure about 10–17 mm and females 15–25 mm.

Description, microscopic: Characterised by a shallow buccal capsule with three pointed teeth, the middle one being the largest. The male spicules are of equal length and are divided into two branches at the posterior. The medium-sized eggs are thin-shelled with a smooth surface, ellipsoidal and measure around 90–110 by 50–80 µm and contain a large number of blastomeres or a segmented embryo when laid (see Fig. 4.7). The egg hatches when the L₃ larva is present.

Hosts: Domestic and wild goose, duck and other aquatic fowl

Geographical distribution: Worldwide

Amidostomum acutum

Synonym: *Amidostomum skrjabini*

Common name: Gizzard worm

Predilection site: Gizzard, occasionally proventriculus, oesophagus

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: Similar to *A. anseris* in possessing a shallow buccal capsule with small teeth.

Hosts: Domestic and wild duck

Geographical distribution: Worldwide

Epidemiology: The hatched L₃ require about 5 days in the environment before they are fully infective.

Epomidiostomum uncinatum

Synonyms: *Epomidiostomum anatinum*, *Strongylus uncinatus*, *Amidostomum anatinum*

Common name: Gizzard worm

Predilection site: Gizzard

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The body is filiform with a very fine tapering anterior region and is yellowish-white in colour. Males measure around 6 mm and females are approximately 10 mm in length.

Description, microscopic: The mouth is surrounded by four protruding papillae. The cuticle bears two lateral epaulettes, the posterior edge of which forms a three-toothed fringe. The dark-brown spicules are of equal length and the tip comprises three branches. A gubernaculum is absent. The tail of the female has a conical appendage with a small rounded tip. Eggs measure about 80 by 50 µm and do not hatch until an L₃ larva has developed.

Hosts: Domestic and wild goose, duck and other aquatic fowl

Geographical distribution: Many parts of the world, especially North America, Africa, Asia and Europe

Notes: A similar species, *Epomidiostomum crami*, is found in Canada geese (*Branta canadensis*) and blue-winged geese (*Chen caerules*) in North America.

Epomidiostomum orispinum

Synonyms: *Strongylus anseris*, *Strongylus orispinum*

Common name: Gizzard worm

Predilection site: Gizzard and oesophagus

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: Males measure around 11 mm and females 16 mm in length.

Description, microscopic: The anterior of the worm possesses four posteriorly pointing offshoots and lateral festoons bearing a pair of papillae. Spicules are equal with three shafts pointing distally. The body of the female tapers abruptly, towards the digitate tail.

Hosts: Duck, goose and swan

Geographical distribution: Africa, Europe

Epomidiostomum skrjabini

Common name: Gizzard worm

Predilection site: Gizzard

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The size of the male and female is similar to that of *E. orispinum*.

Description, microscopic: The head of the worm possesses a cuticular prominence which is armed with four symmetrical, lateral-pointing spines. There are also two epaulette formations. The mouth is surrounded by four small spines. The bursa has three lobes, the central lobe being poorly developed. Spicules are equal and the posterior ends are split into three sharp-tipped branches. The anterior ends are blunt. The female tail terminates in a finger-like appendage, which is bent ventrally.

Hosts: Domestic and wild goose

Geographical distribution: Russia

Cheilospirura hamulosa**Synonym:** *Acuaria hamulosa***Predilection site:** Gizzard**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Acuarioidea**Description, gross:** Males measure up to 15 mm and females 30 mm.**Description, microscopic:** The worms have four wavy, irregular, cuticular cordons that extend to more than half the length of the body. The males have four pairs of pre-cloacal and six pairs of post-cloacal papillae, a short flattened spicule on the right and a longer slender spicule on the left side. The oval eggs measure about 40–45 by 24–47 µm and are embryonated when passed. The egg is very similar in size and appearance to that of *Dispharynx*.**Final hosts:** Chicken, turkey**Intermediate hosts:** Grasshoppers (*Melanoplus*), weevils and beetles**Geographical distribution:** Worldwide, in particular Europe, Africa, Asia and the Americas**Pathogenesis:** Generally, mild to moderate infections are considered to be of low pathogenicity. In heavy infections, many adult worms penetrate under the keratinised layer of the gizzard where they are found embedded in soft orangy-coloured nodules. The keratinised layer of the gizzard may become necrotic and rupture of the gizzard can occur.**Clinical signs:** Mild infections are usually asymptomatic. Severe infections can lead to emaciation, weakness and anaemia.**Diagnosis:** This is best achieved through necropsy of an affected chicken, as the eggs of several species of *Cheilospirura* appear very similar.**Pathology:** In mild infections, the worms are noticed only if the horny lining of the gizzard is removed, and are found in soft yellowish-red nodules. In severe cases, the horny lining may be partly destroyed, with the worms found below the necrotic material within the altered musculature of the gizzard.

Other species of spiruroid worms found in the gizzard are considered to be of minor significance.

Histiocephalus laticaudatus**Predilection site:** Gizzard**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Spiruroidea**Description, gross:** Males measure around 7–7.5 mm and females 13–16 mm in length.**Description, microscopic:** The mouth is surrounded by four lips and the pseudolips are indented forming 10 finger-like expansions,

each with two or three points. Adult worms have ornate leaf-like structures and the presence of a cervical collar. The buccal cavity is cylindrical. Males have two large alae and four pairs of pre-cloacal papillae and two pairs of post-cloacal papillae. Spicules are long and of equal length. A gubernaculum is absent. The vulva in the female is situated anteriorly.

Hosts: Chicken, duck**Geographical distribution:** Europe***Streptocara crassicauda*****Predilection site:** Gizzard**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Acuarioidea**Description, gross:** Males are about 5 mm and females up to 10 mm in length.**Description, microscopic:** The cervical alae are well developed and possess small teeth on the posterior margin.**Final hosts:** Chicken, turkey, duck, goose**Intermediate hosts:** Crustaceans (*Daphnia*, *Gammarus*)***Echinuria uncinata***

For details see section Proventriculus.

SMALL INTESTINE***Ascaridia galli*****Synonyms:** *Ascaridia lineata*, *Ascaridia perspicillum***Predilection site:** Small intestine**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Ascaridoidea**Description, gross:** The worms are stout and densely white; male worms are 50–75 mm and female worms 70–120 mm long (see Fig. 1.54). *Ascaridia* is by far the largest nematode of poultry.**Description, microscopic:** The anterior end is characterised by a prominent mouth, which is surrounded by three large trilobed lips. The edges of the lips bear teeth-like denticles. A posterior bulb is absent from the oesophagus. The tail of the male possesses small alae and also bears 10 pairs of papillae. Spicules are almost equal in length. In the male there is a circular pre-cloacal sucker, which has a thick cuticular rim. The medium-sized pale-brown egg is distinctly oval, with barrel-shaped side walls and they are unsegmented when laid (see Fig. 4.7). They measure about 75–80 by 45–50 µm. The smooth thick shell has three layers, the middle one being more prominent. Eggs cannot easily be distinguished from those of the other common poultry ascaridoid, *Heterakis*.

Hosts: Chicken, turkey, goose, duck, guinea fowl and a number of wild galliform birds

Geographical distribution: Worldwide

Pathogenesis: *Ascaridia* is not a highly pathogenic worm, and any effects are usually seen in young birds of around 1–2 months of age, adults appearing relatively unaffected. The main effect is seen during the prepatent phase, when the larvae are in the duodenal/intestinal mucosa. There they cause enteritis, which is usually catarrhal, but in very heavy infections may be haemorrhagic. In moderate infections the adult worms are tolerated without clinical signs, but when considerable numbers are present the large size of these worms may cause intestinal occlusion and death. Nutritional deficiency may predispose birds to the establishment of infection.

Clinical signs: Heavily infected birds may become anaemic and show intermittent diarrhoea, anorexia, later becoming unthrifty and emaciated. This can lead to a decrease in egg production.

Diagnosis: In infections with adult worms, the eggs will be found in faeces, but since it is often difficult to distinguish these from the slightly smaller eggs of *Heterakis*, confirmation must be made by postmortem examination of a casualty when the large white worms will be found. In the prepatent period, larvae will be found in the intestinal contents and in scrapings of the mucosa.

Pathology: Enteritis or haemorrhagic enteritis may be seen when large numbers of young parasites penetrate the duodenal or jejunal mucosa. The embedded larvae cause haemorrhage and extensive destruction of the glandular epithelium, and proliferation of mucous secretory cells may result in adhesion of the mucosal villi. Damage to the epithelia may not only be caused by the larvae, but also by the adult worms in the form of pressure atrophy of the villi with occasional necrosis of the mucosal layer. In chronic infections a loss of muscle tonus may be seen, and the intestinal wall may assume a flabby appearance. During the histotropic phase, there is loss of blood and reduced blood sugar and the ureters frequently become distended with urates.

Epidemiology: Adult birds are symptomless carriers, and the reservoir of infection is on the ground, either as free eggs or in earth-worm transport hosts. Infection is heaviest in young chicks.

Treatment: Treatment with piperazine salts, levamisole or a benzimidazole, such as flubendazole, mebendazole or fenbendazole, can be administered in the feed (30 ppm over 7 days; 60 ppm over 7 days; 60 ppm over 3 days, respectively). Levamisole is effective at 30 mg/kg given orally, or 300 ppm in the feed.

Control: When birds are reared on a free-range system and ascariidiosis is a problem, the young birds should, if possible, be segregated and reared on ground previously unused by poultry. Rotation of poultry runs is advisable. Since the nematode may also be a problem in deep-litter houses, feeding and watering systems which limit the contamination of food and water by faeces should be used.

Ascaridia dissimilis

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: The worms are stout and densely white; males measure 35–50 mm and females 50–75 mm in length.

Description, microscopic: The males of this species and those of *A. galli* are separated by differences in the position of the first and fourth pairs of ventral caudal papillae, and by the form of the spicules. The egg is distinctly oval, with a smooth shell, and is 80–95 µm in size.

Host: Turkey

Geographical distribution: Presumed worldwide

Pathogenesis: Considered non-pathogenic

Clinical signs: Moderate infections are frequently inapparent.

Diagnosis: Adult worms may be found in the intestine on postmortem or the characteristic ascarid eggs may be seen in faeces.

Pathology: No associated pathology

Epidemiology: Adult birds are symptomless carriers, and the reservoir of infection is on the ground, either as free eggs or in earth-worm transport hosts.

Treatment: Not usually required, although treatment with piperazine salts, levamisole or a benzimidazole, such as fenbendazole, is effective.

Control: Strict hygiene and feeding and watering systems that limit the contamination of food and water by faeces should be used.

Porrocaecum crassum

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: The worms are reddish-white in colour, with males 12–30 mm and female worms 40–55 mm.

Description, microscopic: The tail of the male is conical and there are no caudal alae. The egg is ellipsoidal with a reticulated shell and measures 110 by 85 µm in size.

Hosts: Domestic and wild duck

Geographical distribution: Presumed worldwide

Pathogenesis: Considered non-pathogenic

Contraecum spiculigerum

Synonyms: *Ascaris spiculigera*, *Ascaris variegata*, *Ascaris mergorum*, *Ascaris colyborum*, *Ascaris siluri*, *Contraecum siluri*, *Contraecum trukestanicum*, *Contraecum umiu*, *Contraecum himeu*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Family: Anisakidae

Description, gross: Males worms are around 32–45 mm and female worms 24–64 mm long.

Description, microscopic: An oesophageal appendix is present. The egg is spherical, and measures 50–52 µm in size.

Hosts: Duck, goose, swan and other waterfowl

Geographical distribution: Presumed worldwide

Pathogenesis: Considered non-pathogenic

Capillaria caudinflata

Synonym: *Aonchotheca caudinflata*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description: See *Eucoleus annulata*. Males measure around 6–12 mm and females up to 25 mm. Females have a characteristic projecting vulval appendage. The medium-sized eggs measure 43–69 by 20–27 µm and have a finely sculptured thick shell; their other characteristics are more fully described under *Eucoleus contorta*.

Final hosts: Chicken, turkey, goose, pigeon and wild birds

Intermediate hosts: Earthworms

Geographical distribution: Worldwide

Pathogenesis: The anterior ends of the worms are embedded in the mucosa. Light infections can produce a catarrhal inflammation; heavy infections may cause a haemorrhagic enteritis with bloody diarrhoea.

Clinical signs: Heavy infections often induce anaemia and the birds become weak and emaciated.

Capillaria bursata

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: See *Eucoleus annulata*. Males measure around 6–12 mm and females up to 25 mm in length.

Final hosts: Chicken, turkey, duck, pheasant and wild birds

Intermediate hosts: Earthworms

Geographical distribution: Worldwide

Capillaria obsignata

Synonyms: *Baruscapillaria obsignata*, *Capillaria columbae*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: See *Eucoleus annulata*. Males measure around 10–12 mm and females up to 15 mm in length.

Description, microscopic: The tail of the female worm tapers posteriorly. The medium-sized eggs are barrel-shaped with slightly striated bipolar plugs and possess a shell with a reticulate pattern. They measure around 50–62 by 20–25 µm; their other characteristics are more fully described under *Eucoleus contorta*.

Hosts: Pigeon, chicken, turkey, pheasant and wild birds

Geographical distribution: Worldwide

Pathogenesis: *Capillaria obsignata* can be highly pathogenic in chickens and pigeons, leading to mortalities. Birds become listless, emaciated and diarrhoeic.

Epidemiology: Young birds are most susceptible to *Capillaria* infections while adults may serve as carriers. *Capillaria obsignata* is important since, having a direct life cycle, it occurs indoors in birds kept on deep litter and outdoors in free-range systems, allowing large numbers of infective eggs to accumulate.

Details of the diagnosis, epidemiology, treatment and control for these species are as for *E. annulata*.

Hartertia gallinarum

Predilection site: Small intestine, gizzard

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Slender worms that are exceptionally long for a spiruroid. The males measure up to around 40 mm and the females 110 mm.

Description, microscopic: The gross appearance of the worms closely resembles that of *Ascaridia galli*. They have two lateral lips, each divided medially into three lobes. The male has lateral alae, ventral cuticular bosses, four pairs of pre-cloacal and two pairs of post-cloacal papillae. The left spicule is barbed and is larger than the blunt-ended right spicule. Eggs are thick-shelled, 45–53 by 27–33 µm and are embryonated when passed.

Final hosts: Chicken, bustards

Intermediate hosts: Termites

Geographical distribution: Widespread in Europe, Africa and Asia. It is not found in the New World.

Pathogenesis: Infections are rarely fatal, but when large numbers of worms are present there may be inflammation of the intestine.

Clinical signs: Diarrhoea and emaciation may occur, often accompanied by a decrease in egg production.

Diagnosis: Differentiation of eggs in faeces is difficult as they are morphologically similar to those of other poultry spiruroids. Diagnosis is usually confirmed at necropsy.

Treatment: Not reported

Control: Where feasible, removal of termite nests from areas adjacent to runs used for poultry will be beneficial.

Tapeworms

Tapeworms are a feature of poultry reared on pasture, infection being acquired through ingestion of infected intermediate hosts, such as beetles, earthworms, ants, grasshoppers or flies. Infection is uncommon in intensive indoor systems as suitable intermediate hosts are usually absent. The most important and pathogenic species is *Davainea proglottina*, which penetrates the duodenal mucosa and in young birds can induce a necrotic haemorrhagic enteritis that can be fatal. *Raillietina echinobothrida* is also pathogenic, inducing a hyperplastic enteritis and multiple caseous nodules where the scolex attaches to the wall of the intestine. Many other tapeworm species produce only mild symptoms, unless infections are heavy, when loss of productivity may be seen. Effective treatment of avian tapeworms is achieved with praziquantel, flubendazole, mebendazole, febantel or niclosamide. The dose rate and duration of administration varies between species of poultry. Control depends on the treatment of infected birds with a suitable anthelmintic and the destruction or removal of intermediate hosts where possible.

Davainea proglottina

Predilection site: Small intestine, particularly the duodenum

Phylum: Platyhelminthes

Class: Cestoda

Family: Davaineidae

Description, gross: *Davainea proglottina* is a very small cestode up to 1–4 mm long and, unlike *Amoebotaenia*, usually possesses only four to nine segments (Fig. 13.2).

Description, microscopic: The rostellum bears 80–94 hooks, arranged in a double row, and the suckers bear a few rows of small hooks. Each segment contains a single set of reproductive organs. The genital pores alternate regularly. Eggs are spherical and measure

Fig. 13.2 *Davainea proglottina*: scolex and proglottids.

about 30–40 μm and are found singly within the parenchymatous capsules in the gravid segment.

Final hosts: Chicken, turkey, pigeon and other gallinaceous birds

Intermediate hosts: Gastropod molluscs such as *Agriolimax*, *Arion*, *Cepaea* and *Limax*

Geographical distribution: Most parts of the world

Pathogenesis: This is the most pathogenic of the poultry cestodes, the doubly armed scolex penetrating deeply between the duodenal villi. Heavy infections may cause haemorrhagic enteritis and light infections retarded growth and weakness.

Clinical signs: Moderate infections can lead to reduced weight gain, inappetence and lowered egg production. Large numbers of parasites may induce emaciation and dyspnoea and even be fatal.

Diagnosis: This is best achieved at necropsy through microscopic examination of mucosal scrapings from the duodenum and anterior small intestine. The tapeworm can easily be overlooked due to its minute size.

Pathology: The mucosal membranes are thickened and haemorrhagic with localised patches of necrosis. Fetid mucus may be present.

Epidemiology: Infection can be common in free-range fowl as suitable intermediate hosts are often available. Young birds tend to be more severely affected than older fowl.

Raillietina cesticillus

Synonym: *Skrjabinia cesticillus*

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Davaineidae

Description, gross: A small to medium-sized tapeworm reaching around 10–14 cm in length, but often shorter.

Description, microscopic: The broad scolex is large and the rostellum wide. The unarmed suckers are not prominent and the rostellum is armed with several hundred small hammer-shaped hooks arranged in a double row. The gravid proglottids contain several thin-walled egg capsules, each housing a single egg. Eggs are spherical to slightly ellipsoidal and measure approximately 75 by 90 μm . They have a thick smooth shell and contain a hexacanth embryo (see Fig. 4.7). Eggs are shed only after the gravid proglottid or the egg capsule disintegrates.

Final hosts: Chicken, turkey, guinea fowl

Intermediate hosts: Various genera of beetles, including the families Carabidae, Scarabaeidae, Tenebrionidae, and the meal beetles *Tribolium* spp.

Geographical distribution: Worldwide

Pathogenesis: Heavy infections can induce a catarrhal enteritis.

Clinical signs: Reduction in growth rate. Heavy infection can lead to emaciation and weakness.

Diagnosis: This is best achieved at necropsy through microscopic examination of mucosal scrapings from the small intestine.

Pathology: In heavy infections, the embedded scolices of this parasite can produce caseous nodules in the wall of the small intestine.

Epidemiology: Young birds are usually more susceptible to infection than adults. Infection rates depend on the availability of the intermediate hosts. Beetles are numerous for free-range fowl but some beetles may also breed in litter bedding. Eggs are reasonably resistant to environmental conditions and will survive for several months.

Raillietina echinobothrida

Common name: Nodular tapeworm disease

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Davaineidae

Description, gross: *Raillietina echinobothrida*, which may be up to 25 cm in length, is similar in shape to *R. tetragona*. The suckers are circular and the rostellum is well endowed with two rows of hooks.

Description, microscopic: The suckers are armed with several rows of small hooklets and the rostellum is well endowed with two rows of around 200 hooks (these features enable it to be distinguished from *R. tetragona*). A ‘neck’ is absent behind the scolex. The gravid proglottids contain multiple fibrous-walled egg capsules, each housing several eggs (around 6–12). Eggs are identical to those of *R. cesticillus* and measure approximately 75 by 95 µm.

Final hosts: Chicken, turkey and other fowl

Intermediate hosts: Ants of the genera *Pheidole* and *Tetramorium*

Geographical distribution: Worldwide

Pathogenesis: Hyperplastic enteritis may occur at the site of attachment.

Pathology: *Raillietina echinobothrida* is more pathogenic than either *R. cesticillus* or *R. tetragona*. In heavy infections, the embedded scolices of this parasite produce large caseous nodules in the subserous and muscular layers of the wall of the posterior small intestine.

Notes: The lesions in the intestine are similar to those associated with avian tuberculosis.

Raillietina tetragona

Predilection site: Posterior half of small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Davaineidae

Description, gross: A large tapeworm reaching around 20–25 cm in length.

Description, microscopic: The scolex is smaller than that of *R. echinobothrida* and the ‘neck’ is quite prominent. The oval suckers

Fig. 13.3 *Raillietina tetragona*: scolex and proglottids.

are lightly armed with several rows of fine hooklets and the rostellum bears one or sometimes two rows of around 100 hooks (Fig. 13.3). The gravid proglottids contain multiple fibrous-walled egg capsules, each housing many eggs. Eggs measure approximately 50 by 25 µm. *Raillietina tetragona* has a larger number of egg capsules in the gravid proglottid than either *R. cesticillus* or *R. echinobothrida*.

Final hosts: Chicken, guinea fowl and pigeon

Intermediate hosts: Ants of the genera *Pheidole*, *Onthophagus* and *Tetramorium*, and house flies

Geographical distribution: Worldwide

Pathogenesis: In heavy infections, the embedded scolices of this parasite produce large caseous nodules in the wall of the small intestine.

Pathology: *Raillietina tetragona* is usually less pathogenic than either *R. echinobothrida* or *R. cesticillus*.

Cotugnia digonopora

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Davaineidae

Description, gross: The tapeworm can measure up to 10 cm long.

Description, microscopic: The head is large with a small rudimentary retractile rostellum, which is armed with two rows of small hooklets. The suckers are large and unarmed and the proglottids are wider than long. Segments possess a double set of genital organs.

Final host: Chicken

Geographical distribution: Europe, Asia, Africa

Amoebotaenia sphenoides

Synonym: *Amoebotaenia cuneata*

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Dilepididae

Description, gross: A very small tapeworm, up to 4.0 mm long, with up to 20 proglottids, each wider than long. It is approximately triangular in shape, although the last few segments decrease in size, and its overall appearance is slightly fluke-like.

Description, microscopic: The rostellum bears a single row of 14 hooks. In the single reproductive organ the genital pores alternate regularly. The spherical embryophore measures up to 42 µm in diameter and the inner layer is granular, which is diagnostic for the genus.

Final host: Chicken

Intermediate hosts: Earthworms, particularly *Allolobophora*, *Helodrilus*, *Ocnerodrilus* and *Pheretina* species

Geographical distribution: Most parts of the world

Pathogenesis: Generally considered to be of low pathogenic significance.

Choanotaenia infundibulum

Predilection site: Upper small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Dilepididae

Description, gross: A relatively large tapeworm up to around 20 cm in length and 1.5–3 mm in width. Each segment is wider posteriorly, giving the margin of the tapeworm a 'saw-edge' appearance.

Description, microscopic: The scolex is triangular, pointed anteriorly with a distinctive rostellum, ringed with about 18 slender hooks. A single set of reproductive organs is present in each proglottid and the genital pores alternate regularly. The oval eggs measure about 45 by 55 µm and possess a long distinctive filament at each pole, which is a diagnostic feature of this avian genus (see Fig. 4.7).

Final hosts: Chicken, turkey and several wild game birds

Intermediate hosts: House fly, *Musca domestica*; beetles of the genera *Aphodius*, *Calathus*, *Geotrupes* and *Tribolium*; and grasshoppers

Geographical distribution: Most parts of the world

Metroliaesthes lucida

Synonym: *Hexaparuterins lucida*

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Paruterinidae

Description, gross: The tapeworm is about 20 cm long and 1.5 mm wide.

Description, microscopic: The scolex has no rostellum or hooks and the suckers are devoid of spines. The single genital pores are irregularly alternating and can be prominent. Each gravid proglottid

possesses a single paruterine organ containing one egg. The oval embryophore measures about 75 by 50 µm.

Final hosts: Chicken, turkey

Intermediate hosts: Grasshoppers (*Chorthippus*, *Paroxya*, *Melanopus*)

Geographical distribution: North America, India, Africa

Hymenolepis carioca

Synonym: *Echinolepis carioca*

Predilection site: Small intestine.

Phylum: Platyhelminthes

Class: Cestoda

Family: Hymenolepididae

Description, gross: This is a slender thread-like tapeworm, reaching a length of up to 8 cm.

Description, microscopic: The scolex is unarmed. The proglottids, numbering 500–1100, are broader than long.

Final hosts: Chicken, turkey and other fowl

Intermediate hosts: Dung and flour beetles and sometimes *Stomoxys* spp.

Geographical distribution: Most parts of the world; common in the USA

Pathogenesis: Usually considered to be of low pathogenicity.

Clinical signs: Large numbers of tapeworms may cause diarrhoea.

Hymenolepis cantaniana

Synonym: *Stephylepis cantaniana*

Common name: Branching tapeworm

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Hymenolepididae

Description, gross: A slender tapeworm reaching a length of up to 2 cm.

Description, microscopic: The rostellum is rudimentary and the suckers are unarmed.

Final hosts: Chicken, turkey, pheasant, quail and other fowl

Intermediate hosts: Beetles (Scarabaeidae)

Geographical distribution: Most parts of the world, particularly Europe, Africa and the USA

Hymenolepis lanceolata

Synonym: *Drepanidotaenia lanceolatum*

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Hymenolepididae

Description, gross: This is a slender tapeworm reaching up to 15–20 cm in length.

Description, microscopic: The proglottids are usually wider than they are long.

Final hosts: Duck and goose

Intermediate hosts: Aquatic copepod crustaceans

Geographical distribution: Cosmopolitan

Pathogenesis: Heavy infections can be fatal.

Clinical signs: Large numbers of tapeworms may cause diarrhoea.

Pathology: Moderate to heavy infections can induce a catarrhal enteritis and necrosis of the mucosa.

Fimbriaria fasciolaris

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Hymenolepididae

Description, gross: The adult tapeworms can vary considerably in length, from 2.5 cm up to about 40 cm.

Description, microscopic: The scolex is small with 10 hooks but the anterior part of the body possesses a 'pseudoscolex' (a folded body expansion) for attachment to the host. The presence of this expansion will aid diagnosis. The uterus is a continuous tube that separates into small tubules in the posterior of the worm. These tubules contain eggs which retain the outer spindle-shaped shell and they contain the oval embryophores. The genital pores are unilateral with three testes to each set of genital organs.

Final hosts: Chicken, duck, goose and wild anseriform birds

Intermediate hosts: Copepods (*Cyclops* and *Diaptomus* spp.)

Intestinal flukes

Intestinal flukes are found in both the small and large intestines. The majority of avian intestinal trematodes parasitise aquatic fowl and birds and are of importance where birds forage in habitats that support the snail intermediate hosts.

Large numbers of flukes can irritate the intestinal mucosa, inducing a catarrhal haemorrhagic enteritis and diarrhoea. Young birds are particularly susceptible to infection, showing progressive emaciation, and mortalities can be high. Various anthelmintics are available for treatment. Praziquantel or flubendazole, administered over several days, are effective in aquatic fowl. Niclosamide (not for geese) and fenbendazole are effective against Echinostomatidae.

Echinoparyphium recurvatum

Predilection site: Small intestine, particularly the duodenum

Phylum: Platyhelminthes

Class: Trematoda

Family: Echinostomatidae

Description, gross: The fluke is about 4 by 0.7 mm and curved ventrally.

Description, microscopic: Spines are present anterior to the ventral sucker and the head-crown is armed with spines. Eggs measure about 110 by 82 µm.

Final hosts: Duck, goose, chicken and pigeon

Intermediate hosts: Host 1: snails such as *Lymnaea* spp. and *Planorbis* spp. Host 2: frogs, tadpoles, snails such as *Valvata piscinalis* and *Planorbis albus*, freshwater clams and mussels

Geographical distribution: Worldwide, particularly Asia and North Africa

Pathogenesis: Heavy infections may induce weakness, anaemia and emaciation.

Pathology: A catarrhal enteritis is often present and the intestinal mucosa is oedematous.

Hypoderaeum conoideum

Predilection site: Posterior small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Echinostomatidae

Description, gross: Adult fluke have an elongate body, 5–12 mm long, and tapering posteriorly.

Description, microscopic: The anterior body is armed with about 50 small spines and bears a large ventral sucker. The testes are elongate and slightly lobed, and situated just beyond the midline. Eggs measure about 95–108 by 61–68 µm.

Final hosts: Chicken, turkey, duck, goose, swan, pigeon and other aquatic birds

Intermediate hosts: As for *E. recurvatum*.

Geographical distribution: Worldwide

Pathogenesis: Enteritis may occur where large numbers of flukes infect the intestine.

Apatemon gracilis

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Strigeidae

Description, gross: Adult fluke measure 1.5–2.5 by 0.4 mm.

Description, microscopic: There is a cup-like anterior region, containing an adhesive organ, and a posterior cylindrical region. The suckers are fairly well developed and the testes and ovary are arranged one behind the other with the ovary foremost. Vitellaria are limited to the posterior region of the body.

Final hosts: Duck, pigeon, wild birds

Intermediate hosts: Host 1: snails. Host 2: various species of leeches

Geographical distribution: Europe, the Americas and Far East

Parastrigea robusta

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Strigeidae

Description, gross: The flukes are 2–2.5 mm long and broader in the anterior region (1.5 mm) than posterior region (1 mm).

Description, microscopic: The genital papilla is large and oviform and the testes are compact and only slightly lobed. The vitellaria are mainly located in the adhesive organ and the lateral expansions, although some extend into the posterior part of the body.

Final hosts: Duck

Intermediate hosts: Unknown

Geographical distribution: Europe

Cotylurus cornutus

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Strigeidae

Description, gross: The adult flukes are about 1.2–1.5 by 0.5 mm with a rounded anterior region and an ovoid posterior region.

Description, microscopic: The oral sucker is smaller than the ventral sucker. The testes and ovary are arranged one behind the other. They are similar to *Apatemon* species but a strong copulatory organ is located in the bursa.

Final hosts: Ducks, pigeon, wild birds

Intermediate hosts: Host 1: snails. Host 2: snails of the same or other species

Geographical distribution: Europe, Asia, Africa, North and South America

Thorny-headed worms

Polymorphus boschadis

Synonyms: *Polymorphus minutus*, *Echinorhynchus polymorphus*

Common name: Thorny-headed worm

Predilection site: Small intestine

Phylum: Acanthocephala

Family: Polymorphidae

Description, gross: Males measure around 3 mm and females up to 10 mm in length and are orange coloured when fresh.

Description, microscopic: The anterior region possesses small spines and the cylindrical body has a constriction along its length about one-third distance from the head. The proboscis has 16 rows of small hooks, their size increasing anteriorly. The spindle-shaped eggs have a thick middle shell, which is irregularly constricted towards the poles, and a thin outer shell, the embryo being slightly orange in colour. Eggs measure around 110 by 20 µm.

Final hosts: Duck, goose, chicken, swan and various wild aquatic birds

Intermediate hosts: Crustaceans: freshwater shrimp *Gammarus pulex*, and sometimes the crayfish *Potamobius astacus*

Geographical distribution: Worldwide

Pathogenesis: The worm produces inflammation of the intestinal mucosa and localised haemorrhages, which in heavy infection can induce anaemia.

Diagnosis: Identification of the characteristic eggs in faeces or the adult worms at necropsy.

Pathology: Worms use their armed proboscis to penetrate deep into the mucosa of the intestine and nodules frequently form at the point of attachment. Heavy infections can be fatal.

Filicollis anatis

Common name: Thorny-headed worm

Predilection site: Small intestine

Phylum: Acanthocephala

Family: Polymorphidae

Description, gross: The whitish male is about 7 mm in length and the anterior region possesses many small spines. The ovoid proboscis is armed with 18 longitudinal rows of small hooks. The neck of the female worm is elongate, slender and bears a globular-shaped proboscis, the crown of which is armed with 18 rows of minute hooks in a star-shaped pattern.

Description, microscopic: The oval eggs measure approximately 62–67 by 19–23 µm. The eggs are smaller than those of *Polymorphus* and are oval rather than spindle-shaped.

Final hosts: Duck, goose, swan and wild aquatic birds

Intermediate hosts: Crustaceans: isopods such as *Asellus aquaticus*

Geographical distribution: Worldwide

Pathogenesis: The worm produces inflammation of the intestinal mucosa and localised haemorrhages.

Clinical signs: Loss of weight, emaciation and, in heavy infections, death.

Diagnosis: Identification of the characteristic eggs in faeces or the adult worms at necropsy.

Pathology: Male worms penetrate into the mucosa of the intestine and nodules may occur at the point of attachment. The female penetrates deep into the wall of the intestine and often its proboscis is

Table 13.2 Predilection sites and prepatent periods of *Eimeria* species in chickens.

| Species | Predilection site | Prepatent period (hours) |
|---------------------------|--------------------------------------|--------------------------|
| <i>Eimeria acervulina</i> | Duodenum | 89 |
| <i>Eimeria brunetti</i> | Lower small intestine, caeca, rectum | 120 |
| <i>Eimeria maxima</i> | Mid-small intestine | 120 |
| <i>Eimeria mitis</i> | Small intestine, caeca, rectum | 91 |

| <i>Eimeria praecox</i> | Small intestine | 84 |
| <i>Eimeria tenella</i> | Caeca | 132 |

situated directly under the peritoneum, leading to rupture in severe cases.

Treatment and control: Details of treatment and control are as for *P. boschadis*.

Coccidiosis in chickens

Seven species of *Eimeria* are found in domestic chickens (Table 13.2); identification is based on location in the intestine and associated pathology. Specific identification is based on the nature and location of the lesions in the intestine together with careful examination of fresh smears for developmental stages of the parasite.

Diagnosis: Diagnosis is best based on postmortem examination of a few affected birds. This can be made at microscopic level, either by examining the faeces for the presence of oocysts or by examination of scrapings or histological sections of affected tissues. Although oocysts may be detected on faecal examination, it would be wrong to diagnose solely on such evidence for two reasons. First, the major pathogenic effect usually occurs prior to oocyst production and, secondly, depending on the species involved, the presence of large numbers of oocysts is not necessarily correlated with severe pathological changes in the gut. At necropsy, the location and type of lesions present provide a good guide to the species and this can be confirmed by examination of the oocysts in the faeces and the meronts and oocysts present in scrapings of the gut. A reliable species diagnosis based on oocyst morphology is not possible as the dimensions and other features overlap between species (see Table 4.12).

Species diagnosis is based on a combination of characteristics, including site of development in the intestinal tract, the type of macroscopic lesions and size of meronts in mucosal smears. The mature meronts may be identified histologically by their location, size and the number of merozoites they contain.

Epidemiology: The appearance and development of coccidiosis in poultry houses is dependent on a complex interplay of many factors. In fresh litter, few coccidia are present and there may be only a few oocysts scattered around. From the moment a few chicks are infected, rapid multiplication commences and a week later, new oocysts are excreted in large quantities. The infection usually begins to spread at full rate around the third or fourth week after housing. As exposure and immunity increases, the chicks will then gradually recover and withstand the infection. Rearing of thousands of birds on litter-covered floors in enormous houses may result in a

tremendous and dangerous build-up of the oocyst population. Whether or not infection leads to the occurrence of disease outbreaks is to a great extent determined by the numbers of oocysts to which birds are exposed. However, serious outbreaks of clinical coccidiosis with acute mortality are highly exceptional in modern broiler farms because of the stringent monitoring and control measures employed. Where outbreaks do occur, clinical signs can be ascribed to one, or a combination of two or rarely three, coccidial species. Management-related factors, such as stocking density, size of the farm, period of vacancy, quality of the litter, inadequate cleaning, ventilation system, presence of animals of different ages and anticoccidials used, will play an important part in influencing the numbers of oocysts that birds will be exposed to, and whether and to what extent coccidiosis will develop. The occurrence and incidence of disease is also, to a great extent, affected by the type of chicks reared, breed sensitivities to infection, their initial health, acquired immunity and the interference of other diseases. The damaging nature and the location of the coccidia in the intestine will differ to such an extent that ultimately a complex and unique picture will develop on individual poultry farms. A change from litter-covered floors to wire-floored pens greatly reduces the exposure to coccidia. Outbreaks of coccidiosis in laying hens maintained in cages rarely occur. In general, the prophylactic use of anticoccidial drugs is not required if the cages are kept clean and the faeces do not contaminate watering and feeding systems.

Oocysts are disseminated via the faeces and the litter, with dust within the poultry buildings, inside and outside the house by invertebrates and vermin, while mechanical ventilation systems serve to scatter the oocysts outside the house. Faecal contamination of vehicles and personnel can spread the infection to other farms. Measures such as thorough cleaning and disinfecting with oocidal agents, batch depopulation between grow-outs, and admitting as few visitors as possible are essential in order to maintain proper hygiene standards. Today most poultry enterprises rely on floor-rearing methods for broiler production or breeder flocks and use continuous medication programmes. Poultry producers also attempt to control coccidiosis by employing good sanitary programmes. Litters should be kept dry so that oocysts cannot sporulate. Wet litter must be cleaned out and replaced with dry litter. When broiler houses are emptied for a new batch of chickens, the litter should be piled up for about 24 hours so that the heat generated can destroy the majority of oocysts. Disinfection is usually impractical since oocysts are resistant to disinfectants used against bacteria, viruses or fungi.

Treatment: This should be introduced as early as possible after a diagnosis has been made. Sulphonamide drugs have been the most widely used and it is recommended that these be given for two periods of 3 days in the drinking water, with an interval of 2 days between treatments. Where resistance has occurred to sulphonamides, mixtures of amprolium and ethopabate have given good results. Toltrazuril has been introduced for the treatment of outbreaks of coccidiosis and its use is restricted to those cases where other treatments have been ineffective.

In the successful treatment of an outbreak of coccidiosis the aim is to treat birds already affected and at the same time allow sufficient merogonous development in the clinically unaffected birds to stimulate their resistance.

Control: Prevention of avian coccidiosis is based on a combination of good management and the use of anticoccidial compounds in the

feed or water. Thus, litter should always be kept dry and special attention given to litter near water fonts or feeding troughs. Fonts that prevent water reaching the litter should always be used and they should be placed on drip trays or over the droppings pit. Feeding and watering utensils should be of such a type and height that droppings cannot contaminate them. Good ventilation will also reduce the humidity in the house and help to keep litter dry. Preferably, clean litter should always be provided between batches of birds. If this is not possible, the litter should be heaped and left for 24 hours after it has reached a temperature of 50°C; it should then be forked over again and the process repeated to ensure that all the oocysts in the litter have been destroyed.

The use of anticoccidial agents depends on the type of management concerned. Broiler chicks are on lifetime-medicated feed and the anticoccidials used are maintained at a level sufficient to prevent merogony. The drugs available for use singly or in various combinations are amprolium, clodolol, diclazuril, ethopabate, halofuginone, lasalocid, maduramicin, monensin, narasin, nicarbazin, robenidine, salinomycin and sulphamonomethoxime. It is recommended that drugs are switched between batches of broilers, the so-called 'rotation programme', or within the lifespan of each batch, the 'shuttle programme'. Most drugs have a minimum period for which they must be withdrawn before the birds can be slaughtered for human consumption. This is usually 5–7 days.

Where replacement laying birds spend their whole life on wire floors, no medication is necessary; if they are reared on litter, for eventual production on wire, then a full level of coccidiostat is given as for broilers. If they are reared on litter, for production on litter, then a programme of anticoccidials designed to stimulate immunity is used. Preparations frequently used either singly, or in combination, are amprolium, ethopabate, lasalocid, monensin and sulphamonomethoxime. The procedure is to administer these drugs in a decreasing level over the first 16 or 18 weeks of life. This may be done as a two-stage reduction, i.e. between 0 and 8 weeks and 8 and 16 weeks, or, alternatively, as a three-stage reduction, from 0–6 weeks, 6–12 weeks and 12–18 weeks. Using this technique, complete protection against coccidial challenge is maintained in the very young birds and the reduced drug rate in older birds allows limited exposure to developing coccidia so that acquired immunity can develop.

When in-feed coccidiostats are used, there are two further factors to consider. First, outbreaks of coccidiosis may occur in birds on medicated feed either because the level of coccidiostat used is too low or because conditions in the house have changed to allow a massive sporulation of oocysts which, on ingestion, the level of drug can no longer control. Secondly, the influence of intercurrent infections in affecting appetite, and therefore uptake of coccidiostat, should also be considered.

Several commercial vaccines have been developed for the control of coccidiosis in chickens. Live vaccines containing oocysts of wild-type strains of four, or eight, species of coccidia are available in the USA. Young chicks are given the vaccine either in a spray cabinet or orally on the feed. Successful immunisation has also been achieved with oocysts attenuated by irradiation or by selection of selected 'precocious' strains of each of the pathogenic species of coccidia that affect poultry. These strains show rapid development *in vivo* with minimal damage to the intestine but stimulate an effective immunity. For success, both techniques depend on subsequent exposure to oocysts to boost immunity and this may not occur unless litter is sufficiently moist to allow sporulation. There

is considerable interest in developing more efficient vaccines, in view of the increasing problem of drug resistance in coccidiosis. A subunit transmission-blocking vaccine which targets the sexual macrogametocyte stages and thus reduces oocyst output has been developed. The vaccine comprises affinity-purified antigens from the gametocyte stages of *Eimeria maxima*. It provides a good level of protection across three species of *Eimeria* (*E. maxima*, *E. tenella* and *E. acervulina*) and is administered to laying hens where protection is passed, via the yolk, to their broiler offspring. Unfortunately, it is an expensive vaccine to manufacture and work is ongoing to test whether recombinant forms of the gametocyte proteins are as effective at producing antigenicity as the natural proteins.

Intestinal coccidiosis

This form of the disease tends to be chronic and may be associated with several species of *Eimeria*. Mortality may not be heavy but morbidity may retard growth significantly. Usually more than one species is present. Specific identification is based on the nature and location of the lesions in the intestine together with careful examination of fresh smears for developmental stages of the parasite.

Eimeria acervulina

Predilection site: Duodenum (Fig. 13.4)

Phylum: Apicomplexa

Class: Conoidasida

Fig. 13.4 Predilection site of *Eimeria acervulina*.

Fig. 13.5 Oocysts of *Eimeria acervulina*.

Family: Eimeriidae

Description: Oocysts are ovoid, smooth, 12–23 by 9–17 μm (mean $18 \times 14 \mu\text{m}$), without a micropyle or residuum but with a polar granule (Fig. 13.5). The sporocysts are ovoid, with a Stieda body and without a residuum. First-generation meronts are 9–11 μm long and mature in 36–48 hours to produce 8–16 merozoites with a small residuum. Second-generation meronts mature in 41–56 hours to produce 16 merozoites with no residuum; third-generation meronts mature 56–72 hours after inoculation to produce eight merozoites with a residuum and fourth-generation meronts mature 80–96 hours after inoculation and produce 32 merozoites with a large residuum. The macrogamonts are 14.5–19 μm in diameter, and the microgamonts 7–8 μm . The latter produce many tri-flagellate microgametes 2–3 μm long.

Host: Chicken

Life cycle: The sporocysts emerge from the oocysts in the gizzard and the sporozoites are activated and emerge in the small intestine. Most enter the duodenum. The meronts are found in the epithelial cells of the villi of the anterior small intestine where they lie above the host nucleus. There are four merogony generations. The first-generation meronts lie at the base of the glands of the crypts of the duodenum. Second-generation meronts are found at the neck of the glands, third-generation meronts lie at the base of the villi and fourth-generation meronts lie on the sides and the tips of the villi. The sexual stages are found above the host cell nuclei, in the epithelial cells of the villi and to a lesser extent in the gland cells, and are seen 4 days after infection and take 40 hours to mature. The prepatent period is 89 hours. The sporulation time is 24 hours.

Geographical distribution: Worldwide

Pathogenesis: The disease is usually chronic, with birds showing poor weight gains but little mortality. Clinical disease occurs about 3 days following the ingestion of large numbers of oocysts.

Clinical signs: *Eimeria acervulina* is generally considered to be moderately pathogenic, but heavy infections can cause severe signs and death. Symptoms include diarrhoea, dejection, ruffled feathers and drooping wings, inappetence, weight loss and depressed weight gain.

Pathology: The lesions in light infections consist of white transverse streaks in the duodenum and upper small intestine (Fig. 13.6). In heavier infections the lesions coalesce and the intestinal wall be-

Fig. 13.6 Duodenal lesions of *Eimeria acervulina*.

comes thickened and congested with marked whitish mucoid exudate. Very large numbers of gamonts and oocysts can be seen in smears from the duodenum and on histopathology (Fig. 13.7).

Lesions are scored +1 to +4 as follows.

- 1 Scattered white plaque-like lesions containing developing oocysts confined to the duodenum. These lesions are elongated with the longer axis transversely oriented on the thickened intestinal walls like the rungs of a ladder. They may be seen from either the serosal or mucosal intestinal surfaces. The birds would not be affected clinically and weight gains would not be affected.
- 2 Lesions are much closer together but not coalescent and may extend below the duodenum in young birds. The intestinal walls

Fig. 13.7 Gamonts of *Eimeria acervulina* within enterocytes of small intestinal villi.

are not thickened and the gut contents are normal. The birds would show a depression in weight gain.

- 3 The lesions are clearly recognisable from the mucosal and serosal surfaces, are more numerous and beginning to coalesce. The intestinal wall is thickened and the intestinal contents are watery due to excessive mucus secretion. The birds have diarrhoea, and their weight gains are decreased.
- 4 The mucosal wall is greyish with colonies completely coalesced. In extremely heavy infections the entire mucosa may be bright red in colour. Individual lesions may be indistinguishable in the upper intestine. Typical ladder-like lesions appear in the middle part of the intestine. The intestinal wall is very much thickened, and the intestine is filled with a creamy exudate, which may contain numbers of oocysts. The birds show diarrhoea, severe weight loss, poor feed conversion and skin depigmentation.

Eimeria acervulina

Lesions: Whitish ladder-like streaks to coalescent plaques affecting mainly duodenum (Fig. 13.6)

Mean oocyst size (mm): 18 × 14

Shape and length/width index: Ovoid, 1.25

Prepatent period (hours): 89

Sporulation time (hours): 24

Eimeria brunetti

Predilection site: Small and large intestine (Fig. 13.8)

Phylum: Apicomplexa

Fig. 13.8 Predilection site of *Eimeria brunetti*.

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, smooth, 14–34 by 12–26 μm (mean 26 × 22 μm), without a micropyle or residuum but with a polar granule. The sporocysts are ovoid (13 × 7.5 μm), with a Stieda body and a sporocyst residuum. First-generation meronts are 28 by 21 μm long and contain 318 merozoites. Second-generation meronts are smaller than first-generation meronts and contain 15–120 merozoites. The microgamonts contain several centres of microgamete development and are larger than the macrogamonts, which are 25 by 22 μm .

Host: Chicken

Life cycle: The first-generation meronts are found in the epithelial cells in the base of the villi in the mid intestine. There are at least three merogony generations. Second-generation meronts are found subepithelially at the tips of the villi in the lower small intestine 3 days post infection. Third-generation meronts are first seen at 84 hours, and mature by 4 days after infection and are located in the lower small intestine and large intestine. Gamonts are seen from day 5 at the tips and sides of the villi in the lower small intestine and large intestine, either above the host cell nuclei or on the basement membrane. The prepatent period is 120 hours. The sporulation time is 24–48 hours.

Geographical distribution: Worldwide

Pathogenesis: The pathogenicity of this species is high but mortality is variable. Lesions are most pronounced in the posterior small intestine.

Clinical signs: *Eimeria brunetti* is markedly pathogenic, but its effects depend on the degree of infection. Light infections may be asymptomatic. Heavier infections reduce weight gain or cause weight loss. The birds develop fluid droppings containing blood-tinged mucus and mucous casts. The birds become depressed and deaths may occur. The symptoms continue for 5 days before recovery.

Pathology: The gut wall becomes thickened and a pink or blood-tinged catarrhal exudate appears 4–5 days after experimental inoculation. In early or light infections, haemorrhagic ladder-like streaks are present on the mucosa of the lower small intestine and rectum. In heavy infections, a characteristic necrotic enteritis appears that may involve the entire intestinal tract, but which is more usually found in the lower small intestine, colon and tubular part of the caeca (Fig. 13.9). A patchy or continuous dry caseous necrotic

Fig. 13.9 Lesions of *Eimeria brunetti* in lower small intestine.

membrane may line the intestine, and the intestine may be filled with sloughed necrotic material. Circumscribed white patches may be visible through the serosa and there may be intestinal perforation with resultant peritonitis.

Lesions are scored +1 to +4 as follows.

- 1 Gross lesions are very distinct with some greying and reddening of the mucosal surfaces with a few petechiae visible from the serosal surface, appearing as pits on the mucosal surface.
- 2 Intestinal wall may appear grey in colour and the lower portion may be thickened with flecks of pinkish material sloughed from the intestine. More petechiae are present, with the greatest number appearing on day 5 after infection. They may appear as early as day 3.5 and occur from the yolk stalk posteriorly. Mild mucosal roughening can be detected by feel.
- 3 Intestinal wall thickened, and a blood-tinged exudate is present. Transverse streaks may be present in the lower rectum with lesions in the caecal tonsils. Weight gains and feed conversion are reduced.
- 4 Severe coagulative necrosis of the lower intestine can result in erosion of the entire mucosa. This is apparent as a thickening of the intestine wall and in some birds a dry necrotic membrane may line the intestine (pseudomembranous necrosis) and caseous cores may plug the caeca. Lesions may extend into the middle or upper intestine and the necrosis may be severe enough to cause intestinal obstruction and death of the bird.

Eimeria brunetti

Lesions: Coagulation necrosis and bloody enteritis in lower intestine (Fig. 13.9)

Mean oocyst size (mm): 26 × 22

Shape and length/width index: Ovoid, 1.31

Prepatent period (hours): 120

Sporulation time (hours): 24–48

Eimeria maxima

Predilection site: Small intestine (Fig. 13.10)

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, yellowish and smooth, 21–42 by 16–30 µm (mean 30 × 20 µm), without a micropyle or residuum but with a polar granule (Fig. 13.11). Sporocysts are ovoid, 15–19 by 8–9 µm, with a Stieda body and without a residuum. The sporozoites are 19 by 4 µm and each has a conspicuous clear globule.

Host: Chicken

Life cycle: The meronts are located above the host cell nuclei (or occasionally beside them) in the epithelial cells of the tips of the villi of the duodenum and upper ileum. There are three asexual generations. The first-generation meronts lie deep in the epithelial cells of the deep glands of the duodenum. They appear 48 hours after inoculation and contain 25–50 loosely packed merozoites. The second-generation meronts are in the epithelial cells of the small intestine villi near the openings of the crypts and appear on the third day after infection and produce about 12 merozoites. Third-generation meronts are in the epithelial cells along the sides of the superficial villi and sometimes near the tips, appearing during the

Fig. 13.10 Predilection site of *Eimeria maxima*.

fourth day after infection and produce about 12 merozoites. Gamonts are located below the host cell nuclei, and as they enlarge the host cells are displaced towards the centre of the villi and come to lie in their interior. After fertilisation, an oocyst wall is laid down and the oocysts break out of the villi and are passed in the faeces. The prepatent period is 120 hours. Sporulation time is 30–48 hours.

Geographical distribution: Worldwide

Pathogenesis: Strains of *Eimeria maxima* differ in their pathogenicity, which can be very variable, but some strains can be responsible for high morbidity, and mortality may approach 25%. Lesions occur most frequently in the mid small intestine, although the whole of the small intestine may be involved. Clinical disease occurs about 3 days following the ingestion of large numbers of oocysts. Asexual stages cause relatively little damage, with the most serious effects being due to the sexual stages.

Clinical signs: Symptoms include diarrhoea, depression, ruffled feathers, decreased growth rate or weight loss and, in some cases, death. Birds that recover soon return to normal.

Pathology: The principal lesions are haemorrhages in the mid small intestine. The intestinal muscles lose their tone and the intestine becomes flaccid and dilated with a somewhat thickened wall. There is catarrhal enteritis; the intestinal contents are viscid and mucoid, and are grey–brown or pink–orange in colour (Fig. 13.12). Occasionally there are blood flecks in the intestinal contents, but in heavy infections haemorrhage may be pronounced and blood may pass into the caeca. Gametocytes or characteristic large yellowish oocysts may be seen in smears from the intestinal mucosa (Fig 13.13).

Fig. 13.11 Oocysts of *Eimeria maxima*.

Fig. 13.12 Lesions of *Eimeria maxima*: mid small intestine.

Lesions are scored +1 to +4 as follows.

- 1 Small red petechiae may appear on the serosal side of the mid-intestine surface on days 6 and 7 of infection. There is no thickening of the intestine, although small amounts of orange mucus may be present. Birds show some weight loss and skin depigmentation.
- 2 Serosal surface may be speckled with numerous red petechiae. Intestine may be filled with orange mucus, with little or no thickening of the intestine.
- 3 Intestinal wall is ballooned and thickened. The mucosal surface is roughened, and intestinal contents filled with pin-point blood clots and mucus.
- 4 The intestinal wall may be ballooned for most of its length and greatly thickened, and contains numerous blood clots and digested red blood cells giving a characteristic colour and putrid odour.

Fig. 13.13 Oocysts and gamonts of *Eimeria maxima* in mucosal smear of the mid small intestine.

Eimeria maxima

Lesions: thickened mid intestine with petechial haemorrhage and blood-tinged exudate (Fig. 13.12)

Mean oocyst size (mm): 30 × 20

Shape and length/width index: Ovoid, 1.47

Prepatent period (hours): 120

Sporulation time (hours): 30–48

Eimeria mitis

Predilection site: Small and large intestine (Fig. 13.14)

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are subspherical, smooth, 10–21 by 9–18 µm (mean 16 × 15 µm), without a micropyle or residuum but with a polar granule. The sporocysts are ovoid, 10–16 µm, with a Stieda body and without a residuum. Merogony stages have not been described. The microgamonts are 9–14 µm in diameter, and the microgamonts somewhat larger.

Host: Chicken

Life cycle: The endogenous stages are in the epithelial cells of the villi and occasionally in the crypts of the small intestine (Fig. 13.15); also caeca and rectum. The number of meront generations is

Fig. 13.14 Predilection site of *Eimeria mitis*.

Fig. 13.15 Endogenous stages of *Eimeria mitis* in the villi of the small intestine.

unknown. Asexual and sexual stages occur together. The prepatent period is 91 hours. The sporulation time is 18–24 hours.

Geographical distribution: Worldwide

Pathogenesis: No discrete lesions are produced with this species, but infection can cause loss in body weight gain.

Clinical signs: Generally, older chickens are affected by the species found in the small intestine, and clinical signs are similar to those of caecal coccidiosis. Subclinical infections are more common than overt disease and may be suspected when pullets have poor rates of growth and feed conversion, and the onset of egg-laying is delayed.

Pathology: Infection produces little pathology, although there may be small petechiae in the lower small intestine and mucoid exudates in the lumen.

Eimeria mitis

Lesions: no discrete lesions, mucoid exudate and areas of small petechiation

Mean oocyst size (mm): 16 × 15

Shape and length/width index: Subspherical, 1.09

Prepatent period (hours): 91

Sporulation time (hours): 18–24

Fig. 13.16 Predilection site of *Eimeria necatrix*.

Eimeria necatrix

Predilection site: Small intestine (Fig. 13.16)

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, smooth, colourless, 12–29 by 11–24 μm (mean $20 \times 17 \mu\text{m}$), without a micropyle or residuum but with a polar granule. The sporocysts are ovoid, with a Stieda body and without a residuum.

Host: Chicken

Life cycle: Following ingestion of sporulated oocysts and excystation, sporozoites enter the epithelial cells of the small intestine, pass through the epithelium into the lamina propria at the centre of the villi, and migrate towards the muscularis mucosae. Many sporozoites are engulfed by macrophages during this passage, and are transported to the epithelial cells of the fundus. The macrophages invade these cells and appear to disintegrate leaving the sporozoites unharmed. The sporozoites round up to form first-generation meronts, found above the host cell nuclei in the epithelial cells of the crypts of the small intestine. Second-generation meronts develop deep in the mucosa (Fig 13.17). The prepatent period is 138 hours and the patent period about 12 days. Sporulation time is 18–24 hours.

Geographical distribution: Worldwide

Fig. 13.17 Histological section showing second-generation meronts of *Eimeria necatrix* deep in the mucosa.

Pathogenesis: *Eimeria necatrix* is one of the most pathogenic species of coccidia affecting chickens.

Clinical signs: Symptoms seen include diarrhoea (mucoid and sometimes bloody), dejection, ruffled feathers and drooping wings, inappetence, weight loss and depressed weight gain. Death usually occurs 5–7 days after infection, often before oocysts are passed in the faeces. Birds that recover often remain unthrifty and emaciated.

Pathology: The principal lesions are in the small intestine, especially the middle third. Small white opaque foci are seen by the fourth day after infection. These are the second-generation meronts (Fig 13.18), and they are often so deep in the mucosa that they are most visible from the serosal surface. Severe haemorrhage may occur by day 5 or 6 and the small intestine may be markedly swollen and filled with clotted or unclotted blood. The wall is thickened and dull red and petechiae are present in the white foci as a result of release of the second-generation merozoites (Fig. 13.19). The gut wall may lose its contractility, become friable, and the epithelium may slough and be replaced by a network of fibrin-containing mononuclear cells. This network is replaced by connective tissue resulting in permanent scarring, which interferes with intestinal absorption.

Fig. 13.18 Second-generation meronts of *Eimeria necatrix* in mucosal smear of mid small intestine.

Lesions are scored +1 to +4 as follows.

- 1 The presence of small scattered petechiae and white spots visible from the serosal surface.
- 2 Numerous petechiae on the serosal surface and some slight ballooning of the intestine.
- 3 Extensive haemorrhage into the lumen and the presence of red or brown mucus, extensive petechiae on the serosal surface, marked ballooning of the intestine and absence of normal intestinal contents.
- 4 Ballooning may be extensive and haemorrhage may give an intensive dark colour to the intestinal contents.

Eimeria praecox

Predilection site: Small intestine (Fig. 13.20)

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, smooth, colourless, 20–25 by 16–20 μm (mean 21 × 17 μm), without a micropyle or residuum but with a polar granule. The sporocysts are ovoid, with a Stieda body and without a residuum.

Host: Chicken

Life cycle: The endogenous stages occur in the epithelial cells of the villi, usually along the sides of the villi, and lie below the host cell nucleus. There are at least three, and possibly four, generations of merogony. The second meront generation is seen as early as

Fig. 13.20 Predilection site of *Eimeria praecox*.

36 hours after infection. Later development is irregular, and both asexual and sexual generations are seen together. The prepatent period is 84 hours and the patent period approximately 4 days. The sporulation time is 48 hours.

Geographical distribution: Worldwide

Pathogenesis: *Eimeria praecox* is generally considered to be non-pathogenic.

Clinical signs: No associated clinical signs

Pathology: A mucoid exudate is the only lesion seen. Endogenous stages can be detected in the wall of the small intestine by histopathology.

Coccidiosis in turkeys

Seven species of *Eimeria* have been identified in turkeys; identification is based on location in the intestine and associated pathology (Table 13.3). Specific identification is based on the nature and location of the lesions in the intestine together with careful examination of fresh smears for the developmental stages of the parasite.

Table 13.3 Predilection sites and prepatent periods of *Eimeria* species in turkeys.

| Species | Predilection site | Prepatent period (hours) |
|------------------------------|---------------------------------|--------------------------|
| <i>Eimeria adenoides</i> | Lower small intestine, caeca | 104–132 |
| <i>Eimeria dispersa</i> | Duodenum, upper small intestine | 120–144 |
| <i>Eimeria meleagridis</i> | Ceaca | 144 |
| <i>Eimeria meleagritidis</i> | Duodenum | 144 |
| <i>Eimeria gallopavonis</i> | Ileum, rectum, caeca | 144 |
| <i>Eimeria innocua</i> | Small intestine | 120 |
| <i>Eimeria subrotunda</i> | Small intestine | 96 |

Diagnosis: Diagnosis is best based on postmortem examination of a few affected birds. The oocysts may be identified according to shape and size. At necropsy, the location and type of lesions present provide a good guide to the species, which can be confirmed by examination of the oocysts in the faeces and the meronts and oocysts present in scrapings of the gut.

Epidemiology: The appearance and development of coccidiosis is similar to that described for chickens. Acute infections with pathogenic species occur in young turkey poults 2–10 weeks of age, causing enteritis with variable mortality. Deep-litter houses offer optimal conditions of temperature and humidity for oocyst sporulation, and with overcrowding the risk of heavy infection is further increased.

Treatment: Anticoccidial drugs, such as lasalocid, monensin, robenidine, amprolium, ethopabate and clodol/methylbenzoate, can be used for prophylaxis by incorporation in the feed for the first 12–16 weeks of life. Low doses of anticoccidial drugs can be used to allow immunity to develop, particularly in breeding birds. Monensin should be used under veterinary guidance because of its greater toxicity for turkeys than for chickens.

Control: Prevention of turkey coccidiosis is based on a combination of good management and the use of anticoccidial compounds in the feed or water. Thus litter should always be kept dry and special attention given to litter near water fonts or feeding troughs. Drinkers that prevent water reaching the litter should always be used and they should be placed on drip trays or over the droppings pit. Feeding and watering utensils should be of such a type and height that droppings cannot contaminate them. Good ventilation will also reduce the humidity in the house and help to keep litter dry. Preferably, clean litter should always be provided between batches of birds. If this is not possible, the litter should be heaped and left for 24 hours after it has reached a temperature of 50°C; it should then be forked over again and the process repeated to ensure that all the oocysts in the litter have been destroyed.

When in-feed coccidiostats are used, there are two further factors to consider. First, outbreaks of coccidiosis may occur in birds on medicated feed either because the level of coccidiostat used is too low or because conditions in the house have changed to allow a massive sporulation of oocysts which, on ingestion, the level of drug can no longer control. Secondly, the influence of intercurrent infections in affecting appetite, and therefore uptake of coccidiostat, should also be considered.

Intestinal coccidiosis

As with coccidiosis in chickens, more than one species is usually present in outbreaks of disease. Specific identification is based on the nature and location of the lesions in the intestine together with careful examination of fresh smears for the developmental stages of the parasite.

Eimeria adenoides

Predilection site: Lower small intestine and caeca

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal or ovoid, smooth, colourless, 19–31 by 13–21 μm (mean 26 \times 17 μm), with a micropyle, one to three polar granules but with no oocyst residuum. The sporocysts are elongate, with a Stieda body and a residuum and contain a clear globule at the large end. First-generation meronts are 30 by 18 μm when mature (after 30 hours) and contain approximately 700 merozoites, 4–7 by 1.5 μm , with a central nucleus. Second-generation meronts are 10 by 10 μm and produce 12–24 merozoites, 10 by 3 μm , with the nucleus slightly nearer the rounded end. The mature macrogamonts and microgamonts are 20 by 18 μm .

Host: Turkey

Life cycle: *Eimeria adenoides* is found in the lower small intestine, caeca and rectum and has two generations of meronts. First-generation meronts can be seen in the epithelial cells as early as 6 hours after inoculation. Second-generation meronts mature 96–108 hours after inoculation. Sexual stages can be detected as early as 120 hours post infection. The prepatent period is 104–132 hours and the patent period 7–20 days. Sporulation time is 24 hours.

Geographical distribution: Worldwide

Pathogenesis: *Eimeria adenoides* is one of the most pathogenic species of coccidia in turkeys. Clinical signs first appear 4 days after infection, coincident with the rupture of the second-stage meronts. Initially the intestines appear grossly normal until this point; thereafter, the walls of the lower third of the small intestine, caeca and rectum become swollen and oedematous, with petechial haemorrhages visible from the mucosal surface only. The lower intestine becomes filled with mucus. The infected epithelial cells break away, leaving the villi denuded. The blood vessels become engorged and cellular infiltration of the submucosa and epithelium increases progressively. In birds that recover from the disease, and in those that received a low infection dose, resolution is rapid. Vascularity is greatly reduced and the deep glands are almost free of parasites by day 7. The intestine is almost normal by day 9 or 10 post infection.

Clinical signs: The affected poult are dull, listless and anorexic, stand with ruffled feathers and have their heads tucked under their wings. Their droppings are white and mucoid and may contain blood. Heavy infections can result in mortality.

Pathology: Most of the terminal intestine is congested and contains large numbers of merozoites and long streaks of blood. Caseous material, composed of cellular debris, gametes and a few immature oocysts, accumulates. With time, the caseous exudate is composed

largely of oocysts. The faeces in severe cases are relatively fluid and may be blood-tinged and contain mucous casts 2.5–5 cm long. Caseous plugs may be present in the caeca. The terminal intestine may contain creamy white mucus, and petechiae may be present in the mucosa. As recovery proceeds, the intestinal contents appear normal but still contain large numbers of oocysts.

Eimeria dispersa

Predilection site: Duodenum and upper small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, smooth, 22–31 by 18–24 μm (mean 26 \times 21 μm), with no micropyle, polar granule or oocyst residuum. Sporocysts are ovoid and have a Stieda body. First-generation meronts are 14 by 13 μm and contain an average of 19 merozoites; second-generation meronts are 8 by 7 μm and contain an average of 13.5 merozoites; third-generation meronts are 9 by 9 μm and contain an average of 15 merozoites; and fourth-generation meronts are 12 by 10.5 μm and contain an average of seven merozoites. Mature macrogametes are 18–20 μm in diameter, with microgamonts slightly smaller.

Host: Turkey

Life cycle: First-, second-, third- and fourth-generation meronts are present 30, 48, 72 and 96 hours after infection, respectively. Sporozoites and first-generation meronts lie close above the epithelial cell nuclei; second-, third- and fourth-generation meronts are also above the host cell nucleus, but lie near the brush border of the host cell. The mature macrogamonts and microgamonts can be found in the small intestine villous epithelial cells 96 hours after infection. The prepatent period is 120–144 hours. Oocyst sporulation time is 48 hours.

Geographical distribution: Worldwide

Pathogenesis: A mildly pathogenic species that produces creamy mucoid exudates in the small intestine of young turkeys and depressed weight gains.

Clinical signs: Diarrhoea, weight loss, ruffled feathers, droopiness and growth retardation

Pathology: With pathogenic strains, the most severe lesions occur 5–6 days after infection. The entire small intestine is markedly dilated, and the duodenum and anterior jejunum are creamy white when seen through the serosal surface. The anterior half of the small intestine is filled with creamy, yellowish, sticky, mucoid material. The wall of the anterior intestine is oedematous, but there is little epithelial sloughing. Recovery is rapid and the intestine appears virtually normal 8 days post infection.

Eimeria gallopavonis

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, smooth, 22–31 by 18–24 μm (mean 26 \times 21 μm), with no micropyle, polar granule or oocyst residuum. Sporocysts are ovoid and have a Stieda body. First-generation meronts are 14 by 13 μm and contain an average of 19 merozoites; second-generation meronts are 8 by 7 μm and contain an average of 13.5 merozoites; third-generation meronts are 9 by 9 μm and contain an average of 15 merozoites; and fourth-generation meronts are 12 by 10.5 μm and contain an average of seven merozoites. Mature macrogametes are 18–20 μm in diameter with microgamonts slightly smaller.

Host: Turkey

Life cycle: Endogenous stages occur in the epithelial cells at the tips of the villi and lie above the host cell nucleus. The first-generation meronts occur in the ileum and rectum. There appear to be two sizes of second-generation meronts, with smaller ones occurring in the rectum and ileum, more rarely the caeca, and larger ones only in the rectum. A few third-generation meronts are found in the rectum producing 10–12 merozoites. These and second-generation meronts develop into gamonts found primarily in the rectum and occasionally the ileum and caeca. The prepatent period is 144 hours. Oocyst sporulation time is 24 hours.

Geographical distribution: Worldwide

Pathogenesis: Reported to be moderately pathogenic.

Clinical signs: Watery or mucoid diarrhoea, depression, ruffled feathers, anorexia

Pathology: This species is found in the ileum, rectum and less commonly the caeca. The intestine is inflamed and oedematous with soft white caseous material in the lumen.

Eimeria meleagrimitis

Predilection site: Duodenum

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are subspherical, smooth, colourless, 16–27 by 13–22 μm (mean 19 \times 16 μm), with no micropyle or oocyst residuum, but with one to three polar granules. The sporocysts are ovoid, with a Stieda body and a residuum and contain a clear globule at the large end. First-generation meronts are 17 by 13 μm when mature (after 48 hours) and contain approximately 80–100 merozoites, 4.5 by 1.5 μm , with a nucleus at the larger end. Second-generation meronts are 8 by 7 μm and produce 8–16 merozoites, 7 by 1.5 μm , with the nucleus slightly near the centre. Third-generation meronts are the same size as the second-generation meronts but differ in possessing a residuum and have a nucleus nearer the large end. The mature macrogamonts and microgamonts are 15 by 11 μm and the macrogamonts contain a residuum.

Host: Turkey

Life cycle: The sporocysts emerge from the oocysts in the gizzard and the sporozoites are activated and emerge from the sporocysts in the small intestine. The sporozoites invade the tips of the villi and migrate down the villi in the lamina propria until they reach the glands.

First-generation meronts can be found in the gland epithelial cells as early as 12 hours after infection and are mature by 48 hours. The first-generation merozoites invade the adjacent epithelial cells, forming colonies of second-generation meronts that mature at about 66 hours after infection. Third-generation meronts may appear as early as 72 hours after inoculation and are mature by 96 hours. Macrogametes and microgamonts appear 114 hours after infection. The prepatent period is 144 hours. Oocyst sporulation time is 24–72 hours.

Geographical distribution: Worldwide

Pathogenesis: *Eimeria meleagrimitis* is moderately to markedly pathogenic and has three generations of merogony, with disease occurring after the rupture of the third-stage meronts, at about 4 days after infection. It is usually located in the small intestine anterior to the yolk stalk, but may extend throughout the intestine.

Clinical signs: Disease is seen in turkey poults 2–10 weeks of age and rarely in older birds because of acquired immunity. The affected poults are dull and listless, stand with ruffled feathers and have their heads tucked under their wings. Feed consumption drops following infection and affected birds are huddled together with closed eyes, drooping wings and ruffled feathers. Their droppings are white and mucoid and, at the peak of the disease, intestinal cores may be passed and the faeces may contain a few flecks of blood. Death occurs 5–7 days after infection, particularly in young poults under 6 weeks old.

Pathology: Lesions are seen from the end of the fourth day after infection. The jejunum is slightly thickened and dilated and contains an excessive amount of clear colourless fluid, or mucus containing merozoites, small amounts of blood and other cells. By days 5–6 after infection, the duodenum is enlarged and its blood vessels are engorged. It contains a reddish-brown necrotic core that is firmly adherent to the mucosa and extends a little way into the upper small intestine. The remainder of the intestine is congested and petechial haemorrhages may be present in the mucosa of most of the small intestine. The mucosa begins to regenerate on day 6 or 7 after infection. A few petechiae are present in the duodenum and jejunum. There are small streaks of haemorrhage and spotty congestion in the ileum. The posterior part of the jejunum and ileum may contain greenish mucoid casts, 5–10 cm long and 3–6 mm in diameter. Necrotic material may be found in the ileum or faeces.

The following two non-pathogenic species of coccidia in turkeys are uncommon.

Eimeria innocua

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are subspherical, smooth, 16–26 by 17–25 μm (mean 22 \times 21 μm), without a micropyle or polar granules.

Host: Turkey

Life cycle: Endogenous stages occur in the epithelial cells at the tips of the villi, which are heavily parasitised. The prepatent period is 120 hours and patency is 9 days. The sporulation time is 48 hours.

Geographical distribution: North America, Bulgaria

Eimeria subrotunda**Predilection site:** Small intestine**Phylum:** Apicomplexa**Class:** Conoidasida**Family:** Eimeriidae**Description:** Oocysts are subspherical, smooth, 16–26 by 14–24 µm (mean 22 × 20 µm), without a micropyle or polar granules.**Host:** Turkey**Life cycle:** Endogenous stages occur in the epithelial cells at the tips of the villi, extending along the side of the villi to some extent. The prepatent period is 96 hours and patency is 12–13 days. The sporulation time is 48 hours.**Geographical distribution:** North America**Coccidiosis in ducks and geese*****Eimeria anseris*****Predilection site:** Small and large intestine**Phylum:** Apicomplexa**Class:** Conoidasida**Family:** Eimeriidae**Description:** Oocysts are small and pear-shaped, with a truncated cone, smooth, colourless, 16–24 by 13–19 µm (mean 21 × 17 µm), with a micropyle, and without a polar granule but with a residuum just beneath the micropyle. Sporocysts are ovoid and almost completely fill the oocysts, 8–12 by 7–9 µm, with a slightly thickened wall at the small end and with a residuum. Mature meronts are 12 by 20 µm and contain approximately 15–25 merozoites. The macrogametes are usually spherical and 12–26 by 10–15 µm. The microgamonts are 12–66 by 8–18 µm.**Hosts:** Domestic goose, blue goose (*Anser caerulescens*), Richardson's Canada goose (*Branta canadensis hutchinsi*)**Life cycle:** The life cycle is typically coccidian, although precise details are lacking. There appears to be only one merogony generation. Endogenous stages occur in compact clumps under the intestinal epithelium near the muscularis mucosae and also in the epithelial cells of the villi of the small intestine, and in heavy infections also in the caeca and rectum. The gamonts are mostly in the subepithelial tissues but invade the epithelium in heavy infections. The prepatent period is 6–7 days and patent period 2–8 days.**Geographical distribution:** Europe**Pathogenesis:** There is comparatively little information on coccidiosis of ducks and geese. *Eimeria anseris* has been reported as causing acute intestinal coccidiosis with haemorrhage in goslings.**Clinical signs:** Diarrhoea with mucus and haemorrhage**Diagnosis:** Diagnosis is best based on postmortem examination of a few affected birds. At necropsy the location and type of lesions present provide a good guide to the species, which can be confirmed by examination of the oocysts in the faeces and the meronts and oocysts present in scrapings of the gut.**Pathology:** There may be intestinal hyperaemia and mucus production with flecks of coagulated blood within the gut lumen. Oocysts are found in small discrete papilliform lesions.**Epidemiology:** *Eimeria anseris* occurs in young birds and is associated with birds kept under intensive conditions.**Treatment:** Little is known about treatment but, by analogy with other hosts, one of the sulphonamide drugs should be tried.**Control:** Prevention is based on good management, avoidance of overcrowding and stress, and attention to hygiene. Contact with wild geese should be avoided wherever possible.***Eimeria nocens*****Predilection site:** Small intestine**Phylum:** Apicomplexa**Class:** Conoidasida**Family:** Eimeriidae**Description:** Oocysts are ellipsoidal or ovoid, thick-walled, brown, 25–33 by 17–24 µm (mean 29 × 20 µm), with a distinct micropyle, which is covered by the outer layer of the oocyst wall. Mature meronts are 15 by 30 µm and contain approximately 15–35 merozoites. The macrogametes are usually ellipsoidal or irregularly spherical and 20–25 by 16–21 µm. The microgamonts are spherical or ellipsoidal and 28–36 by 23–31 µm.**Hosts:** Domestic goose, blue goose (*Anser caerulescens*)**Life cycle:** Precise details of the life cycle are lacking. Developmental stages occur in the epithelial cells of the tips of villi at the posterior part of the small intestine but may also occur beneath the epithelium. The younger developmental stages lie near the host cell nuclei, and as they grow they displace the nuclei and eventually destroy the cell and come to lie free and partly beneath the epithelium. The prepatent period is 4–9 days.**Geographical distribution:** Europe, North America**Pathogenesis:** *Eimeria nocens* has been reported as causing acute intestinal coccidiosis in goslings.**Clinical signs:** Diarrhoea with mucus and flecks of blood**Diagnosis:** As for *E. anseris*.**Pathology:** There may be intestinal hyperaemia and mucus production with small flecks of coagulated blood within the gut lumen.**Epidemiology:** *Eimeria nocens* occurs in young birds and is associated with birds kept intensively under conditions which offer optimal conditions of temperature and humidity for oocyst sporulation. Overcrowding further exacerbates infection levels and risks from disease.**Treatment and control:** As for *E. anseris*.***Tyzzeria perniciosia*****Predilection site:** Small intestine**Phylum:** Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal, colourless, 10–13 by 9–11 μm (mean $12 \times 10 \mu\text{m}$), without a micropyle and with a residuum. Sporulated oocysts have no sporocysts and contain eight free sporozoites (see Table 2.2). First-generation meronts are 12 by 8 μm and contain only a few merozoites. Further meront generations are 15–16 by 14–15 μm and contain more and larger merozoites.

Hosts: Domestic duck, pintail duck, diving duck (*Aythya erythropus*)

Geographical distribution: Presumed worldwide

Pathogenesis: *Tyzzeria pernicioso* is highly pathogenic for ducklings. Infected birds stop eating, lose weight and become weak; there can be a high mortality.

Clinical signs: Anorexia, diarrhoea with mucus and haemorrhage

Diagnosis: Diagnosis is best based on postmortem examination and by examination of the oocysts in the faeces. Masses of very small rounded oocysts are present in smears and scrapings of the gut.

Pathology: On postmortem, inflammation and haemorrhagic areas are seen throughout the small intestine and especially in the upper part of the intestine. The intestinal wall is thickened and round white spots are visible through the serosal surface. In severe cases, the lumen is filled with blood and often cheesy exudates. The intestinal epithelium sloughs off in long pieces often forming a lifting 'tube'.

Treatment and control: As for *E. anseris*.

Eimeria anatis

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, smooth, colourless, 14–19 by 11–16 μm (mean $17 \times 14 \mu\text{m}$), with thickened ring-forming shoulders around the micropyle, and without a polar granule or residuum. Sporocysts are ovoid or ellipsoidal, with a slight thickening at the small end and with a few residual granules.

Hosts: Duck and wild mallard (*Anas platyrhynchos*)

Life cycle: The life cycle has not been described.

Geographical distribution: Europe (Germany, Russia and CIS states)

Pathogenicity: Unknown

Tyzzeria anseris

Synonym: *Tyzzeria parvula*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal, colourless, 10–16 by 9–14 μm , without a micropyle or residuum.

Hosts: Domestic goose, Canada goose and other wild geese

Geographical distribution: Worldwide

Coccidiosis in gamebirds

Pheasants

The development of intensive management systems by pheasant-rearing farms has led to an increase in coccidiosis. The significance of coccidiosis in wild pheasants is difficult to assess because natural predators and scavengers deal promptly with weak or dead birds. Treatment with clodipol, lasalocid, amprolium or potentiated sulphonomides (sulphaquinolaxaline or sulphadimidine) is generally effective, although specific efficacy data are lacking.

Apart from the usual measures of isolation and rigorous hygiene, the use of preventive medication in intensively reared pheasants provides a means of controlling the disease where outbreaks occur.

Eimeria colchici

Predilection site: Caeca

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are elongate, ellipsoidal with one side less rounded than the other, colourless, 19–33 by 11–21 μm (mean $27 \times 17 \mu\text{m}$) with an inconspicuous micropyle, a polar granule but no oocyst residuum (Fig. 13.21). Sporocysts are elongate, 11.5–15.5 by 6–7.5 μm (mean $14.6 \times 6.6 \mu\text{m}$). Sporozoites are arranged head to tail in the sporocysts and possess a single large refractive globule. First-generation meronts are 18 by 13 μm and contain 50–100 elongate merozoites; second-generation meronts are 28 by 21 μm and contain large numbers of merozoites; and third-generation meronts measure 8.5 by 7 μm and contain on average 19 merozoites.

Hosts: Pheasants

Life cycle: The life cycle is typically coccidian. First-generation meronts are found deep in the glands of the mucosal lining of the mid small intestine; second-generation meronts appear in colonies in the lamina propria at the base of the villi; small third-generation meronts develop in the glands of the caeca. The gametocytes develop in the epithelial cells lining the caecal mucosa. The prepatent period is 6 days. Sporulation time is 2 days.

Geographical distribution: USA, Europe (UK, Bulgaria, Czech Republic, Slovakia)

Pathogenesis: *Eimeria colchici* is the most pathogenic species of coccidia in pheasants, producing weight loss and mortality in infected birds.

Clinical signs: Diarrhoea and white soiling around the vent

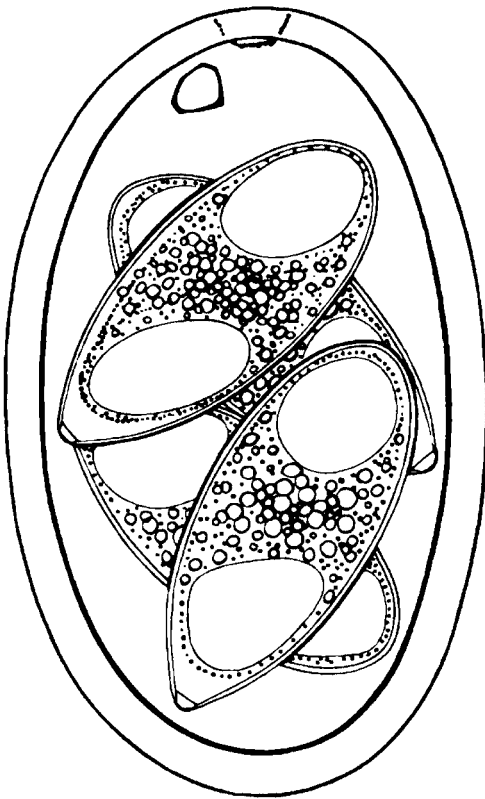

Fig. 13.21 Oocyst of *Eimeria colchici*.

Diagnosis: Postmortem examination of affected birds reveals the characteristic white cores and examination of scrapings or histological sections of affected tissues shows large numbers of gametocytes in the caeca. On faecal examination there are large numbers of oocysts in a white caseous exudate and these are readily identifiable after sporulation (Fig. 13.22).

Pathology: There is hyperaemia and mucoid enteritis in the small intestine caused by the second-generation meronts. Dead birds have soft white cores in the caeca and lower small intestine. In the caeca there is extensive invasion of the mucosa by gametocytes with

Fig. 13.22 Sporulated oocysts of *Eimeria colchici* isolated from faeces.

the entire epithelium and subepithelial cells of the lamina propria infected. The cores are composed of oocysts, necrotic debris and food material.

Eimeria duodenalis

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are subspherical to broadly ellipsoidal, smooth, colourless to pale yellowish-brown, 18–24 by 15.4–21.4 μm (mean 21.2 \times 18.6 μm), with no micropyle and no oocyst residuum (Fig. 13.23). The ellipsoidal sporocysts measure 11.6–13.6 by 6.1–6.8 μm (mean 12.6 \times 6.7 μm). There is a small Stieda body and a larger sub-Stieda body. The sporocyst residuum largely obscures the sporozoites, which possess a large refractile body and occasionally a second smaller one.

Hosts: Pheasants

Life cycle: First-generation meronts appear in the epithelial cells towards the tips of the duodenal villi. Second- and third-generation meronts follow on quickly in the same site but extending further along the intestinal tract. Gametocytes and third-generation meronts are both present together, and the infection may extend throughout the entire small intestine with the villi heavily parasitised, and multiple infections of individual epithelial cells occurring frequently. The prepatent period is 5 days. Sporulation time is 1–2 days.

Geographical distribution: Europe (UK, France, Lithuania, Kazakhstan), USA

Fig. 13.23 Oocyst of *Eimeria duodenalis*.

Pathogenesis: As the specific name implies, this parasite develops in the duodenum and upper small intestine where it can cause a mucoid enteritis.

Clinical signs: Light infections are generally asymptomatic but heavier infections may cause mucoid diarrhoea.

Diagnosis: Postmortem examination of affected birds reveals a mucoid enteritis in the duodenum and upper small intestine and examination of scrapings or histological sections of affected tissues shows large numbers of small subspherical oocysts in the small intestine.

Pathology: The intestines of the birds that die are congested and contain a pinkish mucoid exudate, while the caeca may be distended with a foamy yellow fluid. Scrapings from the small intestine show masses of small subspherical oocysts.

Epidemiology: Coccidiosis in pheasants occurs most frequently in young birds reared under intensive conditions. Disease surveys carried out in the UK have shown that *E. duodenalis* accounted for 10–15% of the coccidiosis cases where species identification was possible.

Eimeria megalostoma

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, yellowish-brown, 24 by 19 μm , with a thick oocyst wall and prominent micropyle.

Hosts: Pheasants

Life cycle: Not described

Geographical distribution: North America, UK, Kazakhstan

Pathogenesis: No information available. Occurs only rarely in small numbers and has not been associated with outbreaks of disease.

Clinical signs: Not reported

Diagnosis: Diagnosis is based on oocyst morphology from faecal samples. Where possible, postmortem examination of affected birds and examination of scrapings or histological sections of affected tissues should be undertaken.

Pathology: Not described

Epidemiology: The significance of coccidiosis in wild pheasants is difficult to assess because natural predators and scavengers deal promptly with weak or dead birds.

Eimeria pacifica

Predilection site: Small intestine, caeca

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, 17–26 by 14–20 μm , with a mammillated oocyst wall.

Hosts: Pheasants

Life cycle: The life cycle is typically coccidian. Endogenous stages have been reported to occur in the epithelial cells of the duodenum but have also been reported in the caeca.

Geographical distribution: North America, Kazakhstan, Lithuania

Pathogenesis: Infection produces mucoid enteritis with low mortality but high morbidity.

Clinical signs: Mucoid diarrhoea

Diagnosis: Postmortem examination of affected birds reveals a mucoid enteritis and examination of scrapings or histological sections of affected tissues shows large numbers of small subspherical oocysts in the small intestine and caeca.

Pathology: Not described

Epidemiology: As for other species of coccidia.

Eimeria phasiani

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal, smooth, yellowish, 20.1–30.9 by 13.4–20.5 μm (mean $25 \times 17 \mu\text{m}$), with no micropyle and no oocyst residuum, but with one to three polar granules. Sporocysts are elongate, pyriform, each with a prominent Stieda body, 12.9–15.9 by 5.6–7.4 μm (mean $14.3 \times 6.7 \mu\text{m}$). Sporozoites contain a single refractile body.

Hosts: Pheasants

Life cycle: Development of the endogenous stages occurs in the small intestine and there is a gradual spread down the gut as the infection proceeds. First-generation meronts develop in the epithelial cells lining the glands of the ascending duodenum and upper small intestine. Second-generation meronts are most numerous towards the tips of the villi in the upper small intestine. Third-generation meronts and gametocytes are found throughout the small intestine and also in the proximal part of the caeca, being most numerous towards the tips of the villi. The prepatent period is 5 days. Sporulation time is 2 days.

Geographical distribution: Europe (UK, France, Germany, Czech Republic, Slovakia, Lithuania, Kazakhstan), USA

Pathogenesis: Mortality can reach 50% in 2- or 3-week-old pheasants.

Clinical signs: Infection can result in anorexia, depression and a reduction in weight gain and in heavy infections causes liquid faeces with mucus and a little blood.

Diagnosis: Postmortem examination of affected birds reveals a mucoid enteritis and examination of scrapings or histological sections of affected tissues shows large numbers of gametocytes in the small intestine and proximal part of the caeca.

Fig. 13.24 Caecal lesions of *Eimeria phasiani*.

Pathology: The main lesions consist of mucoid enteritis in the small intestine. The intestines of heavily infected birds are hyperaemic and show petechial haemorrhages, while the lumen may be filled with blood-streaked mucus (Fig. 13.24). The developmental stages of *E. phasiani* occur below the nucleus of the host cell, causing ballooning of the infected cell with enlargement of the nucleus. Oocysts occur throughout the small intestine and in the proximal part of the caeca.

Epidemiology: Coccidiosis in pheasants occurs most frequently in young birds reared under intensive conditions. Disease surveys carried out in the UK have shown that *E. phasiani* accounted for approximately 15% of the coccidiosis cases where species identification was possible. In studies conducted in the Czech Republic/Slovakia, *E. phasiani* occurred less frequently than *E. colchici* in wild pheasants but was most prevalent during the winter and spring, when it was identified in 18–41% of the samples examined.

Partridge

Several species of coccidia have been described in partridge, based mainly on oocyst morphology. Details on life cycle, pathogenesis, treatment and control are lacking. Prevention, as with other hosts, should be based on good management, avoidance of overcrowding and stress, and attention to hygiene.

Eimeria caucasica

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are elongate, rarely ovoid, 25–36 by 14–21 μm (mean 33 \times 19 μm).

Hosts: Rock partridge (*Alectoris graeca*)

Geographical distribution: Eastern Europe, Kazakhstan

Notes: Thought to be a *nomen nudum* (fails to qualify as a valid scientific name because of an inadequate description).

Eimeria procera

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are elongate–ellipsoidal, 28–31 by 16–17 μm (mean 29.5 \times 16.5 μm).

Hosts: Grey partridge (*Perdix perdix*)

Geographical distribution: Unknown

Eimeria koifoidi

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, 16–25 by 14–20 μm (mean 20 \times 18 μm).

Hosts: Grey partridge (*Perdix perdix*), chukar partridge (*Alectoris chukar*), rock partridge (*Alectoris graeca*).

Geographical distribution: Unknown; reported in UK and Bulgaria

Eimeria legionensis

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are elliptic, almost symmetrical, sometimes slightly flattened, 18–24 by 12–16 μm (mean 21.3 \times 14.6 μm).

Hosts: Red-legged partridge (*Alectoris rufa*), rock partridge (*Alectoris graeca*)

Geographical distribution: Unknown; reported in UK and Bulgaria

Diagnosis: Postmortem examination of affected birds reveals the characteristic white cores and examination of scrapings or histological sections of affected tissues shows large numbers of gametocytes in the caeca. On faecal examination there are large numbers of oocysts in a white caseous exudate.

Pathology: Dead birds have soft white cores in the caeca and lower small intestine. In the caeca there is extensive invasion of the mucosa by gametocytes with the entire epithelium and subepithelial cells of the lamina propria infected. The cores are composed of oocysts, necrotic debris and food material.

Quail

Several species of coccidia have been described in these species, based mainly on oocyst morphology. Details on life cycle, pathogenesis, treatment and control are lacking.

Eimeria bateri

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoid, ovoid or infrequently round, 15–28 by 14–23 μm (mean 23 \times 18 μm).

Hosts: Japanese quail (*Coturnix japonica*), common quail (*Coturnix coturnix*)

Geographical distribution: Unknown

Eimeria coturnicus

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are oval, 26–39 by 20–26 μm (mean 32.5 \times 23 μm).

Hosts: Common quail (*Coturnix coturnix*)

Geographical distribution: Unknown

Eimeria taldykurganica

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, 21.9–25.4 by 11.9–13.1 μm (mean 23.65 \times 12.5 μm).

Hosts: Japanese quail (*Coturnix japonica*), common quail (*Coturnix coturnix*)

Geographical distribution: Japan, USA

Eimeria tsunodai

Predilection site: Caeca

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, 15.5–22.5 by 16.5–18.5 μm (mean 19 \times 17.5 μm).

Hosts: Japanese quail (*Coturnix japonica*)

Geographical distribution: Japan, USA

Pathogenesis and clinical signs: Produces a distinctive haemorrhagic caecal coccidiosis with bloody diarrhoea.

Eimeria uzura

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are broad elliptic or ovoid, 19–30 by 15–23 μm (mean 24.4 \times 18.7 μm).

Hosts: Japanese quail (*Coturnix japonica*)

Geographical distribution: Japan, USA

Pathogenesis and clinical signs: Reported to cause outbreak of coccidiosis in commercially reared Japanese quail in USA.

Guinea fowl

Eimeria grenieri

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal, smooth, 15–27 by 12–18 μm (mean 21 \times 15 μm), with a micropyle and polar granules but without a residuum. Sporocysts are ovoid, with a Stieda body and a residuum.

Hosts: Guinea fowl

Life cycle: The life cycle is typically coccidian and there appear to be three merogony generations. First-generation meronts are in the epithelial cells of the crypts below the host cell nucleus near the muscularis mucosae of the duodenum. Second-generation meronts are in the crypts of the lower part of the villi of the upper and middle small intestine. Third-generation meronts are in the middle to tips of the villi of the middle to lower small intestine. The gamonts are in the caecal epithelium. The prepatent period is 4–5 days and the patent period 3 days.

Geographical distribution: Europe, Africa

Pathogenesis and clinical signs: *Eimeria grenieri* has been reported to cause disease in guinea fowl, inducing diarrhoea and weight loss.

Eimeria numidae

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal, smooth, 15–21 by 12–17 μm , with a button-shaped micropyle, a polar granule but without a residuum. Sporocysts are elongate, pointed at one end without a Stieda body.

Hosts: Guinea fowl

Life cycle: First-generation meronts are in the epithelial cells of the duodenum. Second-generation meronts are in the epithelial cells of the jejunum and ileum and also in the large intestine as far as the rectum. Some of the second-generation meronts form third-generation meronts. The prepatent period is 5 days. Sporulation time is 1–2 days.

Geographical distribution: Europe (Hungary)

Pathogenesis and clinical signs: Not considered markedly pathogenic, although may cause mortality in heavy infections. Symptoms include mucous diarrhoea and depression.

Other protozoa

Cryptosporidium baileyi

For more details see section Large intestine.

Cryptosporidium meleagridis

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Description: Oocysts are ellipsoid, 5.6–6.3 by 4.5–4.8 μm (mean $6.2 \times 4.6 \mu\text{m}$).

Hosts: Turkey, chicken, duck, parrot

Geographical distribution: Presumed worldwide

Pathogenesis: Infection with this parasite has been associated with diarrhoea and a low death rate in 10- to 14-day-old turkey poults. *Cryptosporidium meleagridis* also infects other avian hosts (e.g. parrots) and is also the third most common *Cryptosporidium* parasite in humans.

Clinical signs: Diarrhoea

Diagnosis: Oocysts may be demonstrated using Ziehl–Neelsen-stained faecal smears in which the sporozoites appear as bright-red granules. Speciation of *Cryptosporidium* is difficult, if not impossible, using conventional techniques. A range of molecular and immunological techniques has been developed that includes immunofluorescence and enzyme-linked immunosorbent assay (ELISA). More recently, DNA-based techniques have been used for the molecular characterisations of *Cryptosporidium* species.

Pathology: Following ingestion, the sporozoites invade the microvillous brush border of the proventriculus, intestines and lungs and the trophozoites rapidly differentiate to form meronts with four to

eight merozoites. Only a single merogony generation has been reported. There is villous atrophy and crypt hyperplasia in the ileum of affected turkeys and humans.

Epidemiology: Transmission appears to be mainly via the faecal–oral route.

Treatment and control: There is no reported effective treatment. Good hygiene and management are important in preventing disease from cryptosporidiosis. Thus litter should always be kept dry and special attention given to litter near water fonts or feeding troughs. Fonts that prevent water reaching the litter should always be used and they should be placed on drip trays or over the droppings pit. Feeding and watering utensils should be of such a type and height that droppings cannot contaminate them. Batch rearing of birds, depopulation and adequate disinfection procedures should help limit levels of infection. Antibiotics to control secondary bacterial infections of the respiratory form may be required. Good ventilation in poultry houses is also essential.

Spiroucleus meleagridis

Synonym: *Hexamita meleagridis*

Common names: Infectious catarrhal enteritis, hexamitosis, spiro-nucleosis

Predilection site: Small intestine, caeca

Phylum: Fornicata

Class: Trepamonadea

Family: Hexamitidae

Description: Trophozoites are bilaterally symmetrical, 6–12 by 2–5 μm , and possess two nuclei, two sets of three anterior flagella, and two flagella that pass through the body to emerge posteriorly (see Fig. 2.20).

Hosts: Turkey, duck, gamebirds (pheasant, quail, partridge)

Geographical distribution: Worldwide

Pathogenesis: Spiro-nucleosis is a disease of young birds with adult birds symptomless carriers. The mortality in a flock varies and can be as high as 80%, reaching a peak in the flock at 7–10 days after the first bird dies, but heavy losses seldom occur in birds over 10 weeks old. The incubation period is 4–7 days.

Clinical signs: Affected birds are ruffled, have a foamy watery diarrhoea, lose weight rapidly and may become weak and die.

Diagnosis: Infection can be diagnosed by finding the characteristic motile protozoa in fresh scrapings from the small intestine. The organism can be differentiated from other flagellates in the gut by its small size, absence of an undulating membrane and characteristic motion. The organism can also be demonstrated in Giemsa-stained smears from the small intestine (Fig. 13.25).

Epidemiology: Infection is transmitted through contaminated feed and water. Carrier adult birds are the most important sources of infection for young poults. Wild gamebirds may be a source of infection to birds reared outdoors in natural pens. Hot weather and overcrowding predispose to infection and the severity of a disease outbreak.

Fig. 13.25 Trophozoites of *Spironucleus meleagridis* (Giemsa stain).

Treatment: Dimetridazole 27 g per 100 L of drinking water for 12 days, or 54 g per 100 L for 3–5 days then 27 g per 100 L for 12 days are effective treatments. However, in many countries products containing dimetridazole (and other nitroimidazole compounds) are becoming unavailable for legislative reasons.

Control: Control depends on good management and hygiene. Young birds should be raised in batches away from others birds of different age groups. Separate utensils should be used for different groups of birds and kept raised or on wire mesh floors. Outdoor natural pens should be moved periodically and contact with pheasants, quail or partridge prevented. Dimetridazole 125–200 g/tonne in feed or 12 g/L in drinking water for up to 15 days can be used in prevention. However, see the proviso in the previous paragraph regarding availability.

LARGE INTESTINE

Several species of *Heterakis* are found in poultry.

Heterakis gallinarum

Synonyms: *Heterakis papillosa*, *Heterakis gallinae*, *Heterakis vesicularis*

Common name: Poultry caecal worm

Predilection site: Caeca; rarely large and small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: Whitish worms up to 1.5 cm long, with elongated pointed tails. The male is 7–13 mm long and the female 10–15 mm (Fig. 13.26). Gross examination readily indicates the genus, but for specific identification microscopic examination is necessary to determine the shape of the oesophagus and the size and shape of spicules.

Description, microscopic: The oesophagus has a large posterior bulb. Generic identity may be confirmed by the presence of a large circular pre-cloacal sucker in the male and prominent caudal alae supported by 12 pairs of caudal papillae (see Fig. 1.55). The spicules are unequal in length, the left (about 0.7 mm) has broad alae and the right is slender (about 2 mm). The egg is ovoid, thick and smooth-shelled with almost parallel side walls (see Fig. 4.7). Eggs measure 65–80 by 35–46 μm and are unsegmented when laid. *Heterakis* eggs are sometimes difficult to distinguish from those of

Fig. 13.26 Adult *Heterakis gallinarum* worms.

Ascaridia, although in the latter species the eggs are larger and have slightly barrel-shaped side walls.

Hosts: Chicken, turkey, pigeon, pheasant, partridge, grouse, quail, guinea fowl, duck, goose and a number of wild galliform birds

Geographical distribution: Worldwide

Pathogenesis: *Heterakis gallinarum* is the commonest nematode parasite of poultry, and is usually regarded as being non-pathogenic, although heavy infections can induce thickening of the caecal mucosa. Its chief pathogenic importance is as a vector of the protozoan *Histomonas meleagridis*, the causal agent of 'blackhead' (enterohepatitis) in turkeys. The organism can be transmitted from fowl to fowl in the egg of *Heterakis* and in earthworms containing hatched larvae of the worm.

Clinical signs: Frequently, *H. gallinarum* alone produces an asymptomatic infection.

Diagnosis: *Heterakis gallinarum* infection is usually only diagnosed accidentally, by the finding of eggs in faeces or the presence of worms at necropsy. Differentiation between the three species of *Heterakis* is based on the shape of the oesophagus and the length and shape of the spicules.

Pathology: The caeca may show marked inflammation and thickening of the mucosa with petechial haemorrhages.

Epidemiology: *Heterakis gallinarum* is widespread in most poultry flocks and is of little pathogenic significance in itself, but is of great importance in the epidemiology of *Histomonas*. Larvated eggs can remain viable in soil for about 1 year and can be a source of infection in free-range birds. Additionally, paratenic hosts such as earthworms can transmit infection.

Treatment: Treatment with piperazine salts, levamisole or a benzimidazole is effective. Flubendazole, mebendazole or fenbendazole can be administered in the feed (30 ppm over 7 days; 60 ppm over 7 days; 60 ppm over 3 days; respectively). Levamisole is effective at 30 mg/kg orally or 300 ppm in the feed.

Control: Control of *H. gallinarum* is only necessary when histomonosis is a problem in turkeys. It is largely based on hygiene, and in backyard flocks the two most important factors are the segregation of turkeys from other domestic poultry, and the removal and disposal of litter from poultry houses. Where the problem is serious and continuous, it may be advisable to administer either piperazine or levamisole intermittently in the feed or water in addition to continuous *Histomonas* chemoprophylaxis.

Heterakis isolonche

Common name: Caecal worm

Predilection site: Caeca; rarely large and small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: Whitish worms up to 1.5 cm long, with elongated pointed tails. The male is 7–13 mm long and the female 10–15 mm. Gross examination readily indicates the genus, but for specific identification microscopic examination is necessary to demonstrate the spicules.

Description, microscopic: The spicules are asymmetrical and generic identity may be confirmed by the presence of a large circular pre-cloacal sucker in the male and prominent caudal alae supported by large caudal papillae. The egg is ovoid, thick and smooth-shelled, about 65–75 by 38–45 µm. More details of the eggs are given under *H. gallinarum*.

Hosts: Pheasant, grouse, quail, duck, chicken

Geographical distribution: Worldwide

Pathogenesis: *Heterakis isolonche* of gamebirds is in itself pathogenic, causing a severe inflammation of the caeca with nodules projecting from both peritoneal and mucosal surfaces. These can cause ulceration of the mucosa and diarrhoea with progressive emaciation and there may be high mortality in heavily infected flocks.

Clinical signs: Infections with *H. isolonche* may produce nodular typhlitis, diarrhoea, emaciation and death.

Diagnosis: *Heterakis isolonche* infection is diagnosed at necropsy by the finding of caecal nodules containing adult worms and, if necessary, confirmed microscopically by examination of the spicules.

Pathology: In *Heterakis isolonche* infection, the hatched larvae enter the caecal mucosa, and develop to maturity in nodules. Each nodule has an opening into the gut through which the eggs reach the lumen. The caeca may show marked inflammation and thickening of the mucosa with nodule formation and petechial haemorrhages.

Epidemiology: Infection is common in birds raised in permanent grass pens. Larvated eggs can remain viable in soil for about 1 year. Additionally, paratenic hosts such as earthworms can transmit infection.

Treatment: As for *H. gallinarum*.

Control: Where *H. isolonche* infection is endemic in pheasantries, the runs should be abandoned and pheasant chicks reared on fresh ground.

Heterakis dispar

Predilection site: Caeca; rarely large and small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: Refer to *H. gallinarum*, though *H. dispar* is larger than either *H. gallinarum* or *H. isolonche*; males measure 11–18 mm and females 16–23 mm in length.

Description, microscopic: The male spicules are of subequal length (40–50 µm). Eggs measure about 59–62 by 31–41 µm. More details of the eggs are given under *H. gallinarum*.

Hosts: Duck, goose, chicken

Geographical distribution: Many parts of the world

Heterakis brevispeculum

Predilection site: Caeca; rarely large and small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description: See *H. gallinarum* for general information. The spicules are of equal length (about 0.5 mm) and possess a barb near the tip.

Hosts: Duck, goose, guinea fowl, chicken

Geographical distribution: Worldwide

Trichostrongylus tenuis

Predilection site: Small intestine, caeca

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are small and hair-like. Males measure around 5.0–6.5 mm and females 7–9 mm in length. The spicules are curved.

Description, microscopic: The worms have no buccal capsule. A useful generic character is the distinct excretory notch in the oesophageal region. The medium-sized eggs are long and ovoid with dissimilar poles and parallel side walls and are pale coloured with an almost colourless shell (see Fig. 4.7). They have a thin shell with a smooth surface and measure about 65–75 by 35–42 μm .

Hosts: Gamebirds (grouse, partridge and pheasant), chicken, duck, goose, turkey, emu

Geographical distribution: North America, Asia and Europe

Pathogenesis: *Trichostrongylus tenuis* has been implicated in outbreaks of severe enteritis in gamebirds. Moderate to severe infections cause diarrhoea, which is often fatal. Lighter infections result in a chronic syndrome characterised by anaemia and emaciation.

Clinical signs: Reduced appetite, anaemia and general emaciation

Diagnosis: Identification of the adult worms on postmortem

Pathology: Light infections produce few pathological effects, but heavy infections can induce an acute haemorrhagic typhlitis.

Epidemiology: High stocking densities can lead to build-up of large numbers of infective larvae with associated high morbidity and mortality, particularly in grouse.

Treatment: On game farms, therapy with levamisole in the drinking water has proved useful. Formulations of fenbendazole and flubendazole are available for incorporation into feed or grit.

Control: Where gamebirds are farmed, the pens should be moved regularly to prevent the accumulation of larvae and, if possible, the runs should not be placed in the same areas in successive years.

Capillaria anatis

Synonyms: *Capillaria brevicollis*, *Capillaria collaris*, *Capillaria mergi*, *Thornix anatis*

Predilection site: Caeca

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: See *Eucoleus annulata*. Males measure around 16–24 mm and females 28–38 mm.

Description, microscopic: The males have a long thin single spicule and often possess a primitive bursa-like structure. The eggs are slightly barrel-shaped, light brown and with protruding transparent polar plugs (see Fig. 4.7). They measure around 48–65 by 23–35 μm and the outer shell is thick, striated and rugose. More details of the eggs are given under *Capillaria contorta*.

Hosts: Chicken, turkey, gallinaceous birds (pheasant, partridge), pigeon, duck, goose

Geographical distribution: Worldwide

Pathogenesis: The anterior ends of the worms are embedded in the mucosa. Heavy infection can induce haemorrhagic enteritis with bloody diarrhoea. The caecal wall is often thickened.

Clinical signs: Infected birds may become weak and emaciated and be anaemic.

Pathology: Chronically infected birds have thickened intestinal walls covered with a catarrhal exudate.

Treatment and control: As for other *Capillaria* species (Table 13.4).

Subulura suctoria

Synonyms: *Allodapa suctoria*, *Subulura brumpti*, *Subulura differens*

Predilection site: Caeca

Phylum: Nematoda

Class: Secernentea

Superfamily: Subuluroidea

Description, gross: The males measure around 8–10 mm and the females up to 18 mm.

Description, microscopic: The small buccal capsule has three teeth at its base. The oesophagus is dilated posteriorly, followed by a bulb. The tail of the male has large lateral alae and is curved ventrad. A slit-like pre-cloacal sucker is present, surrounded by radiating muscle fibres. In the female, the vulva is situated just anterior to the middle of the body. Eggs are thin-shelled, smooth

Table 13.4 Species of *Eucoleus/Capillaria* found in gamebirds.

| Species | Hosts | Location |
|--|--|------------------------|
| <i>Eucoleus (Capillaria) contorta</i> | Chicken, turkey, duck, pheasant and wild birds | Oesophagus, crop |
| <i>Eucoleus (Capillaria) annulata</i> | Chicken, turkey, duck and wild birds | Oesophagus, crop |
| <i>Eucoleus (Capillaria) perforans</i> | Pheasant, guinea fowl | Oesophagus, crop |
| <i>Capillaria uropapillata</i> | Pheasant | Oesophagus, crop |
| <i>Capillaria phasianina</i> | Pheasant, grey partridge | Small intestine, caeca |
| <i>Capillaria anatis</i> | Chicken, turkey, gallinaceous birds (pheasant, partridge), pigeon, duck, goose | Caeca |

and subspherical, measuring about 52–64 by 41–49 µm. They are embryonated when laid.

Final hosts: Chicken, turkey, guinea fowl, quail, grouse, pheasant and various galliform birds such as ducks

Intermediate hosts: Include various cockroaches, beetles and ear-wigs

Geographical distribution: Asia, Africa and the Americas, Hawaii, parts of Europe (Spain)

Treatment and control: Not usually required.

Notes: Current taxonomic revision suggests this genus falls within its own superfamily, the Subuluroidea.

Strongyloides avium

Common name: Threadworm

Predilection site: Caeca, small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Rhabditoidea

Description, gross: Slender hair-like worms about 2 mm long. Only females are parasitic.

Description, microscopic: The long oesophagus may occupy up to one-third of the body length and the uterus is intertwined with the intestine, giving the appearance of twisted thread (see Fig. 1.51). Unlike other intestinal parasites of similar size the tail has a blunt point. *Strongyloides* eggs are oval, thin-shelled and small, 52–56 by 36–40 µm, being half the size of typical strongyle eggs. The larvated egg is usually passed in the faeces.

Hosts: Chicken, turkey, goose, quail, wild birds

Geographical distribution: Worldwide

Pathogenesis: *Strongyloides* can be a serious pathogen in young floor-reared birds.

Clinical signs: Acute heavy infections cause weakness, emaciation and bloody slimy diarrhoea.

Diagnosis: Small embryonated eggs may be found in the faeces. Adult parasites can be demonstrated in mucosal scrapings from the caecal mucosa on postmortem.

Pathology: Mature parasites in the caeca, if present in large numbers, may cause inflammation with oedema and erosion of the epithelium.

Epidemiology: *Strongyloides* infective larvae are not ensheathed and are susceptible to extreme climatic conditions. However, warmth and moisture favour development and allow the accumulation of large numbers of infective stages.

Treatment and control: No information is available.

Caecal flukes

See general comments in section Intestinal flukes. See also Table 13.5.

Notocotylus attenuatus

Predilection site: Caecum, rectum

Phylum: Platyhelminthes

Class: Trematoda

Family: Notocotylidae

Description, gross: The adult fluke is 2–5 mm long by 0.7–1.5 mm wide and is narrow anteriorly.

Description, microscopic: There is no ventral sucker. The testes are situated posteriorly and the ovary lies between them. The uterus forms regular transverse coils extending from the posterior ovary to the elongate cirrus sac, situated anteriorly. Eggs are small, ovoid and measure 20–22 by 10–11 µm and possess a long filament at each polar plug that measures up to 200 µm in length. The egg contains a miracidium.

Final hosts: Chicken, duck, goose and other aquatic birds

Intermediate hosts: Snails, such as *Planorbis* spp., *Lymnaea* spp. and *Bulinus*

Geographical distribution: Worldwide

Table 13.5 Caecal flukes found in poultry.

| Parasite | Family | Size (mm) | Predilection site | Final host | Intermediate hosts | Geographical location |
|---|------------------|-----------|-------------------|--|---|---|
| <i>Notocotylus attenuatus</i> | Notocotylidae | 3–5 × 1 | Caeca and rectum | Chicken, duck, goose, wild aquatic birds | Various snails | Many parts of the world |
| <i>Catatropis verrucosa</i> | Notocotylidae | 2–6 × 1–2 | Caeca | Chicken, duck, goose, wild aquatic birds | Various snails | Worldwide |
| <i>Brachylaemus commutatus</i> | Brachylaemidae | 4–7 × 1–2 | Caeca | Chicken, turkey, other fowl, pigeon and pheasant | Land snails | Southern Europe, Africa, parts of Asia |
| <i>Postharmostomum commutatum</i> (syn. <i>P. gallinarum</i>) | Brachylaemidae | | Caeca | Chicken, turkey, guinea fowl, pheasant, pigeon | Various snails | North Africa, North America, southern Europe, parts of Southeast Asia |
| <i>Echinostoma revolutum</i> | Echinostomatidae | 1–1.5 | Caeca and rectum | Duck, goose, pigeon, various fowl, aquatic birds | 1: Aquatic snails 2: Various aquatic snails and tadpoles | Worldwide |
| <i>Echinostoma paraulum</i> (syn. <i>Echinoparyphium paraulum</i>) | Echinostomatidae | 1–1.5 | Caeca and rectum | Duck, pigeon | 1: Aquatic snails 2: Fish | Worldwide |

Catatropis verrucosa

Predilection site: Caecum

Phylum: Platyhelminthes

Class: Trematoda

Family: Notocotylidae

Description, gross: The fluke is 2–6 mm long by 0.8–2 mm wide, and rounded anteriorly and posteriorly.

Description, microscopic: There is no ventral sucker. The testes are situated posteriorly and the ovary lies between them. The small oval, slightly reddish eggs measure around 20–25 by 10–11 μm and possess a long filament at each polar plug that measures about 160–200 μm in length. The egg contains a miracidium.

Final hosts: Chicken, duck, goose and other aquatic birds

Intermediate hosts: Snails, such as *Planorbis* spp.

Geographical distribution: Worldwide

Brachylaemus commutatus

Synonyms: *Harmostomum commutatus*, *Postharmostomum gallinum*

Predilection site: Caeca

Phylum: Platyhelminthes

Class: Trematoda

Family: Brachylaemidae

Description, gross: The elongate flukes measure around 4–7 mm in length by 1–2 mm in width and have smooth bodies.

Description, microscopic: Eggs are approximately 30 by 15 μm .

Final hosts: Chicken, turkey, other fowl, pigeon and pheasant

Intermediate hosts: Land snails

Geographical distribution: Southern Europe, Africa, parts of Asia

Echinostoma revolutum

Predilection site: Caeca and rectum

Phylum: Platyhelminthes

Class: Trematoda

Family: Echinostomatidae

Description, gross: The fluke is about 10–20 mm long and up to 2 mm in width.

Description, microscopic: The head-collar is armed with around 37 spines, some forming groups of ‘corner’ spines. The anterior of the cuticle is covered in spines. The ovary is anterior to the tandem testes. The large eggs are slightly yellowish in colour, operculate and measure about 95–120 by 60–70 μm .

Final hosts: Duck, goose, pigeon, various fowl and aquatic birds

Geographical distribution: Worldwide

Notes: *Echinostoma revolutum* can also infect humans. *Echinostoma paraulum* occurs in the small intestine of duck and pigeon and can cause weakness, inappetence and diarrhoea in the latter.

Chicken caecal coccidiosis

Two species of coccidia are found in the chicken, of which *Eimeria tenella* is the most important throughout the world.

Eimeria tenella

Predilection site: Caeca (Fig. 13.27)

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, smooth, colourless, 14–31 by 9–25 μm (mean 25 \times 19 μm), without a micropyle or residuum but with a polar granule (Fig. 13.28). The sporocysts are ovoid, with a Stieda body and without a residuum.

Host: Chicken

Life cycle: Following ingestion, the oocyst wall breaks in the gizzard releasing the sporocysts. The sporozoites are activated by bile or trypsin when the sporocysts reach the small intestine, and they escape from the sporocysts. The sporozoites enter the epithelial cells either directly or following ingestion by a macrophage. The sporozoite rounds up to form a first-generation meront,

Fig. 13.27 Predilection site of *Eimeria tenella*.

Fig. 13.28 Oocysts of *Eimeria tenella*.

each containing about 900 merozoites, which are approximately 2–4 μm long. These emerge into the caeca about 2.5–3 days after infection and invade new host cells. Second-generation meronts are formed, and these lie above the host cell nucleus producing 200–350 merozoites, which are approximately 16 μm long and which are found 5 days after inoculation. They invade new host cells to form either the third-generation meronts (which lie beneath the host cell nucleus and produce 4–30 third-generation merozoites which are about 7 μm long and which invade new cells to form gamonts) or the gamonts directly. The macrogametes and microgamonts lie below the host cell nuclei. The microgamonts form many biflagellate microgametes, which fertilise the macrogametes. The resulting oocysts lay down a resistant wall, break out of the cells into the gut lumen and are then passed in the faeces. The prepatent period is 132 hours. Sporulation time is 18–48 hours.

Geographical distribution: Worldwide

Pathogenesis: The first-stage meronts of this species develop deep in the glands. The second-stage meronts are also unusual in that the epithelial cells in which they develop leave the mucosa and migrate into the lamina propria and submucosa. When these meronts mature and rupture, about 72 hours after ingestion of oocysts, haemorrhage occurs, the mucosal surface is largely detached and clinical signs become apparent.

Clinical signs: Clinical disease occurs when large numbers of oocysts are ingested over a short period and is characterised by the

presence of soft faeces often containing blood. The chicks are dull and listless, with drooping feathers. In subclinical infections, there are poor weight gains and food conversion rates.

Pathology: At postmortem, the caeca are often found to be dilated and contain a mixture of clotted and unclotted blood (Fig. 13.29). In longer-standing infections, the caecal contents become caseous and adherent to the mucosa. As regeneration of the mucosa occurs these caecal plugs are detached and caseous material is shed in the faeces.

Lesions are scored +1 to +4 as follows.

- 1 Very few small scattered petechiae on the caecal wall with no thickening of the caecal walls and normal caecal contents.
- 2 Lesions more numerous with noticeable blood in the caecal contents. The caecal wall is somewhat thickened with normal caecal contents.
- 3 Large amounts of blood and caecal cores present. The caecal walls are greatly thickened with little, if any, faecal contents in the caeca.
- 4 Caecal walls are greatly distended with blood or large caseous cores.

Epidemiology: *Eimeria tenella* is the species primarily responsible for caecal coccidiosis. Coccidiosis due to *E. tenella* occurs principally in chickens of 3–7 weeks of age. The prevalence of disease due to this species, and caecal coccidiosis, has declined since many of the anticoccidial drugs in general use were developed specifically to control this pathogenic species.

Fig. 13.29 Lesions of *Eimeria tenella* in caeca.

Eimeria tenella

Lesions: Haemorrhage in caecal lumen followed by thickening of mucosa and formation of caecal cores with clotted blood (Fig. 13.29)

Mean oocyst size (mm): 25 × 19

Shape and length/width index: Ovoid, 1.16

Prepatent period (hours): 132

Sporulation time (hours): 18–48

Wenyonella gallinae

Predilection site: Caeca, rectum

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, rough, punctate, 29–34 by 20–23 µm (mean 31 × 21 µm). There are four sporocysts, which are flask-shaped, 19 by 8 µm, and each contain four sporozoites.

Host: Chicken

Geographical distribution: India

Pathogenesis and clinical signs: May cause diarrhoea with blackish green, semi-solid excreta.

Diagnosis: Diagnosis is based on postmortem examination and by examining the faeces for the presence of oocysts or by examination of scrapings or histological sections of affected tissues. At necropsy,

the location and type of lesions present provide a good guide to the species and this can be confirmed by examination of the sporulated oocysts, which contain four sporocysts each with four sporozoites.

Pathology: The terminal part of the intestine is thickened and congested with pin-point haemorrhages in the mucosa.

Epidemiology: Not described

Treatment and control: Prevention of infection is based on good management. Chicken-rearing areas should always be kept dry and special attention given to litter near water drinkers and feeders. Anticoccidial compounds used for control of *Eimeria* species in chickens should be equally effective.

Turkey caecal coccidiosis

Eimeria adenoides

For more details see section Small intestine.

Eimeria gallopavonis

For more details see section Small intestine.

Eimeria meleagridis

Predilection site: Caeca

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal, smooth, 19–31 by 14–23 μm (mean $23 \times 16 \mu\text{m}$), with no micropyle and no oocyst residuum but with one to two polar granules. Sporocysts are ovoid with a Stieda body and a residuum. First-generation meronts are 20 by 15 μm and contain 50–100 merozoites; second-generation meronts are approximately 9 μm in diameter and contain 8–16 merozoites. Mature gamonts are 18 by 13 μm .

Host: Turkey

Life cycle: There are two to three merogony stages. The first-generation meronts appear in the middle small intestine 2–5 days after infection; second-generation meronts appear 60 hours after infection in the caeca, and are mature by 70 hours. There may be a third asexual generation, but most of the second-generation merozoites develop into sexual stages. Gamonts appear in the caeca, rectum and to a small extent the ileum. The prepatent period is 144 hours. The sporulation time is 15–72 hours.

Geographical distribution: Worldwide

Pathogenesis: A relatively non-pathogenic species, producing masses of ovoid oocysts in a white discharge from the caeca and lower small intestine.

Clinical signs: Infection is not associated with clinical signs.

Pathology: Non-pathogenic. The endogenous stages can be seen on histopathology in the caeca.

Cryptosporidium baileyi

Predilection site: Small and large intestine, cloaca, bursa of Fabricius, nasopharynx, sinuses, trachea, conjunctiva

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Description: Oocysts are ellipsoid, 5.6–6.3 by 4.5–4.8 μm (mean $6.2 \times 4.6 \mu\text{m}$).

Hosts: Chicken, turkey, duck, cockatiel, quail, ostrich

Life cycle: Oocysts, each with four sporozoites, are liberated in the faeces. Following ingestion, the sporozoites invade the microvillous brush border of the proventriculus, intestines and lungs and the trophozoites rapidly differentiate to form meronts with four to eight merozoites. There appear to be three merogony generations and both thin- and thick-walled oocysts have been observed. The prepatent period is 3 days and patent period 10–20 days.

Geographical distribution: Presumed worldwide

Pathogenesis: *Cryptosporidium baileyi* cryptosporidiosis is a disease of the epithelial lining of the bursa of Fabricius and cloaca of chickens, although the trachea and conjunctiva are lesser sites of infection. The presence of developmental stages in the microvillous region of enterocytes of the ileum and large intestines are not usually associated with clinical signs. Similarly, heavy infection of the

Fig. 13.30 *Cryptosporidium baileyi*: cloacal bursa.

bursa of Fabricius and cloaca does not appear to result in clinical illness (Figs 13.30, 13.31 and 13.32). In the respiratory form of infection, up to 50% of a broiler flock may show clinical signs, and mortalities may reach 10%. Conjunctivitis in several species of birds has been reported.

Clinical signs: Enteric infections are not associated with clinical signs. In the respiratory form, initially disease is accompanied by sneezing and coughing, followed by head extension to facilitate breathing. Severe signs of respiratory disease last up to 4 weeks after infection.

Fig. 13.31 Scanning electron micrograph of cloacal bursa showing numerous stages of *Cryptosporidium baileyi*.

Fig. 13.32 Scanning electron micrograph of meront of *Cryptosporidium baileyi*.

Diagnosis: As for *C. meleagridis*.

Pathology: Villous atrophy, shortening of microvilli and enterocyte detachment are the major pathological changes associated with intestinal cryptosporidiosis. In respiratory cryptosporidiosis, gross lesions consist of excess mucus in the trachea, nasal mucosal congestion and atrophic bursa of Fabricius. Cryptosporidia are found in the nasopharynxes, trachea, bronchi and bursa, but are not seen in the small intestine. With the respiratory form of cryptosporidiosis, there is epithelial cell deciliation and hyperplasia, mucosal thickening and discharge of mucocellular exudate into the airways in young broilers. Bronchopneumonia may be present in severely infected birds.

Epidemiology: Transmission appears to be mainly by the faecal-oral route, although in the respiratory form infection may be spread by coughing and sneezing.

Treatment and control: As for *C. meleagridis*.

Histomonas meleagridis

For details see Parasites of the liver.

The following protozoal infections are not associated with disease, with the possible exception of *Tetratrichomonas gallinarum*. Numbers of these protozoa can increase considerably in association with other gut enteropathies, and disruption of the normal bacterial flora.

Diagnosis: Trichomonads and amoebae are differentiated by morphological identification of the organisms from fresh and stained faecal preparations. The organisms can also be cultured in a range of media used for culture of protozoa.

Epidemiology: Birds become infected by ingestion of trophozoites, and cysts in the case of *Chilomastix gallinarum* and amoebae, in contaminated water or feed.

Treatment and control: Not required

Tetratrichomonas gallinarum

Synonyms: *Trichomonas gallinarum*, *Trichomonas pullorum*

Predilection site: Caeca

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is pyriform and measures 7–15 by 3–9 μm . There are four anterior flagella, and a posterior flagellum that runs along the undulating membrane and extends beyond it. An accessory filament is present. The axostyle is long, pointed and slender, and lacks a chromatic ring at its point of emergence. Supracostal granules are present, but there are no subcostal or endoaxostylar granules. The pelta is elaborate and terminates in a short ventral extension which is more or less free from the ventral edge of the axostyle. The parabasal body usually consists of a ring of variously spaced granules plus one or two fibrils or rami.

Hosts: Chicken, turkey, guinea fowl, quail, pheasant, partridge

Geographical distribution: Worldwide

Tritrichomonas eberthi

Synonym: *Trichomonas eberthi*

Predilection site: Caeca

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is elongate, 8–14 by 4–7 μm , with vacuolated cytoplasm and three anterior flagella (see Fig. 2.9). The undulating membrane is prominent and extends the full length of the body. The posterior flagellum extends about half the length of the body beyond the undulating membrane. An accessory filament is present. The blepharoplast is composed of four granules; the axostyle is massive and hyaline, and its anterior end is broadened to form a capitulum and a ring of chromatin granules is present at the point that the axostyle emerges from the body. The parabasal body is shaped like a flattened rod and is of variable length.

Hosts: Chicken, turkey

Geographical distribution: Worldwide

Tetratrichomonas anatis

Synonym: *Trichomonas anatis*

Predilection site: Small and large intestine

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is broadly beet-shaped, 13–27 by 8–18 μm , with four anterior flagella and an undulating membrane that extends most of the length of the body and terminates in a free posterior flagellum. There is a costa and a slender fibrillar axostyle.

Hosts: Duck

Geographical distribution: Worldwide

Tetratrichomonas anseris

Synonym: *Trichomonas anseris*

Predilection site: Caeca

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is elongate, 8–14 by 4–7 μm , with vacuolated cytoplasm and three anterior flagella. The undulating membrane is prominent and extends the full length of the body. The posterior flagellum extends about half the length of the body beyond the undulating membrane. An accessory filament is present. The blepharoplast is composed of four granules; the axostyle is massive and hyaline, and its anterior end is broadened to form a capitulum and a ring of chromatin granules is present at the point that the axostyle emerges from the body. The parabasal body is shaped like a flattened rod and is of variable length.

Hosts: Goose

Geographical distribution: Worldwide

Pentatrichomonas gallinarum

Predilection site: Caeca

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is usually spherical, 7 by 5 μm , with five anterior flagella and an undulating membrane that extends the length of the body with a free flagellum at its end. The axostyle is slender, projecting from the posterior end.

Hosts: Chicken, turkey, guinea fowl

Cochlosoma anatis

Synonym: *Cochlosoma rostratum*

Predilection site: Large intestine, cloaca, caeca

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is beet-shaped, 6–12 by 4–7 μm , with a nucleus in the middle of the body. There are six flagella of unequal length arising from a blepharoplast at the anterior end, and two trailing flagella lying in a longitudinal groove. A sucker covers one-third to half of the body length.

Hosts: Duck, Muscovy duck, mallard and other wild ducks

Geographical distribution: Presumed worldwide

Pathogenicity: Unknown

Chilomastix gallinarum

Predilection site: Caeca

Phylum: Fornicata

Class: Retortamonadea

Family: Retortamonadorididae

Description: The body is pear-shaped, 11–20 by 5–12 μm , with a nucleus at the anterior end of the body (see Fig. 2.19). There are three anterior flagella and a short fourth flagellum that undulates within a cytostomal cleft that is shaped like a figure eight, which is located on the ventral body, spiralling to the left and extending half to two-thirds of the body length. Cysts are lemon-shaped, 7–9 by 4–6 μm , with a single nucleus.

Hosts: Chicken, turkey

Life cycle: Trophozoites are formed by binary fission. Cyst stages are formed.

Geographical distribution: Worldwide

Entamoeba anatis

Predilection site: Caeca

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites measure 3–10.5 μm , and the spherical cysts measure 13–14 μm in diameter and contain one to four nuclei.

Hosts: Duck

Geographic distribution: Unknown

Entamoeba gallinarum

Predilection site: Caeca

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites measure 9–25 μm , and the cytoplasm is highly vacuolated containing many food vacuoles. Mature cysts are 12–15 μm in diameter and contain eight nuclei.

Hosts: Chicken, turkey, other birds

Geographic distribution: Unknown

Parasites of the respiratory system***Syngamus trachea***

Synonyms: *Syngamus parvis*, *Syngamus gracilis*

Common name: Gapeworm

Predilection site: Trachea or lungs

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: The large reddish female (around 1–3 cm) and the small whitish male (up to 0.5 cm) are permanently *in copula* forming a 'Y' shape (see Fig. 1.46); they are the only parasites found in the trachea of domestic birds (Fig. 13.33).

Description, microscopic: The worms have large, shallow, cup-shaped buccal capsules that have up to 10 teeth at their base. There are no leaf-crowns. The bursal rays are short and thick and the two spicules are long and of simple form. The ellipsoidal thin-shelled eggs are 70–100 by 43–46 µm with a thick operculum at both ends. They are in the 16-cell stage when ejected.

Hosts: Chicken, turkey, gamebirds (pheasant, partridge, guinea fowl), pigeon and various wild birds

Geographical distribution: Worldwide

Pathogenesis: The effects of *S. trachea* are most severe in young birds, especially game chicks and turkey poults. In these, migration through the lungs in heavy infections may cause emphysema, oedema and result in pneumonia and death. In less severe infections the adult worms cause a haemorrhagic tracheitis with excess mucus production, which may lead to partial occlusion of the airways and difficulty in breathing. In turkeys, the male worms can be substantially embedded in the mucosa of the trachea, inducing the formation of nodules.

Clinical signs: These are most commonly seen in young chicks and poults. Pneumonia during the prepatent phase may cause signs of dyspnoea and depression, whereas the presence of adult worms and excess mucus in the trachea lead to signs of respiratory distress, asphyxia or suffocation with the bird gasping for air; often there is a great deal of head shaking and coughing as it tries to rid itself of the obstruction. The clinical picture of 'gapes' may thus range from gasping, dyspnoea and death to, in less severely affected animals, weakness, anaemia and emaciation.

Diagnosis: This is based on clinical signs and the finding of eggs in the faeces. Disease is probably best confirmed by postmortem examination of selected cases, when reddish worms will be found attached to the tracheal mucosa. The infected trachea often contains an increased amount of mucus.

Fig. 13.33 *Syngamus trachea*: adult *in situ* (arrow).

Pathology: The carcasses of infected birds are emaciated and anaemic and worms are found in the posterior part of the trachea, attached to the mucosa and surrounded by mucus, which may be streaked with blood. In turkeys, male worms become deeply embedded in the wall of the trachea, causing the development of nodules.

Epidemiology: Gapeworm infection primarily affects young domestic chickens of less than 2–3 months of age, but turkeys of all ages are susceptible, the adults often acting as carriers. All ages of other passeriform and galliform species are susceptible to infection. Infrequently, *S. trachea* can infect anseriform birds. Eggs may survive for up to 9 months in soil and L₃ for years within the earthworm or other transport hosts. Disease is seen most frequently in breeding and rearing establishments where outdoor pens, such as those used for breeding pheasants, are in use. Eggs, passed by wild birds such as rooks and blackbirds, may initiate infection; these may also infect earthworms. Infection is usually highest during the summer when earthworms are active. Infected chicks normally develop an age resistance by 2–3 months of age and markedly reduce their worm burdens. Partial immunity to reinfection is established.

Treatment: In-feed modern benzimidazoles are effective, administered usually over a period of several days. Birds need to be monitored, as severely affected ones may not ingest adequate anthelmintic. Nitroxynil and levamisole are also very efficacious when given in the water.

Control: Young birds should not be reared with adults, especially turkeys, and to prevent infection becoming established runs or yards should be kept dry and contact with wild birds prevented. Avoid the continuous rearing of birds on the same ground. Drug prophylaxis may be practised over the period when outbreaks are normally expected. It is not usually feasible to eliminate the paratenic hosts.

Cyathostoma bronchialis

Synonym: *Syngamus bronchialis*

Common name: Gapeworm

Predilection site: Trachea, bronchi

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: The worms are reddish in colour when fresh. Adult worms are 0.4–3 cm long; males are 4–5.8 mm and females 15–30 mm.

Description, microscopic: The buccal capsule is cup-shaped with six to seven teeth at its base. The male bursa is well developed but worms in this species are not permanently *in copula*, which contrasts to the situation with *Syngamus trachea*. The medium-sized, lightly coloured eggs are ovoid with a smooth shell and possess a hardly perceptible operculum at one pole. They measure about 74–89 by 47–62 µm and the morula contains eight blastomeres.

Hosts: Goose, duck, swan

Geographical distribution: Worldwide

Pathogenesis: Young birds are most susceptible to disease and heavy infections can be pathogenic, leading to emaciation and death.

Clinical signs: In heavy infections these may include depression of food intake, asphyxia and dyspnoea.

Epidemiology: Severe infections are often associated with the ingestion of transport hosts such as earthworms, slugs, snails and invertebrates. Larvae may encyst and survive for years within invertebrate hosts. Infections often occur seasonally when, for instance, large numbers of earthworms occur on the surface after heavy rain.

Typhlocoelum cymbium

Synonym: *Tracheophilus sisowi*

Predilection site: Trachea, bronchi

Phylum: Platyhelminthes

Class: Trematoda

Family: Cyclocoelidae

Description, gross: Adult fluke are around 6–11.5 by 3 mm. The body has rounded ends and is wide in the middle.

Description, microscopic: The testes are rounded, not lobed, and lie in a diagonal position in the posterior part of the body with the unlobed ovary situated in front of the anterior testis. Eggs measure about 122 by 63 µm.

Hosts: Duck

Intermediate hosts: Snails of the genera *Helisoma* and *Planorbis*

Geographical distribution: Europe, Asia, Central America

Pathogenesis and clinical signs: The parasites cause obstruction of the trachea and affected birds may die of asphyxia.

Treatment and control: There is no reported treatment. Control is impractical.

Typhlocoelum cucumerinum

Synonyms: *Distoma cucumerinum*, *Typhlocoelum obovlae*

Predilection site: Trachea, air sacs, oesophagus

Phylum: Platyhelminthes

Class: Trematoda

Family: Cyclocoelidae

Description, gross: Adult fluke are 6–12 by 2–5 mm. The body is oval and blunter anteriorly than posteriorly.

Description, microscopic: The testes are deeply lobed and lie diagonally one behind the other with the unlobed ovary situated in front of the posterior testis. Eggs measure around 156 by 85 µm.

Hosts: Duck

Intermediate hosts: Snails

Geographical distribution: Europe, North and South America

Pathogenesis and clinical signs: Affected birds suffer from dyspnoea and asphyxia.

Hyptiasmus tumidus

Synonyms: *Hyptiasmus arcuatus*, *Cyclocoelum arcuatum*

Predilection site: Nasal and orbital sinuses

Phylum: Platyhelminthes

Class: Trematoda

Family: Cyclocoelidae

Description, gross: Adult fluke measure 7–20 by 2–5 mm. The body is pyriform and more rounded posteriorly.

Description, microscopic: The gonads are arranged in a straight line. Eggs are around 95 by 55 µm.

Hosts: Duck, goose

Geographical distribution: Europe, Japan

Pathogenesis and clinical signs: Infection causes nasal catarrh.

Cytodites nudus

Common name: Air sac mite

Predilection site: Lung, air sac

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Cytoditidae

Description: The mite is oval and about 500 µm long, with a smooth cuticle (see Fig. 3.97). The chelicerae are absent and the palps are fused to form a soft sucking organ through which fluids are imbibed. Legs are stout and unmodified, ending in a pair of stalked suckers and a pair of small claws.

Hosts: Birds, particularly poultry and canaries

Geographical distribution: Worldwide

Pathogenesis: Small infestations may have no obvious effect; large infestations may cause accumulation of mucus in the trachea and bronchi, leading to coughing and respiratory difficulties, air sacculitis and weight loss. Balance may be affected in infested birds. Weakness, emaciation and death have been described with heavy infections.

Clinical signs: Coughing, respiratory difficulties, pulmonary oedema, weight loss, loss of balance or coordination

Diagnosis: Positive diagnosis is only possible at postmortem, when necropsy reveals white spots on the surface of air sacs.

Pathology: Death is usually associated with peritonitis, enteritis, emaciation and respiratory complications.

Epidemiology: Infestation may be spread by the host through coughing.

Treatment: Treatment with topical moxidectin every 3 weeks as necessary may be effective.

Control: It is important to treat all the birds in an aviary when commencing a preventive programme.

Parasites of the liver

Histomonas meleagridis

Common names: 'Blackhead', infectious enterohepatitis

Predilection site: Caeca, liver

Phylum: Parabasalia

Class: Trichomonadea

Family: Dientamoebidae

Description: A pleomorphic organism, with morphology depending on the organ location and the stage of disease. In the caecum, the organism is round or oval, amoeboid, with clear ectoplasm and granular endoplasm, 6.0–20 µm in diameter, and bears a single flagellum (see Fig. 2.17), although this appears to be lost when in the mucosal tissue or the liver. The nucleus is vesicular and a flagellum arises from a small blepharoplast near the nucleus. In the caecal mucosa and liver, the organism is found singly or in clusters and is amoeboid, 8–15 µm in diameter, with no flagellum. Both luminal and tissue stages exhibit pseudopodial movement.

Hosts: Turkey, gamebirds (pheasant, partridge), occasionally chickens

Geographical distribution: Worldwide

Pathogenesis: The disease is essentially one of young turkeys up to 14 weeks old and is characterised by necrotic lesions in the caeca and liver. The earliest lesions are small ulcers in the caeca, but these quickly enlarge and coalesce so that the entire mucosa becomes necrotic and detaches, forming, with the caecal contents, a caseous plug. The liver lesions are circular and up to 1.0 cm in diameter with yellow depressed centres; they are found both on the surface and in the substance of the liver.

Mortality in poults may reach 100% and in birds which recover the caecum and liver may be permanently scarred.

Clinical signs: Infection is often mild and asymptomatic in chickens. Turkey poults become dull, the feathers are ruffled and the faeces become sulphur-yellow in colour 8 days or more after infection. Unless treated, the birds usually die within 1 or 2 weeks.

In older turkeys, the disease is more usually a chronic wasting syndrome followed by recovery and subsequent immunity. The name 'blackhead' was first coined to describe the disease when cyanosis of the head and wattles was thought to be a characteristic feature. However, this sign is not necessarily present, and anyway is not confined to histomonosis.

Diagnosis: This is based on history, clinical signs and necropsy findings. Although rarely necessary, histological sections of liver or caecum may be prepared for specialist examination.

Pathology: The principal lesions of histomonosis appear in the caecum and liver. One or both caeca may be affected with small raised pin-point ulcers, which subsequently enlarge and may affect the whole mucosa, occasionally ulcerating and perforating the caecal wall causing peritonitis. The mucosa becomes thickened and necrotic and may be covered with a characteristic foul-smelling yellowish exudate that can eventually form hard dry caecal cores adhering to the caecal wall. The caeca are markedly inflamed and often enlarged. Liver lesions are pathognomonic and consist of circular, depressed, yellowish areas of necrosis and tissue degeneration, varying in size

Fig. 13.34 Liver lesions due to *Histomonas meleagridis*.

up to 1 cm or more and extending deeply into the liver (Fig. 13.34). In older birds the lesions may be confluent and other organs such as the kidney and lung may occasionally be involved. The parasites can be readily found on histopathological examination. Affected lesions are hyperaemic, haemorrhagic and necrotic with lymphocytic and macrophage infiltration and the presence of giant cells.

Epidemiology: Although showing no signs of *Histomonas* infection, the domestic chicken is commonly infected with *Heterakis gallinarum*, whose eggs, if fed to turkeys, will regularly produce histomonosis. Typically, histomonosis occurs when turkey poults are reared on ground shared with, or recently vacated by, domestic chickens. However, since the organism may survive in embryonated *Heterakis* eggs in soil, or as larvae in earthworms, for over 2 years, outbreaks may arise on apparently clean ground. Young turkeys may also become infected when reared by broody hens which are carriers.

Treatment: A number of drugs are effective, particularly the nitroimidazole compounds such as dimetridazole. These have been withdrawn in many countries because of concerns over human toxicity and carcinogenicity, and therefore few, if any, effective treatments are available.

Control: Histomonosis can be prevented through good management. Turkeys should be reared on ground not used by domestic chickens for at least 2 years, or on fresh litter or wire floors raised above the ground. In gamebird rearing facilities (pheasant, partridge), young birds should be cared for in raised pens and their droppings removed regularly. When poults are old enough to be moved to rearing pens, they should be placed on clean ground where birds have not been previously kept for at least 2 years, as *Heterakis* eggs may remain viable in soil or earthworms for some time, depending on the climate and soil type. The use of anthelmintics for the control of *Heterakis* worms can be an effective control measure in limiting infection and spread.

Parasites of the circulatory system

Bilharziella polonica

Predilection site: Mesenteric and pelvic veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The body is lancet-shaped posteriorly and the sexes are separate. Male worms are about 4 mm and females 2 mm long.

Description, microscopic: The female genital pore is just behind the ventral sucker and the short uterus contains one egg at a time. The eggs have a long, narrow and elongate anterior end and a swollen posterior end with a terminal spine, and measure 400 by 100 µm.

Hosts: Duck

Intermediate hosts: Snails of the genus *Planorbis*

Geographical distribution: Europe, North America

Pathogenesis and clinical signs: Generally considered to be non-pathogenic. Eggs in the wall of the intestine may produce inflammation. Parasites have been found in the pancreas, spleen and kidneys, but in these organs they eventually die.

Treatment and control: Not required

Leucocytozoon caulleryi

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Description: Gamonts present in erythrocytes when mature are round, 15.5 by 15 µm, and distort the host cell causing the host cell nucleus to form a narrow dark band extending about one-third of the way around the parasite. Megalomeronts present within tissues are 26–300 µm in diameter.

Hosts: Chicken, guinea fowl

Geographical distribution: Asia

Pathogenesis: Some strains of *L. caulleryi* are non-pathogenic and others are highly pathogenic, killing a high percentage of chickens in a flock.

Clinical signs: Affected chickens are listless, diarrhoeic and anaemic with pallid combs and wattles.

Diagnosis: Gamonts can be seen in Giemsa-stained blood smears, the gamont being rounded in *L. caulleryi*. There are no pigment granules. On postmortem there are haemorrhages, splenomegaly and hepatomegaly and many organs have grossly visible white dots due to the presence of the meronts.

Pathology: There is marked haemorrhage in the lungs, liver and kidneys and there may be gross haemorrhage from the kidney lesions into the peritoneal cavity due to the presence of megalomeronts, which cause haemorrhage on rupture.

Epidemiology: The incidence of disease is linked to the presence and relative abundance of the midge vectors, *Culicoides* spp. In Japan, outbreaks occur frequently in June when the rice paddy fields are ready for planting and offer ideal conditions for midges to breed.

Treatment: Treatment is not usually effective, although pyrimethamine (1 ppm), sulphadimethoxine (10 ppm) or clopidol (125 ppm) in feed may prevent but not cure infections of *L. caulleryi*.

Control: Control requires elimination of the arthropod vector from the environment of the host. Insecticidal sprays and repellents sprayed within houses may be used to reduce the insect populations.

Leucocytozoon sabrazesi

Synonyms: *Leucocytozoon schueffneri*, *Leucocytozoon macleani*

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Description: Gamonts present in erythrocytes when mature are elongate, 22–24 by 4–7 µm, and distort the host cell, which becomes spindle-shaped, 67 by 6 µm, with long cytoplasmic horns extending beyond the parasites. The host cell nucleus forms a narrow darkly staining band along one side of the parasite.

Hosts: Chicken, guinea fowl

Geographical distribution: Southeast Asia, Indonesia

Pathogenesis: Occurs uncommonly but can cause significant losses in flocks.

Clinical signs: Clinical signs include pyrexia, diarrhoea, leg paralysis, discharge from the mouth and anaemia.

Diagnosis: Gamonts can be seen in Giemsa-stained blood smears, the gamont being elongate in *L. sabrazesi*. On postmortem there are haemorrhages, splenomegaly and hepatomegaly and many organs have grossly visible white dots due to the presence of the meronts.

Pathology: As for *L. caulleryi*.

Epidemiology: The incidence of disease is linked to the presence and relative abundance of the midge vectors, *Culicoides* spp.

Treatment: Treatment is not usually effective.

Leucocytozoon smithi

Synonyms: *Leucocytozoon schueffneri*, *Leucocytozoon macleani*

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Description: The mature gamonts are rounded at first but later become elongate, averaging 20–22 µm in length. Their host cells are elongate, averaging 45 by 14 µm, with pale cytoplasmic horns extending out beyond the enclosed parasite. The host cell nucleus is elongate, forming a long, thin, dark band along one side of the parasite (see Fig. 2.30), often splitting to form a band on each side of the parasite. Hepatic meronts in the hepatocytes are 10–20 by 7–14 µm (mean 13.5 × 10.5 µm).

Host: Turkey

Geographical distribution: Europe, North America

Pathogenesis: *Leucocytozoon smithi* is markedly pathogenic for turkeys, and extremely heavy losses have been reported. Adult birds are less seriously affected than poults, and the disease runs a slower course, but even they may die. Recovered birds continue to carry parasites in their blood. Some birds recover completely, but in other birds persistent infection may lead to lethargy, lack of libido in male birds and persistent coughing. Sudden stress in these birds may lead to death.

Clinical signs: Affected poults are anorexic and lethargic and have difficulty in moving; in the later stages there may be incoordination, and the birds may suddenly collapse, become comatose and die. Birds surviving for 2–3 days after signs of disease appear tend to recover.

Diagnosis: Diagnosis is based on finding and identifying the gamonts in Giemsa-stained blood smears, or the meronts in tissue sections.

Pathology: Affected birds are anaemic and emaciated. The spleen and liver are enlarged, and there is enteritis involving the duodenum, sometimes extending throughout the small intestine.

Epidemiology: The vectors of *L. smithi* are blackflies of the genus *Simulium* and disease occurs in domestic and wild turkeys in North America and Europe in mountainous or hilly areas where suitable blackfly breeding habitats occur.

Treatment: No effective treatment has been reported.

Control: Prevention depends on blackfly control. Ideally, turkeys should not be raised in areas where blackflies occur in significant numbers, or they should be raised under conditions that prevent them from being bitten by blackflies by rearing in screened quarters using 32–36 mesh screening.

Leucocytozoon simondi

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Description: Mature macrogametes and microgamonts are elongate, sometimes rounded, 14–22 µm long, and are present within erythrocytes or leucocytes, which become elongate, up to 45–55 µm long, with their nucleus forming a long, thin, dark band along one side. Infected host cells have pale cytoplasmic horns extending out beyond the parasite and the nucleus. Hepatic meronts are 11–18 µm in diameter; megalomeronts found in various tissues of the body are 6–164 µm in diameter when mature.

Hosts: Duck, goose

Geographical distribution: Northern USA, Canada, Europe, Vietnam

Pathogenesis: *Leucocytozoon simondi* is markedly pathogenic for ducks and geese. The heaviest losses occur among young birds with very rapid onset. Adult birds are more chronically affected, and the

disease develops more slowly in them. Mortality is low but if it does occur is seldom less than 4 days after the appearance of signs. Death usually occurs as the peripheral parasitism approaches its peak, 10–12 days after infection. Ducklings that recover often fail to grow normally, and recovered birds remain carriers.

Clinical signs: Acutely affected ducklings are listless and inappetent, with rapid laboured breathing due to obstruction of the lung capillaries with meronts. They may go through a short period of nervous excitement just before death. Adult birds are thin and listless.

Diagnosis: Diagnosis is based on finding and identifying the gamonts in Giemsa-stained blood smears, or the meronts in tissue sections.

Pathology: The principal lesions are splenomegaly with liver hypertrophy and degeneration. Anaemia and leucocytosis are present, and the blood clots poorly.

Epidemiology: The vectors of *L. simondi* are various species of blackflies (*Simulium* and other simuliids) and disease occurs commonly in domestic ducks and geese in mountainous or hilly areas where cold rapid streams act as suitable blackfly breeding habitats.

Treatment: No effective treatment has been reported.

Control: Prevention depends on blackfly control. Ideally, ducks and geese should not be raised in areas where blackflies occur in significant numbers, or they should be raised under conditions that prevent them from being bitten by blackflies by rearing in screened quarters using 32–36 mesh screening. Since wild ducks and geese are reservoirs of infection for domestic birds, the latter should not be raised close to places where wild birds congregate.

Plasmodium gallinaceum

Synonym: *Plasmodium metataticum*

Common name: Avian malaria

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Subgenus: *Haemamoeba*

Description: The trophozoite is a small rounded form containing a large vacuole, which displaces the cytoplasm of the parasite to the periphery of the red blood cell (see Fig. 2.28). The nucleus is situated at one of the poles, giving the young form a 'signet ring' appearance when stained by Giemsa. Both gametocytes and meronts of *P. gallinaceum* can be round, oval or irregular in shape. The nucleus of host cells is rarely expelled during infection, but may be displaced by the parasite (Fig. 13.35). Each meront produces 8–36 merozoites and on average there are 16–20 merozoites in erythrocytic meronts.

Hosts: Chicken, guinea fowl

Geographical distribution: Southeast Asia, Indonesia, Malaysia, Borneo, India, Sri Lanka. The distribution in domestic chickens coincides with the natural host, the jungle fowl.

Pathogenesis: *Plasmodium gallinaceum* can be highly pathogenic in domestic chickens, particularly when European breeds are introduced into endemic areas where the cycle is maintained in wild

Fig. 13.35 Intraerythrocytic stages of *Plasmodium gallinaceum*.

red jungle fowl. Anaemia is caused by destruction of circulating erythrocytes by developing meronts. Neurological complications are caused by obstruction of capillaries in the brain by extraerythrocytic meronts.

Clinical signs: Birds with acute infection may be lethargic, anaemic with pale combs, diarrhoeic and show partial or total paralysis.

Diagnosis: Parasites can be seen in Giemsa-stained blood smears. The presence of meronts with numerous merozoites and round gametocytes that displace the host cell nucleus are distinctive for *P. gallinaceum*.

Pathology: There may be pallor of the carcass due to anaemia, brown-tinged skin and mucous membranes due to pigment deposition, splenomegaly, and darkening of the viscera, especially liver, spleen, lungs and brain due to accumulation of pigment. Microscopic lesions are most evident in the blood. In the kidneys there may be accumulation of pigment in macrophages, fatty degeneration of the parenchyma and possibly immune complex glomerulonephritis. In the lungs there may be accumulation of pigment in macrophages in the capillaries, obstruction of the blood vessels and lymphatics and pulmonary oedema.

Epidemiology: In Sri Lanka the mosquito vector is *Mansonia crassipes*. In other areas of its geographical range the vectors are unknown and detailed epidemiological studies have not been conducted. A range of anopheline species of the genera *Anopheles*, *Armigeres*, *Culex*, *Culiseta* and *Mansonia* have been shown experimentally to be capable of transmitting infection.

Treatment: Sulphonamide drugs (sulphachloropyrazine and sulphamonomethoxine) and halofuginone have been shown to be effective in the laboratory.

Control: Mosquito control can potentially reduce transmission of this parasite but detailed control methods have not been studied. More potentially effective measures include keeping poultry in mosquito-proof buildings or keeping domestic chickens in areas away from the wild reservoir hosts.

Plasmodium juxtannucleare

Synonym: *Plasmodium japonicum*

Common name: Avian malaria

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Subgenus: *Novyella*

Description: Meronts are small, round, ovoid or irregular and usually in contact with the erythrocyte host cell nucleus and produce two to seven (mean four) merozoites. Gamonts are round, ovoid, irregular or elongate pyriform, leading to the host erythrocyte often being distorted.

Hosts: Chicken, red jungle fowl (*Gallus gallus*) in Sri Lanka, grey-wing francolin (*Francolinus africanus*) in South Africa, bamboo partridge (*Bambusicola thoracica*) in Taiwan

Geographical distribution: South and Central America (Mexico, Brazil, Uruguay), Asia (Sri Lanka, Philippines, Taiwan, Japan, Malaysia), East Africa (Tanzania) and South Africa

Pathogenesis: This species is highly pathogenic, causing severe anaemia through erythrocyte destruction and organ damage due to massive numbers of exoerythrocytic forms. Central nervous system (CNS) signs are associated with exoerythrocytic forms, causing damage to endothelial cells of the brain capillaries.

Clinical signs: Affected birds are lethargic, depressed, progressively emaciated and anaemic. Severely affected birds have a protruding abdomen caused by splenic and hepatic enlargement and ocular haemorrhage may occur. Affected birds may show paralysis or CNS signs. Coma and death occur in heavy infections after a short period of time.

Diagnosis: Giemsa-stained blood smears usually reveal numerous meronts and gamonts in the erythrocytes and infected cells also have dark pigment granules (digested haemoglobin). As blood samples cool, motile microgametes may be seen in the plasma in wet smears. This species can be distinguished from *P. gallinaceum* by its more elongate gametocytes and by the tendency of the meront stages to cling closely to the host cell nucleus.

Pathology: The liver and spleen are enlarged and dark brown–black in colour. Exoerythrocytic stages can be seen in the endothelial cells and reticuloendothelial cells of the liver, spleen and brain.

Epidemiology: *Plasmodium juxtannucleare* is a parasite of wild birds that infects domestic chickens when wild reservoir birds and mosquito vectors are present. Infection is spread by culicine mosquitoes of the genus *Culex* (*C. sitiens*, *C. annulus*, *C. gelidus* and *C. tritaeniorhynchus* in Malaysia; *C. saltanensis* in Brazil). Natural vectors in other parts of its range are unknown and detailed epidemiological studies have not been undertaken.

Treatment: Affected birds or flocks may be treated with primaquine 100 mg/kg orally or sulphonamide–trimethoprim combinations may be tried. Sulphonamide drugs (sulphachloropyrazine, sulphamonomethoxine) and halofuginone, which are effective against other *Plasmodium* species in birds, may also be effective.

Control: Since mosquitoes spread malaria, prevention depends on mosquito control. Residual spraying of poultry houses with insecticides may be effective. Birds can also be raised in screened quarters in areas where mosquitoes are particularly prevalent.

Notes: Closely related species that occur in cage birds, pigeon, waterfowl, guinea fowl, pheasant, quail and turkey include *P. vaughani*, *P. rouxi*, *P. nucleophilum*, *P. kempfi*, *P. leanucleus* and *P. dissanaikai*.

Plasmodium durae

Synonym: *Plasmodium japonicum*

Common name: Avian malaria

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Subgenus: *Giovannolaia*

Description: Trophozoites are amoeboid in appearance. Mature meronts rarely displace the host cell nucleus and contain six to fourteen (mean eight) merozoites. Gamonts are elongate, at the end or side of the host cell, and often displace the host cell nucleus, although the host cell is not usually enlarged. Pigment granules are usually large, round and black.

Hosts: Turkey, francolins (*Francolinus leucoscepus*, *F. levaillantii levaillantii*)

Geographical distribution: Sub-Saharan Africa (Kenya, Nigeria, Zimbabwe, South Africa)

Pathogenesis: *Plasmodium durae* is highly pathogenic in domestic turkeys and, depending on strain and geographic location, causes death in up to 90% of young turkey poults. Adult birds often develop right pulmonary hypertension as a consequence of hypoxic pulmonary arterial hypertension. Developing exoerythrocytic meronts may block cerebral capillaries such that infected birds can exhibit neurological signs and paralysis before death.

Clinical signs: Young poults show few clinical signs until immediately prior to death, when severe convulsions may occur. Adult birds are lethargic and anorexic and may develop oedematous legs and gangrene of the wattles.

Diagnosis: The parasites can be identified in Giemsa-stained thin blood smears. Meronts are small and rounded and the gametocytes are elongate and do not curve around the host erythrocyte nucleus.

Pathology: As for *P. juxtannucleare*.

Epidemiology: The vectors involved in transmission are not fully known.

Treatment: Sulphonamide drugs (sulphachloropyrazine, sulphamonomethoxine) and halofuginone may be effective in treatment. Sulphamonomethoxine does not provide full protection from mortality when given after the appearance of circulating parasites and sulphachloropyrazine, while reducing mortality, has no effect on the parasitaemia, suggesting activity against exoerythrocytic meronts.

Control: As for other avian malaria species.

Notes: Closely related species of the subgenus *Giovannolaia* reported in duck, goose, turkey, francolin, guinea fowl, quail, partridge and pigeon include *P. fallax*, *P. circumflexum*, *P. polare*, *P. lophurae*, *P. gabaldoni*, *P. pinotti*, *P. pediocetti*, *P. formosanum*, *P. anasum* and *P. hegneri*.

Haemoproteus meleagridis

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Description: Macrogametes and microgametes present in erythrocytes are elongate and curve around the host cell nucleus (see Fig. 2.29), occupying about half to three-quarters of the host cell. The nucleus of macrogametocytes is generally more compact, the cytoplasm denser, and melanin granules more evenly distributed compared with the polar clustering in microgametocytes.

Host: Turkey

Geographical distribution: North America

Pathogenesis and clinical signs: Generally considered non-pathogenic, or only slightly pathogenic.

Epidemiology: Vectors are thought to be midges (*Culicoides*) or hippoboscids.

Treatment and control: Not usually required, although general insect control or preventive measures may limit infection.

Haemoproteus nettionis

Synonyms: *Haemoproteus anatis*, *Haemoproteus anseris*, *Haemoproteus hermani*

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Description: Macrogametes and microgametes present in erythrocytes are elongate and curve around the host cell nucleus, partially encircling the host cell nucleus and often displacing it. They contain a few to 30 or more pigment granules, which are usually coarse and round and often grouped at the ends of the cell. The host cell is not enlarged.

Hosts: Duck, goose, wild duck and swan

Geographical distribution: Worldwide

Pathogenesis and clinical signs: As for *Haemoproteus meleagridis*.

Diagnosis: As for *Haemoproteus meleagridis*.

Epidemiology: Vectors are midges (*Culicoides*). The parasite is essentially a parasite of wild waterfowl and may infect domestic birds in endemic areas.

Treatment and control: As for *Haemoproteus meleagridis*.

Trypanosoma gallinarum

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplasta

Family: Trypanosomatidae

Description: Pleomorphic organisms, 26–29 µm long, or even longer, with a free flagellum.

Host: Chicken

Geographical distribution: Africa

Trypanosoma avium

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplasta

Family: Trypanosomatidae

Description: As for *T. gallinarum*.

Pathogenesis: Avian trypanosomes are considered non-pathogenic.

Diagnosis: Detection is by examination of Giemsa-stained thin blood smears or examination of buffy coat from a microhaematocrit tube following centrifugation (Fig. 13.36).

Epidemiology: Species are transmitted by a variety of blood-sucking arthropods including mosquitoes, simuliids, hippoboscids and red mites. Trypanosomes persist during periods of adverse conditions in the bone marrow and reappear in the spring.

Treatment and control: Not required

Aegyptianella pullorum

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Fig. 13.36 Tryptomastigote of *Trypanosoma avium*.

Description: *Anaplasma*-like bodies of various sizes found in the cytoplasm of erythrocytes. The organisms occur as initial bodies followed by development forms and marginal bodies ('signet-ring') in the cytoplasm of erythrocytes. The early trophozoites or initial bodies occur in erythrocytes, are small (0.5–1.0 µm) and round to oval. Spherical bodies up to 4 µm containing up to 25 small granules may occur.

Hosts: Chicken, turkey, goose, duck

Geographical distribution: Africa, Asia, southern Europe

Aegyptianella moshkovskii

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: The organism usually produces four to six trophozoites. The early trophozoites within the erythrocytes are small (0.2–0.6 µm). Larger mature forms are 2.1 by 1.4 µm with large oval or irregular forms (0.9–5.3 µm).

Hosts: Chicken, turkey, pheasant, wild birds

Life cycle: As for *A. pullorum*.

Geographical distribution: Africa, India, Southeast Asia, Egypt, Russia and parts of eastern CIS states

Pathogenesis: Both species of *Aegyptianella* are pathogenic. The following descriptions apply to both species. The intraerythrocytic parasites cause severe anaemia, jaundice and frequent death. The incubation period is 12–15 days.

Clinical signs: Affected animals show ruffled feathers, anorexia, droopiness and diarrhoea and hyperthermia may be found. The clinical condition is often complicated by fowl spirochaetosis, which is also transmitted by *Argas persicus*.

Diagnosis: Diagnosis is based on the demonstration of organisms in Giemsa-stained blood smears. Intraerythrocytic forms (marginal bodies) and extra-erythrocytic forms may be seen in leucocytes, lymphocytes, monocytes and also in the plasma.

Pathology: Anaemia, jaundice, enlargement of the liver and the spleen, yellow–green kidneys and petechial haemorrhage of the serosa may be seen at necropsy.

Epidemiology: Infection is transmitted by the soft tick, *Argas persicus*. Indigenous poultry rarely suffer the acute disease, but freshly introduced stock are especially susceptible and may die within a few days. Recovered birds are frequently carriers.

Treatment: Tetracycline compounds (oxytetracycline, chlortetracycline, 15–30 mg/kg orally) are effective and usually recommended for treatment.

Control: Tick control and treatment of premises where adults and nymphal ticks may hide in cracks and crevices. After cleaning, premises should be treated with an acaricide, such as carbaryl, coumaphos or malathion.

Parasites of the nervous system

Oxyspirura mansoni

Synonym: *Oxyspirura parvorum*

Common name: Eye worm

Predilection site: Eye

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: These are slender worms with a smooth cuticle and a globular-shaped pharynx. The males measure around 10–15 mm and the females 14–20 mm.

Description, microscopic: The tail of the male is curved ventrally and alae are absent. Spicules are uneven, the right being short and stubby, the left long (about 15 times the length of the right spicule) and slender. In the female worm, the vulva is near the tail. The medium-sized ovoid egg is embryonated when laid and measures on average about 65 by 45 µm.

Final hosts: Chicken, turkey, guinea fowl, peafowl

Intermediate hosts: Cockroaches (*Pycnoscelus surinamensis*), mayflies

Geographical distribution: Many areas of the world, particularly the tropical and subtropical regions. It is not present in Europe.

Pathogenesis: It occurs on the conjunctiva, under the nictitating membrane, or in the nasal/lacrimal ducts or the conjunctival sacs. Although not a highly pathogenic genus, moderate infections can induce inflammation of the eye, with the nictitating membrane becoming oedematous. Heavy infections may cause blindness or occlusion of the nasal passages.

Clinical signs: Birds may be observed scratching the eyes if they become irritated. Affected birds develop ophthalmitis, the eye becoming inflamed and watery.

Diagnosis: A definitive diagnosis is made by finding the parasite in the conjunctival sac. It may be necessary to instill local anaesthetic into the eye to allow removal. Examination of lacrimal secretions may reveal eggs or first-stage larvae.

Pathology: Untreated heavy infections can cause ophthalmia with erosion of the eyeball.

Treatment: Oral or topical levamisole or tetramisole and ivermectin have been used successfully to treat infections. Removal with fine forceps after instillation of local anaesthetic has been reported.

Control: Attempts to control the poultry spiruroidea are unlikely to be fully successful because of the ready availability of the intermediate hosts. Reduction and restriction of cockroaches will be beneficial.

Notes: The genus *Oxyspirura* in birds is the equivalent of *Thelazia* in mammals.

Philophthalmus gralli

Common name: Oriental avian eye fluke

Predilection site: Conjunctival sac

Phylum: Platyhelminthes

Class: Trematoda

Family: Philophthalmidae

Description, gross: Adult fluke are very small (2–3 mm in size) and fusiform shaped.

Description, microscopic: The body surface is covered by small spines and the two suckers are orally and subterminally located. The pharynx is located immediately posterior to the oral sucker.

Final hosts: Ostrich, chicken, wild birds, human

Intermediate hosts: Freshwater snails

Geographical distribution: USA, Indo-China, parts of Europe and Africa

Pathogenesis: Infection may cause congestion and erosion of the conjunctivae, and conjunctivitis with persistent lacrimation.

Clinical signs: The flukes can cause lacrimation and conjunctivitis and can be a localised problem in captive farmed ostriches where they have access to standing water.

Parasites of the reproductive/urogenital system

Prosthogonimus pellucidus

Synonyms: *Prosthogonimus intercalandus*, *Prosthogonimus cuneatus*

Common name: Oviduct fluke

Predilection site: Cloaca, oviduct and bursa of Fabricius

Phylum: Platyhelminthes

Class: Trematoda

Family: Prosthogonimidae

Description, gross: Adults are tear-drop shaped, semi-transparent, pale orange when fresh and measure around 9–12 mm in length, being broader towards the posterior.

Description, microscopic: The fluke have a spiny cuticle and two suckers are present. The posterior width of the fluke increases from the middle region. The ovoid eggs are around 26–32 by 10–15 µm in size, dark brown and have a small spine at the opposite pole to the operculum.

Final hosts: Chicken, turkey, other fowl, goose and duck

Intermediate hosts: Host 1: aquatic snails such as *Bithynia tentaculata*. Host 2: nymphal stage of various dragonflies.

Geographical distribution: Worldwide

Pathogenesis: *Prosthogonimus* is considered to be the most pathogenic of the trematodes that infect poultry and ducks in America and Europe. Usually chickens are mainly affected. Even moderate infections can inflame the oviduct resulting in the formation of eggs with a soft shell or lacking a shell. Large numbers of flukes can be fatal.

Clinical signs: Infected birds may have an enlarged flaccid abdomen, become listless, show discharge of a limey secretion from the cloaca and may lay abnormally formed eggs. The feathers around the cloaca become soiled. Sometimes there is complete cessation of egg-laying.

Diagnosis: Fluke eggs can be identified in secretions from the cloaca or found in the abdominal cavity at necropsy.

Pathology: The oviduct is often severely inflamed with a thick yellow–white secretion in the lumen. Irritation in the oviduct can cause a reversal of peristalsis, resulting in egg, bacteria and parasite material entering the abdominal cavity and causing peritonitis. The comb and wattles can become cyanotic in chronically infected birds. Sometimes there is a whitish milky discharge from the cloaca.

Epidemiology: The occurrence is seasonal, with the main peak of infection in the spring and summer in temperate regions.

Treatment: Albendazole, fenbendazole, flubendazole 5 mg/kg; or praziquantel 5–10 mg/kg.

Control: Reduction of snails and their habitats will limit infection in the final hosts and, where possible, flocks should be denied access to the margins of ponds and lakes.

Prosthogonimus macrorchis

Common name: Oviduct fluke

Predilection site: Cloaca, oviduct and bursa of Fabricius

Phylum: Platyhelminthes

Class: Trematoda

Family: Prosthogonimidae

Description, gross: Adults are pear-shaped, semi-transparent, reddish coloured and measure around 7–8 mm in length, being broader towards the posterior.

Description, microscopic: The testes are larger than in *P. pellucidus*. Eggs are around 25 µm and have a small spine at the opposite pole to the operculum.

Final hosts: Chicken, turkey, other fowl and duck

Intermediate hosts: As for *P. pellucidus*

Geographical distribution: North America

Prosthogonimus ovatus

Common name: Oviduct fluke

Predilection site: Cloaca, oviduct and bursa of Fabricius

Phylum: Platyhelminthes

Class: Trematoda

Family: Prosthogonimidae

Description, gross: Adults are pear-shaped, semi-transparent and smaller than *P. pellucidus* and *P. macrorchis*, measuring about 4–6 mm in length. The cuticle is covered with spines.

Description, microscopic: The small ovoid eggs measure around 22–24 by 13 µm and have a small spine at the opposite pole to the operculum.

Final hosts: Chicken, turkey, other fowl and goose

Intermediate hosts: As for *P. pellucidus*

Geographical distribution: Europe, Asia, Africa and North and South America

Plagiorchis arcuatus

Synonym: *Leptoderma arcuatus*

Predilection site: Oviduct and bursa of Fabricius

Phylum: Platyhelminthes

Class: Trematoda

Family: Plagiorchiidae

Description, gross: The fluke is oval, about 4–5 mm in length by 1.5 mm in breadth, and tapers to a point at both ends.

Description, microscopic: The cuticle possesses small spines, which are more numerous in the anterior region. The testes are rounded or oval and lie obliquely behind each other. The ovary is rounded and is situated near the end of the cirrus sac, and to the right of the ventral sucker.

Final hosts: Chicken, turkey and other poultry

Intermediate hosts: Host 1: snails, particularly *Lymnaea* and *Physa* spp. Host 2: various crustacea, molluscs and insects.

Geographical distribution: Parts of Europe and Russia

Details of the pathogenesis, clinical signs, diagnosis, pathology, epidemiology, treatment and control for these species are as for *P. pellucidus*.

Eimeria truncata

Predilection site: Kidney

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, smooth, with a narrow truncate small end, 14–27 by 12–22 µm, with a micropyle and micropylar cap, sometimes with a residuum. Mature meronts in the renal epithelial cells are 13 µm in diameter and contain 20–30 merozoites. Macrogametes are 12–18 by 11–15 µm and microgamonts are 15–22 by 13–18 µm.

Hosts: Domestic goose, greylag goose (*Anser anser*), Canada goose (*Branta canadensis*), Ross' goose (*Anser rossii*) and duck

Life cycle: Complete details on the life cycle are lacking. Meronts and gamonts occur in the epithelial cells of the kidney tubules. The prepatent period is 5–14 days. Sporulation time is 1–5 days.

Geographical distribution: Worldwide

Pathogenesis: *Eimeria truncata*, found in the kidneys of geese, can cause an acute nephritis especially where domestic geese are reared intensively. It is highly pathogenic for young goslings and can cause up to 100% mortality within a few days of onset of clinical symptoms. Outbreaks have also been recorded in geese in wildfowl sanctuaries.

Clinical signs: Marked weakness, emaciation, polydipsia, muscular incoordination and death

Diagnosis: Infection is diagnosed by identification of oocysts in urates or by the characterised kidney lesions on postmortem or histopathology.

Pathology: The kidneys are markedly enlarged, light in colour, and show numerous small white nodules, streaks and lines on the surface and throughout the cortex and medulla. Infected cells are eventually destroyed and the adjacent cells show pressure atrophy and destruction. Affected tubules are packed with urates and oocysts and gamonts in various stages of development (Fig. 13.37), and may be enlarged up to five to ten times the diameter of normal tubules.

Epidemiology: *Eimeria truncata* occurs as a sporadic parasite in domestic geese and is most likely to occur when geese are kept in crowded unsanitary conditions. Contact with wild geese may introduce the infection.

Treatment: Little is known about treatment but, by analogy with other hosts, one of the sulphonamide drugs should be tried.

Control: Prevention is based on good management, avoidance of overcrowding and stress, and attention to hygiene. Contact with wild geese should be avoided wherever possible.

Parasites of the locomotory system

Sarcocystis hovarathi

Synonym: *Sarcocystis gallinarum*

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: In the chicken, the tissue cysts are 1–10 mm long with striated walls and are found in skeletal muscles of the breast, thigh, neck and oesophagus.

Final host: Dog

Intermediate host: Chicken

Geographical distribution: Unknown, presumed worldwide

Pathogenesis: Infections in chickens are generally inapparent, but have been reported to cause severe myositis or muscular dystrophy.

Clinical signs: Muscle weakness and inability to stand have been reported.

Diagnosis: Antemortem diagnosis is difficult and most cases of *Sarcocystis* infection are only revealed at postmortem when grossly visible sarcocysts in the muscle are discovered or detected by microscopic examination.

Epidemiology: Little is known of the epidemiology, but it is clear that where dogs are kept in close association with chickens or their feed, then transmission is likely.

Treatment and control: Treatment is not indicated. The only control measures possible are those of simple hygiene. Farm dogs should not be housed in, or allowed access to, fodder stores nor should they be allowed to defecate in pens where chickens are housed. It is also important that dogs are not fed raw or uncooked chicken.

Fig. 13.37 Gamonts of *Eimeria truncata* in kidney epithelial cells.

Toxoplasma gondii

Predilection site: Muscle, lung, liver, reproductive system, CNS

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: Tachyzoites are found developing in vacuoles in many cell types, for example fibroblasts, hepatocytes, reticular cells and myocardial cells. In any one cell there may be 8–16 organisms, each measuring 6.0–8.0 µm. Tissue cysts, measuring up to 100 µm in diameter, are found mainly in the muscle, liver, lung and brain and may contain several thousand lancet-shaped bradyzoites.

Final hosts: Cat, other felids

Intermediate hosts: All warm-blooded mammals and birds

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Most *Toxoplasma* infections in animals are light and consequently asymptomatic. Toxoplasmosis has been occasionally reported in poultry and is usually mild and unnoticed.

Diagnosis: Tachyzoites of *T. gondii* are often difficult to find in tissue sections, but are more likely to be present in sections of brain and placenta. Identification can be confirmed by immunohistochemistry, while the polymerase chain reaction may be used to identify parasite DNA in tissues.

Epidemiology: The cat plays a central role in the epidemiology of toxoplasmosis and infection in poultry may occur through ingestion of feed contaminated with cat faeces or through ingestion of bradyzoites and tachyzoites in the flesh of another intermediate host, such as rats.

Treatment and control: As for *Sarcocystis hovarathi*.

Parasites of the integument

Avioserpens taiwana

Synonyms: *Filaria taiwana*, *Oshimaia taiwana*, *Avioserpens denticulophasma*, *Petroviprocta vigissi*

Predilection site: Subcutaneous tissue

Phylum: Nematoda

Class: Secernentea

Superfamily: Dracunculoidea

Description, gross: The male is unknown. The female is up to around 25 cm long by 0.8 mm in width.

Description, microscopic: The anterior end is rounded, the mouth being surrounded by a chitinous rim bearing two prominent lateral papillae. There are four smaller papillae further back on the head. The uterus is large and filled with larvae. The vagina, vulva and anus are atrophied and the tail ends in a conical papilla.

Final host: Duck

Intermediate hosts: Copepods (*Cyclops*)

Geographical distribution: China, Taiwan

Pathogenesis: The worms cause the formation of swellings under the mandible, which are at first soft and movable and, after about 1 month, hard and painful and may reach the size of a large nut. They interfere with swallowing and respiration and may cause death from inanition or asphyxia. Occasionally the swellings occur on the shoulders and legs and interfere with the bird's movements. Numerous microfilariae are found in the blood. The adult worms eventually rupture and disintegrate and healing occurs, although if the worms die in the swellings, abscesses may form. The disease lasts about 11 months.

Clinical signs: Hard painful swellings located under the mandible, and occasionally on the shoulders and legs. Surviving birds have poor growth rates.

Diagnosis: Identification of the adult worms within subcutaneous swelling.

Pathology: Not described

Epidemiology: Found in domesticated ducks in China, mainly in the dry season (January to April), and in Taiwan, where disease may also occur in September to October. It affects ducks aged 3 weeks to 2 months.

Treatment: Removal of the worms through an incision into the most prominent part of the swelling and antiseptic treatment of the swelling is effective.

Control: Ducklings should be provided with water free from *Cyclops* and should not be allowed access to marshland.

Splendidofilaria fallisensis

Synonym: *Ornithofilaria fallisensis*

Predilection site: Subcutaneous tissue

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Delicate transparent nematodes; male worms are 9–15 mm and female worms 24–40 mm long.

Description, microscopic: Male worms have relatively long tails and subequal spicules.

Final host: Duck

Intermediate hosts: Blackflies (*Simulium*)

Geographical distribution: North America

Collyriclum faba

Synonym: *Monostoma faba*

Common name: Skin or cystic fluke

Predilection site: Skin, subcutaneous tissues, particularly around the cloacal opening

Phylum: Platyhelminthes

Class: Trematoda

Family: Collyriclidae

Description, gross: The flukes occur in pairs in a tissue cyst. The fluke has a spiny tegument, is dorsally convex and ventrally flattened and measures about 4 by 5 mm.

Description, microscopic: There is no ventral sucker and the oral sucker is small. The ovary is multilobular and the vitellaria are located in the anterior half of the body. Eggs are very small, measuring about 19–21 by 9–11 µm.

Final hosts: Chicken, turkey and wild birds

Intermediate hosts: Host 1: snails. Host 2: dragonfly nymphs.

Geographical distribution: Europe, Asia, North and South America

Pathogenesis: Commonly found in tissue around the cloaca but in heavy infections flukes may also be present along the thorax, abdomen, beak and neck. Such infections produce anaemia and loss of body condition and can be fatal.

Clinical signs: Young birds may show difficulty in moving, inappetence, anaemia, emaciation and even death. The presence of cysts can lead to disfigurement of the skin.

Diagnosis: Typical cysts are found around the cloacal opening and along the thorax and abdomen. Each cyst has a central opening and a pair of flukes.

Pathology: The flukes are located in hard whitish-grey subcutaneous cysts that measure around 3–10 mm in diameter. These cysts have a central pore and contain a pair of flukes and are usually filled with dark fluid and eggs.

Epidemiology: Only birds with access to marshy areas where the intermediate hosts occur are likely to become infected.

Treatment: Surgical removal is the only effective treatment.

Control: Birds should be restricted from entering marshy areas.

Laminosioptes cysticola

Common names: Subcutaneous mite, fowl cyst mite

Predilection site: Subcutaneous tissues, lung, peritoneum

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Laminosioptidae

Description, gross: *Laminosioptes cysticola* is a small oval mite, approximately 250 µm in length.

Description, microscopic: The posterior two pairs of legs end in claws and suckerless pedicels, while the anterior two pairs of legs end in claws (see Fig. 3.98). This mite has a smooth elongated body and few setae. The gnathosoma is small and not visible when viewed from above.

Hosts: Chicken, turkey and pigeons, occasionally wild birds

Geographical distribution: Worldwide. It is abundant in Europe and is also found in the USA, South America and Australia.

Pathogenesis: *Laminosioptes* is not usually associated with clinical signs and is only discovered at meat inspection, when infected carcasses are condemned partly on aesthetic grounds and partly because the infection appears somewhat similar to avian tuberculosis.

Clinical signs: The parasites are not usually regarded as pathogenic, although occasionally neurological signs including circling, loss of balance, wing droop and death have been reported.

Diagnosis: The nodules may be seen in living birds by parting the breast feathers and sliding the skin back and forth with the fingertips. Examination of the nodules under a dissection microscope usually allows the identification of the mite species.

Pathology: Aggregations of these small oval mites are found in yellow nodules, several millimetres in diameter, in the subcutaneous muscle fascia and in deeper tissues in the lungs, peritoneum, muscle and abdominal viscera. The subcutaneous nodules are often calcified, but these only contain dead mites as the calcareous deposits are produced around the mites after they have died. Active mites occur in the deep tissues. The nodules created by the mites reduce the value of meat intended for human consumption.

Epidemiology: It is estimated that around 1% of free-living urban pigeons harbour *Laminosioptes cysticola*. The mode of transmission of this mite is unknown.

Treatment: Ivermectin may be effective, but euthanasia may be required for rapid elimination of infected birds.

Control: Destroying or quarantining infected birds reduces infestations within the flock.

Notes: It has been reported that the fowl cyst mite may cause a granulomatous pneumonia in dogs.

ECTOPARASITES

LICE

Heavy louse infestation is known as pediculosis and is particularly common in poultry. All species on birds are chewing lice and are therefore of importance because of the direct damage they cause by chewing the skin or feathers, although some blood-feeding may occur when the base of feathers are damaged. Clinical importance is therefore usually a function of the density of the lice present. Transmission is usually by direct physical contact.

Description: Lice have a segmented body divided into a head, thorax and abdomen. They have three pairs of jointed legs and a pair of short antennae. All lice are dorsoventrally flattened and wingless. The sensory organs are poorly developed; the eyes are vestigial or absent.

Life cycle: The general life cycle of poultry lice is relatively uniform across the various species. During a lifespan of approximately a month the female lays 200–300 operculate eggs ('nits'). These are usually whitish, and are glued singly to the feathers where they may be seen with the naked eye. Eggs hatch within 5–7 days. The nymph that hatches from the egg is similar to, although much smaller than, the adult. The nymph moults three times over 2–3 weeks before giving rise to the adult. The lice normally feed on bits of skin or feather products. Adult lice may live for several weeks on the host but can remain alive only for about 1 week off the host. Bird lice can

digest keratin; they bite off pieces of feather, breaking these up with comb-like structures in their crops and digesting them with secretions aided by bacterial action. They will ingest not only the sheaths of growing feathers but also down and skin scabs.

Clinical signs: Restlessness, feather damage, emaciation and markedly reduced performance are all symptoms of severe pediculosis. Infected birds are unable to rest, cease feeding and may injure themselves by scratching and feather plucking, with results often more serious than any immediate damage by the lice.

Pathogenesis: Although there are differences in pathogenicity between the species of louse found on poultry, the effects of avian pediculosis are broadly similar, varying only in degree. Heavy infestations decrease reproductive potential in males, egg production in females and weight gain in growing chickens. The skin lesions are also sites for secondary bacterial infections. While most lice are not highly pathogenic to mature birds in low numbers, they may be fatal to chicks. As in the other pediculoses, the condition in domestic birds is often itself a symptom of ill-health from other causes, such as other infection, malnutrition or inadequate, overcrowded and unhygienic housing. Chewing lice may occasionally cause severe anaemia by puncturing small feathers and feeding on the blood that oozes out.

Diagnosis: Adult lice and eggs can be seen on the skin and feathers and removed for microscopic examination and identification.

Pathology: The pathology of louse infestation is highly variable. In heavy infestations the skin becomes inflamed, erythematous and eventually covered by scabs and blood clots, involving much of the body surface.

Epidemiology: Infection occurs after direct contact with an infested host animal. Cross-contamination between different host species is possible if the animals have physical contact.

Treatment: Topical insecticidal compounds, such as permethrin, carbaryl, malathion, cypermethrin or rotenone, can be used to kill lice. However, as the insecticides are unable to kill the eggs, two applications are necessary at an interval of 10–14 days. Deep-litter or free-range birds may be more easily treated by scattering carbaryl, coumaphos, malathion or stirophos dust on the litter.

Control: Regular checking and spraying of birds will enable infestation rates to be controlled. In addition, cross-contamination should be avoided. This is achieved by treating any birds in the environment of the chickens and restricting contact between wild birds and poultry. The housing and nesting should be thoroughly cleaned to eliminate sources of reinfestation such as egg-laden feathers. As would be expected, the practice of debeaking allows an increase in infestations by preventing birds from preening and grooming.

Cuclotogaster heterographus

Common name: Head louse

Predilection site: Skin and feathers of the head and neck

Class: Insecta

Order: Phthiraptera

Suborder: Ischnocera

Family: Philopteridae

Description, gross: A grey slow-moving louse found close to the skin. *Cuclotogaster heterographus* has a rounded body with a large slender head, which is rounded at the front (see Fig. 3.63). Adult males measure approximately 2.5 mm and females 2.6 mm in length.

Description, microscopic: The first segment of the antennae of males is long and thick and bears a posterior process. The abdomen is elongate in the male and barrel-shaped in the female, with dark-brown lateral tergal plates. Three long bristles project from each side of the dorsal surface of the head and the five-segmented antennae are fully exposed. Each leg has two tarsal claws.

Hosts: Chicken, other poultry

Geographical distribution: Worldwide

Pathogenesis: As the common name, chicken head louse, suggests, *C. heterographus* occurs mainly on the skin and feathers of the head, although it occurs occasionally on the neck and elsewhere. *Cuclotogaster heterographus* feeds on tissue debris, skin scales and scabs and can digest keratin from feathers and down. Infestation with *C. heterographus* is particularly important in young birds. Infestations of young birds and chicks may be pathogenic and sometimes fatal; the birds become weak and droopy and may die within a month. When birds become fairly well feathered, head lice infestation decreases, but can increase again when the birds reach maturity.

Goniocotes gallinae

Common name: Fluff louse

Predilection site: Feathers

Class: Insecta

Order: Phthiraptera

Suborder: Ischnocera

Family: Philopteridae

Description, gross: The fluff louse, *Goniocotes gallinae*, is one of the smallest lice found on poultry, at about 0.7–1.3 mm in length. It has a pale yellow, almost circular body (see Fig. 3.66).

Description, microscopic: The head is rounded and carries two large bristles projecting from each side of its dorsal surface. The antennae are five-segmented, fully exposed and the same in both sexes. There are two tarsal claws on each leg and few hairs on the dorsal abdomen.

Host: Chicken

Geographical distribution: Worldwide

Pathogenesis: *Goniocotes gallinae* may occur on the down feathers anywhere on the body, but are often found in the fluff at the bases of feathers, the preferred sites being the back and the rump. These lice generally occur in low densities and so have little effect on the host. However, cases of severe *Goniocotes* infestation can cause restlessness, damaged plumage, anaemia and markedly reduced performance.

Goniodes dissimilis

Common name: Brown chicken louse

Predilection site: Skin and body feathers

Class: Insecta

Order: Phthiraptera

Suborder: Ischnocera

Family: Philopteridae

Description, gross: *Goniodes dissimilis* are large lice, about 3 mm in length, and brown in colour (see Fig. 3.65).

Description, microscopic: The broad head is posteriorly concave, producing marked angular corners at the posterior margins. The head carries two large bristles projecting from each side of its dorsal surface. The antennae have five segments and are fully exposed. Each leg has two tarsal claws.

Host: Chicken

Geographical distribution: Worldwide

Pathogenesis: *Goniodes dissimilis* is more abundant in temperate habitats. Birds are unable to rest, cease feeding and may injure themselves by scratching and feather plucking. In general, young birds suffer more severely, with loss of body weight, debility and perhaps death.

Goniodes gigas

Common name: Large chicken louse

Predilection site: Skin and body feathers

Class: Insecta

Order: Phthiraptera

Suborder: Ischnocera

Family: Philopteridae

Description, gross: Very large brown lice occurring on the body and feathers of the fowl. Males measure 3–4 mm and females 5 mm in length.

Description, microscopic: These have a broad head, which is concave posteriorly, producing marked angular corners at the posterior margins. The head bears two large bristles, which project from each side of its dorsal surface. The antennae have five segments and are fully exposed. Each leg has two tarsal claws.

Host: Chicken

Geographical distribution: Worldwide, but *Goniodes gigas* is more abundant in tropical areas.

Goniodes meleagridis

Predilection site: Skin and body feathers

Class: Insecta

Order: Phthiraptera

Suborder: Ischnocera

Family: Philopteridae

Description, gross: These are large lice, the adults reaching up to 5 mm in length.

Description, microscopic: These lice are characterised by broad mandibles located ventrally on the head, short antennae (three to five segments) and a dorsoventrally flattened body.

Host: Turkey

Geographical distribution: Worldwide

Pathogenesis: Birds are unable to rest, cease feeding and may injure themselves by scratching and feather plucking, with results often more serious than any immediate damage by the lice. This species of louse is commonest in adult birds, but young birds that do become infested suffer more severely, with loss of body weight, debility and perhaps death. These lice can digest keratin; they bite off pieces of feather, breaking these up with comb-like structures in their crops and digesting them with secretions aided by bacterial action. They will ingest not only the sheaths of growing feathers but also down and skin scabs.

Clinical signs: In general, young birds suffer more severely, with loss of body weight, debility and perhaps death. In adult laying birds the effect on body weight is slight, and the main loss is in depression of egg production.

Epidemiology: Infection occurs after direct contact with an infested host animal. Cross-contamination between different host species is possible if the animals have physical contact.

Lipeurus caponis

Common name: Wing louse

Predilection site: Skin, wing and tail feathers

Class: Insecta

Order: Phthiraptera

Suborder: Ischnocera

Family: Philopteridae

Description, gross: *Lipeurus caponis* is an elongated narrow species, about 2.2 mm in length and 0.3 mm in width (see Fig. 3.64).

Description, microscopic: The head is long and rounded at the front, and the antennae are five-segmented and fully exposed. The legs are narrow and bear two tarsal claws. Characteristically, the hindlegs are about twice as long as the first two pairs of legs. There are characteristic small angular projections on the head in front of the antennae. There are relatively few dorsal hairs on the abdomen.

Host: Chicken

Geographical distribution: Worldwide

Pathogenesis: *Lipeurus caponis* is common on the underside of the wing and tail feathers of chicken and other fowl throughout the world. Pathogenic effects are usually slight in healthy animals and include restlessness, irritation and general unthriftiness. Young birds may be susceptible to heavy infestation, especially where underlying disease or malnutrition is debilitating.

Menacanthus stramineus

Common name: Yellow body or chicken body louse

Predilection site: Skin

Class: Insecta

Order: Phthiraptera

Suborder: Amblycera

Family: Menoponidae

Description, gross: The chicken body louse or yellow body louse, *Menacanthus stramineus*, is relatively large; the male measures approximately 2.8 mm in length and the female 3.3 mm (see Fig. 3.58).

Description, microscopic: The head is almost triangular in shape and the ventral portion of the front of the head is armed with a pair of spine-like processes. The palps and four-segmented antennae are distinct. The antennae are club-shaped and mostly concealed beneath the head. The flattened abdomen is elongated and broadly rounded posteriorly with two dorsal rows of setae on each abdominal segment. There are three pairs of short two-clawed legs. The eggs have characteristic filaments on the anterior half of the shell and on the operculum.

Hosts: Chicken, turkey, guinea fowl, peafowl, pheasant, quail, cage birds (canary)

Geographical distribution: Worldwide

Pathogenesis: *Menacanthus stramineus* is the most pathogenic louse of adult birds, and may lead to fatalities in chicks. It is an extremely active species which lays its eggs in clusters mainly in the anal region. Infestation can result in severe irritation, causing skin inflammation and localised scabs and blood clots, especially in the region of the vent and, in young birds, on the head and throat. Birds become restless and do not digest their food properly. Ultimately infestation may result in decreased hen weight, decreased clutch size and death in young birds and chicks. Populations may reach as many as 35,000 lice per bird. Lice infestations often accompany manifestations of poor health such as internal parasitism, infectious disease, malnutrition and poor sanitation. Although found naturally infected with the virus of eastern encephalomyelitis, it is not considered an important vector.

Epidemiology: This species is the most common and destructive louse of domestic chickens. It is widespread and often reaches pest proportions. It is most common on the breast, thighs and around the vent. In heavy infestations, the lice may also be found under the wings and on other parts of the body, including the head. After introduction into a flock, *M. stramineus* spreads from bird to bird by contact. Cross-contamination between different host species is possible if the animals have physical contact. Large populations are particularly common on caged layers.

Menopon gallinae

Common name: Shaft louse

Predilection site: Skin and feathers

Class: Insecta

Order: Phthiraptera

Suborder: Amblycera

Family: Menoponidae

Description, gross: Pale yellow, rapidly moving louse. It is a small louse, adults measuring approximately 2 mm in length.

Description, microscopic: *Menopon gallinae* has small palps and a pair of four-segmented antennae, folded into grooves in the head (see Fig. 3.59). The abdomen is tapered posteriorly in the female but rounded in the male and has a sparse covering of small to medium-length setae on its dorsal surface.

Hosts: Chicken, turkey, duck

Geographical distribution: Worldwide

Pathogenesis: This louse feeds only on feathers, and although common is rarely a serious parasite in adult birds. The shaft louse does not usually infest young birds until they are well feathered, but heavy infestations in young birds may prove fatal. *Menopon gallinae* rests on the body feather shafts of chickens and feeds on parts of the feathers. The louse occurs largely on the thigh and breast. It may also infest turkeys and ducks, particularly if kept in close association with chickens.

Menopon leucoxanthum

Common name: Shaft louse

Predilection site: Skin and feathers

Class: Insecta

Order: Phthiraptera

Suborder: Amblycera

Family: Menoponidae

Description: A small, rapidly moving louse that especially favours the preen gland, inhibiting production of the oily secretion and causing 'wet feather'.

Host: Duck

Life cycle: The nymph moults three times over 2–3 weeks before giving rise to the reproductive adult. Individuals are highly mobile and move rapidly.

Geographical distribution: Worldwide

Pathogenesis: Partly due to irritation birds preen continuously, but without the oily secretion the feathers cannot be waterproofed. Unable to repel water and injured by constant preening, the plumage becomes tattered and dirty, with the feathers broken. Water can penetrate to the skin, and when much of the body is affected the birds are soaked, and may die of pneumonia following chilling. Though the damaged plumage may be replaced at the annual moult, it soon degenerates, as a result of the excessive preening, into its former sodden condition.

Clinical signs: Wet damaged plumage

Diagnosis: Lice and their eggs are visible on the skin and feathers of the host animal.

Pathology: The pathology of louse infestation is highly variable. In heavy infestations the skin becomes inflamed, erythematous and eventually covered by scabs and blood clots.

Epidemiology: Infection occurs after direct contact with an infested host animal. Cross-contamination between different host species is possible if the animals have physical contact.

Treatment: Topical insecticidal compounds such as permethrin, carbaryl, malathion, cypermethrin or rotenone can be used to kill

Table 13.6 Lice of ducks, geese and other wildfowl.

| Family | Genus | Key representative species |
|--------------|---------------------|---|
| Phloptoridae | <i>Anaticola</i> | <i>Anaticola anseris</i> , <i>Anaticola crassicornis</i> , <i>Anaticola tadornae</i> , <i>Anaticola thoracicus</i> |
| Phloptoridae | <i>Acidoproctus</i> | <i>Acidoproctus rostratus</i> |

lice. However, as the insecticides are unable to kill the eggs, two applications are necessary at an interval of 10 days.

Control: Although methods such as dusting the nesting material or providing insecticide-treated laying boxes can be used to avoid undue handling of birds, the results obtained from treating individual birds are undoubtedly better.

Large numbers of closely related species of lice may be found on ducks, geese and other waterfowl (Table 13.6). Of epidemiological significance is that these species are among the least specific of all lice. The lice can be found on the skin and feathers in all areas of the body. In ducks, infection with lice can damage feathers, affecting water resistance and insulation so that the birds may die from cold. Treatment and control are as for *Menopon leucoxanthum*.

Similarly, a number of closely related species of lice are found on gamebirds (Table 13.7). Host specificity is unknown.

MITES

Infestation by mites can result in severe dermatitis, which may cause significant welfare problems and economic losses.

Clinical signs: Mites cause feeding lesions most commonly seen on the breast or legs of the bird. The feeding nymphs and adults cause irritation, restlessness and debility, and in heavy infections

there may be severe, and occasionally fatal, anaemia. Newly hatched chicks may die rapidly as a result of mite activity. Egg production may decrease significantly.

Diagnosis: The mites may be found in poultry housing during the day, particularly in cracks or where roost poles touch supports, or on birds at night. The mites can be observed in these locations with the naked eye, particularly after feeding when they appear red. Masses of mites may be found in the nasopharyngeal system of dead birds.

Pathology: The effects of mites are highly variable, but may include hyperkeratosis, acanthosis, epidermitis, dermatitis, poor feather growth and loss of feathers.

Dermanyssus gallinae

Common names: Poultry red mite, roost mite

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Mesostigmata

Family: Dermanyssidae

Description: The adults are relatively large, 0.75–1 mm in length, with long legs (see Fig. 3.108). The body is usually grey–white, becoming red to black when engorged (Fig. 13.38). A single dorsal

**Fig. 13.38** *Dermanyssus gallinae*.

shield is present that tapers posteriorly but which is truncated at its posterior margin. The anal shield is relatively large and is at least as wide as the genitoventral plate. Three anal setae are present. The chelicerae are elongate and stylet-like.

Hosts: Domestic poultry and wild birds; occasionally parasitic on mammals, including human

Geographical distribution: Worldwide

Pathogenesis: The mite is a particular threat to fowl housed in old buildings. It causes feeding lesions, which are most likely to be seen on the breast or legs of the bird. The mites can directly cause irritation and anaemia, and can lower egg production and weight gain. Newly hatched chicks may rapidly die as a result of mite activity. Infestation of pigeons is common. Cats and dogs may become infested as a result of contact with poultry, and human carriers are also important. In Australia, *Dermanyssus gallinae* is a vector of *Borrelia anserina*, the cause of avian spirochaetosis.

Epidemiology: The red mite or chicken mite, *Dermanyssus gallinae*, is one of the most common mites of poultry. It is a mesostigmatid mite that feeds off the blood of fowl, pigeons, caged birds and many other wild birds. It occasionally bites mammals, including humans, if the usual hosts are unavailable. Populations generally increase during the winter months and decrease in the summer months, and infestation intensity increases during the host breeding period. The presence of nestlings may stimulate rapid reproduction and an exponential increase in mite numbers, so that at the time of fledging there is a significantly higher proportion of nymphs in the nest than adults. Mites are transmitted by mite dispersion between farms (via transport of crates, egg flats or even on humans themselves) or by direct contact between birds. *Dermanyssus gallinae* may be an important pest of poultry flocks maintained on the floor in barn or deep-litter systems, but is less important in caged production facilities. Since *Dermanyssus* can survive for long periods in the absence of a host, a poultry house may remain infested several months after birds are removed.

Treatment: Treatment of birds is only palliative, and attention should be paid to the mite habitats in buildings. Individual birds may be treated by spraying or dusting the birds with an acaricide such as a pyrethroid or carbaryl, coumaphos, malathion or stirofos. Systemic control by repeated treatment with ivermectin (1.8–5.4 mg/kg) or moxidectin (8 mg/kg) is effective for short periods.

Control: Buildings and equipment should be cleaned, scalded with boiling water and treated with an acaricide such as carbaryl or synergised pyrethroids. Dimethoate and fenthion may be used as residual house sprays when poultry are not present. Where the mites have invaded dwelling houses their ability to survive in nests, without feeding for several months, makes these important as reservoir sites, and all nests should be removed from eaves once the fledglings have departed. Buying in mite-free birds and using good sanitation practices are important to prevent a build-up of mite populations.

Notes: *Dermanyssus* readily infects other animals, and can cause erythema and intense pruritus in cats that occupy old wooden poultry houses. Humans may develop skin lesions when mites enter rooms from wild birds' nests in the eaves of houses.

Ornithonyssus sylviarum

Synonyms: *Liponyssus sylviarum*, *Macronyssus sylviarum*

Common name: Northern fowl mite

Predilection site: Base of the feathers, particularly the vent area

Class: Arachnida

Subclass: Acari

Order: Mesostigmata

Family: Macronyssidae

Description: The adults are relatively large, oval-shaped, 0.75–1 mm in length, with long legs that allow it to move rapidly (see Fig. 3.106). The body is usually greyish-white, becoming red to black when engorged. A single dorsal shield is wide for two-thirds of its length, then tapers posteriorly to become about half as wide, and is truncated at its posterior margin. The female typically has only two pairs of setae on the sternal shield. The anal shield is relatively large and at least as wide as the genitoventral plate. Three anal setae are present. The chelicerae are elongate and stylet-like. The body carries many long setae and is much more hairy than *Dermanyssus*.

Hosts: Poultry and wild birds

Geographical distribution: Present in temperate areas throughout the world

Pathogenesis: *Ornithonyssus sylviarum* is a blood-sucking ectoparasite. It occasionally bites mammals, including humans, if the usual hosts are unavailable. This mite is capable of transmitting fowlpox, St Louis encephalitis, Newcastle disease, chlamydiosis and western equine encephalomyelitis. The viruses that cause western equine encephalitis and St Louis encephalitis have both been detected in *O. sylviarum* from nests of wild birds in North America, and it is likely that this mite acts as a vector for their transmission among avian hosts. They may bite humans, causing pruritus.

Clinical signs: White or off-white eggs can be seen in the vent area on feather shafts. Feathers may become matted and severe scabbing may develop, particularly around the vent. Infested chickens show a grey–black discoloration of the feathers due to the large number of mites present. In heavy infections, birds are restless and lose weight from irritation, egg production may be reduced, and there may be severe anaemia. Common signs, apart from debility, are thickened crusty skin and soiled feathers around the vent.

Diagnosis: The mites are found on the birds or in their nesting and housing. Although similar in superficial morphology to the common chicken mite *Dermanyssus gallinae*, *Ornithonyssus sylviarum* can be distinguished behaviourally by the fact that it is present on birds in large numbers during the day.

Pathology: Feeding causes pruritus, feather damage, weakness, anaemia and death. Scratching of the bites may result in secondary bacterial infection.

Epidemiology: As *O. sylviarum* is almost a permanent parasite, infection occurs via contact or by placing birds in accommodation recently vacated by infected stock.

Treatment and control: As for *D. gallinae*.

Ornithonyssus bursa

Synonym: *Liponyssus bursa*

Common name: Tropical fowl mite

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Mesostigmata

Family: Macronyssidae

Description: Similar to *O. sylviarum*. However, the ventral plate bears three pairs of setae, while in *O. sylviarum* and *D. gallinae* only two pairs of setae are on the ventral plate.

Hosts: Poultry and wild birds

Geographical distribution: Tropical: southern Africa, India, China, Australia, Columbia, Panama and USA

Epidemiology: In warmer climates *O. bursa* is thought to replace the northern fowl mite, *O. sylviarum*.

For further details see *O. sylviarum*.

Knemidocoptes gallinae

Synonyms: *Knemidokoptes laevis gallinae*, *Cnemidocoptes gallinae*, *Neocnemidocoptes gallinae*

Common name: Depluming itch mite

Predilection site: Feathered areas

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Knemidocoptidae

Description: This is the only burrowing genus of mites on domestic birds, and resembles *Sarcoptes* in many respects. The circular body and short stubby legs and the avian host are usually sufficient for generic diagnosis (see Fig. 3.95). Although similar in appearance to *Knemidocoptes mutans*, individuals are typically smaller and the pattern of dorsal striations is unbroken.

Hosts: Chicken, turkey, pheasant and goose

Geographical distribution: Worldwide

Pathogenesis: The parts of the body most commonly infected are the head, neck, back, abdomen and upper legs. Severe cases can result in emaciation and death.

Clinical signs: *Knemidocoptes gallinae* burrows into the feather shafts, and the intense pain and irritation cause the bird to pull out body feathers. This is known as 'depluming itch'. The condition is characterised by intense scratching and feather loss over extended areas of the body. Feathers fall out, break off or are pulled out by the bird. Mites may be found embedded in the tissue at the base of feather quills, causing scaling, papules and thickening of the skin.

Diagnosis: The progressive feather loss and scratching indicate the presence of the parasite. Identification of the mite species can be

achieved through examination of mites found on feather shafts or skin scrapings taken from the edge of lesions.

Pathology: The burrowing activity of the mites causes hyperkeratosis, thickening and wrinkling of the skin, and sloughing of the keratinous layers. Proliferative skin lesions may be observed on the legs, with digit necrosis observed in some birds.

Epidemiology: Infestation is especially prevalent in spring and summer and may disappear in autumn. New hosts are infected by contact. Infection may remain latent for a long time with a small static mite population until stress, such as chill or movement to a strange cage, occurs and then the population increases.

Treatment: Acaricidal dusts may be applied. Birds may also be treated with ivermectin; two to three treatments at 10-day intervals may be required to completely eliminate the mites. The ivermectin may be applied on the skin behind the neck, orally or injected. For individual birds repeated topical application of paraffin may also be effective, if time-consuming.

Control: Repeated treatments of acaricides will prevent reinfestations. All housing should be thoroughly disinfected.

Knemidocoptes mutans

Synonym: *Cnemidocoptes mutans*

Common name: Scaly leg mite

Predilection site: Beneath the scales of the feet and legs

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Knemidocoptidae

Description and life cycle: Details are as for *K. gallinae*.

Hosts: Chicken, turkey

Pathogenesis: In poultry, *Knemidocoptes mutans* affects the skin beneath the leg scales, causing the scales to loosen and rise, and giving a ragged appearance to the usually smooth limbs and toes (Fig. 13.39). Lameness and distortion of the feet and claws may be

Fig. 13.39 Damage to the scales of the legs and feet caused by burrowing of the mite *Knemidocoptes mutans*.

evident. The mites crawl onto the feet of the birds from the ground, and the lesions develop from the toes upwards.

Clinical signs: Raised scales on the feet and legs. The infestation may result in lameness and malformation of the feet. Occasionally the neck and comb may be affected. As the disease progresses over the course of several months, birds stop feeding and eventually die.

Diagnosis: The raised scales on the legs and feet indicate the presence of the parasite. Confirmation is achieved by finding the mites in skin scrapings taken from lesions. Mature adult mites are often found beneath the crusts.

Pathology: The parasites pierce the skin underneath the scale, causing an inflammation with exudate that hardens on the surface and displaces the scales.

Epidemiology: Infection may remain latent for a long time with a small static mite population until stress, such as chill or movement to a new environment, occurs and then the population increases. The condition is more common in birds allowed access to the ground and therefore tends to be more prevalent in barnyard and deep-litter systems rather than in caged production facilities. The mites are highly contagious.

Treatment: For ‘scaly leg’, the legs should be dipped into an acaricide solution. The treatment should be repeated several times at 10-day intervals. Birds can be treated by dipping the legs in a bath containing hexachlorocyclohexane (0.1%), sulphur solution (10%) or sodium fluoride (0.5%). Oral or topical ivermectin may also be effective.

Control: The poultry house should be thoroughly cleaned and the perches and nesting boxes sprayed with acaricide.

Megninia ginglymura

Common name: Feather mites

Predilection site: At the base of the feathers of the body and wings. Some species in this genus may also occur beneath the skin.

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Analgidae

Description: The male has greatly enlarged third legs and large posterior lobes with copulatory suckers. The female has all legs of similar size.

Hosts: A wide range of birds including chicken, turkey, pigeon and Passeriformes

Clinical signs: *Megninia ginglymura* may cause feather-pulling activity in pullets. Birds may become weak and irritated with damaged feathers.

Pathology: Dermatitis with secretion. Records of economic damage by these mites are rare, but up to 20% decrease in egg production has been reported with heavy infestation.

Epidemiology: More than 25 species of the superfamily Analgoidea are found on domestic poultry throughout the world,

including *Megninia cubitalis*. *Megninia columbae* may be found on pigeons.

Treatment: The application of acaricides such as pyrethrum, trichlorophon, dichlorvos or oral or topical ivermectin or selamectin may be effective.

Megninia cubitalis

Common name: Feather mites

Predilection site: Feathers on body and wings

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Analgidae

Description: Similar to *M. ginglymura* except in the female there is a crescent-shaped pregenital sclerite located between apodemes II. Also the posterior lateral and median pairs of setae near the genital opening are of equal length. In the male, apodemes I are fused into a ‘Y’ shape and the anal suckers are flanked by a pair of sclerites.

Hosts: A wide range of birds including chicken, pigeon and Passeriformes

Megninia ortari

Common name: Feather mites

Predilection site: Feathers on body and wings

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Analgidae

Description: In the female, the pregenital sclerite occupies an anterior position between the posterior part of apodeme I. In the male, apodemes I are fused into a ‘Y’ shape but there are no sclerites flanking the anal suckers.

Hosts: A wide range of birds including chicken, pigeon and Passeriformes

There are a large number of closely related species of feather, follicle and quill mites that may be found on a wide range of birds (Table 13.8). Quill mites may be found within the shaft of living feathers whereas feather mites are located externally, usually at the base of the feather. Feather follicle mites are found in the feather follicles of the skin. The mites cause restlessness and feather plucking. Treatment and control may be achieved through the application of acaricides such as pyrethrum, trichlorophon and dichlorvos; oral or topical ivermectin or selamectin may also be effective.

Several non-specific ectoparasites are found on poultry and are listed in the host–parasite checklists at the end of this chapter. More detailed descriptions of these parasites can be found in Chapter 17.

Table 13.8 Feather and quill mites of domestic and wild birds.

| Family | Genus | Key representative species |
|-----------------|-----------------------|---|
| Dermoglyphidae | <i>Dermoglyphus</i> | <i>Dermoglyphus elongatus</i> , <i>Dermoglyphus passerinus</i> |
| Freyanidae | <i>Freyana</i> | <i>Freyana largifolia</i> , <i>Freyana anatina</i> , <i>Freyana canayi</i> |
| Epidermoptidae | <i>Epidermoptes</i> | <i>Epidermoptes bilobatus</i> |
| Epidermoptidae | <i>Rivoltasia</i> | <i>Rivoltasia bifurcata</i> |
| Epidermoptidae | <i>Microlichus</i> | <i>Microlichus avus</i> |
| Epidermoptidae | <i>Promyialges</i> | <i>Promyialges macdonaldi</i> , <i>Promyialges pari</i> , <i>Promyialges uncus</i> |
| Pterolichidae | <i>Pterolichus</i> | <i>Pterolichus bolus</i> , <i>Pterolichus obtusus</i> |
| Pterolichidae' | <i>Sideroferus</i> | <i>Sideroferus lunula</i> |
| Hypoderidae | <i>Hypodectes</i> | <i>Hypodectes propus</i> |
| Trombiculidae | <i>Neoschongastia</i> | <i>Neoschongastia americana</i> , <i>Neoschongastia kallipygos</i> |
| Syringophilidae | <i>Syringophilus</i> | <i>Syringophilus bipectinatus</i> |

HOST-PARASITE CHECKLISTS

In the following checklists, the codes listed below apply:

Helminths

N, nematode; T, trematode; C, cestode; A, acanthocephalan.

Arthropods

F, fly; L, louse; S, flea; M, mite; Mx, maxillopod; Ti, tick; B, bug.

Protozoa

Co, coccidia; Bs, blood sporozoa; Am, amoeba; Fl, flagellate; Ci, ciliate.

Miscellaneous 'protozoal organisms'

B, blastocyst; Mi, microsporidian; My, *Mycoplasma*; P, Pneumocystidomycete; R, *Rickettsia*.

Parasites of ungulates

DEER

ENDOPARASITES

Parasites of the digestive system

Oesophagus

Gongylonema pulchrum

Synonym: *Gongylonema scutatum*

Common name: Gullet worm

Predilection site: Oesophagus, rumen

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description: A long, slender, whitish worm, the males being about 5.0 cm and the females up to about 14.0 cm in length. Worms are easily distinguished microscopically by the presence of longitudinal rows of cuticular bosses in the anterior region of the body. Asymmetrical cervical alae are prominent. The egg is thick-shelled and possesses two opercula. It measures 50–70 by 25–37 μm and contains an L₁ when passed in faeces.

Final hosts: Sheep, goat, cattle, pig, buffalo, horse, donkey, deer, camel, human and primates

Intermediate hosts: Coprophagous beetles, cockroaches

Geographical distribution: Probably worldwide

For more details see Chapter 9.

Rumen and reticulum

Gongylonema verrucosum

Common name: Rumen gullet worm

Predilection site: Rumen, reticulum, omasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description: Long slender worms, reddish when fresh. The males are about 3.5 cm and the females 7.0–9.5 cm in length. The adult parasites have a festooned cervical ala and cuticular bosses only on the left side of the body. The males' spicules are unequal in length with the left spicule longer than the right.

Final hosts: Cattle, sheep, goat, deer

Intermediate hosts: Coprophagous beetles and cockroaches

Paramphistomum and other rumen fluke

Several species of rumen fluke belonging to genera in the families Paramphistomatidae and Gastrothylacidae are found in deer and are summarised in Table 14.1. The taxonomy of the paramphistomes is complex and unresolved and many of the species described may be synonymous, being differentiated mainly on size and shape of the suckers. For more details on these rumen fluke species refer to Chapters 1, 8 and 9.

Abomasum

A number of ostertagian parasites are found in the abomasa of various deer hosts (Table 14.2). Species descriptions are provided in Chapter 1 (Family Ostertaginae). There have been few specific studies on the pathogenesis of abomasal parasites in deer.

Ostertagia ostertagi

Synonyms: *Ostertagia lyrata*, *Skrjabinagia lyrata*

Common name: Brown stomach worm

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: Adults are small, slender, reddish-brown worms with a short buccal cavity that is not very pronounced. Males measure 6–8 mm and females 8–11 mm in length.

Hosts: Cattle, deer and very occasionally goats

Geographical distribution: Worldwide

Table 14.1 Rumen fluke of deer.

| Species | Hosts | Site | Intermediate hosts |
|--|--|------------------|---|
| Paramphistomatidae | | | |
| <i>Paramphistomum cervi</i> (syn. <i>Paramphistomum explanatum</i>) | Cattle, sheep, goat, deer, buffalo, antelope | Rumen | Freshwater snails (<i>Bulinus</i> spp., <i>Planorbis</i> spp.) |
| <i>Paramphistomum microbothrium</i> | Cattle, sheep, goat, deer, buffalo, antelope | Rumen | Freshwater snails (<i>Fossaria</i> spp., <i>Bulinus</i> spp.) |
| <i>Paramphistomum streptocoelium</i> (syn. <i>Ceylonocotyle streptocoelium</i> , <i>Orthocoelium streptocoelium</i>) | Cattle, sheep, goat and wild ruminants | Rumen | Freshwater snails (<i>Glyptaniscus</i> spp.) |
| <i>Cotylophoron cotylophorum</i> (syn. <i>Paramphistomum cotylophorum</i>) | Sheep, goat, cattle and wild ruminants | Rumen, reticulum | Freshwater snails (<i>Bulinus</i> spp.) |
| <i>Calicophoron calicophorum</i> (syn. <i>Paramphistomum calicophorum</i>) | Cattle, sheep, other ruminants | Rumen, reticulum | Water snails |
| Gastrothylacidae | | | |
| <i>Gastrothylax crumenifer</i> | Cattle, buffalo, zebu, sheep and other ruminants | Rumen, reticulum | Freshwater snails |
| <i>Fiscoederius elongatus</i> | Cattle, buffalo, zebu, sheep and other ruminants; rarely human | Rumen, duodenum | Freshwater snails |
| <i>Fiscoederius cobboldi</i> | Cattle, buffalo, zebu, sheep and other ruminants | Rumen, duodenum | Freshwater snails |

Ostertagia leptospicularis

Synonym: *Ostertagia crimensis*

Morph species: *Skrjabinagia kolchida*, *Ostertagia kolchida*, *Grosspiculagia podjapolskyi*

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: Adults are slender reddish-brown worms with a short buccal cavity. Males measure 6–8 mm and females 8–9 mm in length. Distinguished from other ostertagian species by the length of the oesophagus, which is longer than in other species (0.7 mm compared with approximately 0.6 mm).

Hosts: Fallow deer (*Dama dama*), roe deer (*Capreolus capreolus*), red deer (*Cervus elaphus*), sika deer (*Cervus nippon*), moose (*Alces alces*), reindeer (*Rangifer tarandus*), cattle, sheep, goat, camel

Notes: Considered to be a polymorphic species with two male morphs, *Ostertagia leptospicularis* and *Skrjabinagia kolchida*. For more details see Chapter 1.

Table 14.2 Ostertagian parasites of deer.

| Species | Host |
|--|---|
| <i>Ostertagia ostertagi</i> <i>Ostertagia</i> (syn. <i>Skrjabinagia</i>) <i>lyrata</i> | Cattle, deer and occasionally goat |
| <i>Ostertagia leptospicularis</i> (syn. <i>Ostertagia crimensis</i>) Morph species: <i>Skrjabinagia</i> (<i>Ostertagia</i>) <i>kolchida</i> (syn. <i>Grosspiculagia podjapolskyi</i>) | Deer, cattle, sheep and goat |
| <i>Spiculoptera spiculoptera</i> | Deer (red deer, fallow deer, roe deer), cattle, sheep, goat |
| <i>Spiculoptera asymmetrica</i> | Deer (roe deer, sika deer, fallow deer) |
| <i>Apteragia quadrispiculata</i> | Deer (roe deer, sika deer, fallow deer) |
| <i>Spiculoptera</i> (<i>Apteragia</i>) <i>bohmi</i> Morph species: <i>Spiculoptera</i> (<i>Rinadia</i>) <i>mathevossiani</i> | Mouflon, deer (fallow deer, roe deer) |

Spiculoptera spiculoptera

Synonyms: *Apteragia spiculoptera*, *Rinadia spiculoptera*, *Mazamostrongylus spiculoptera*

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: The spicules are of equal length, bifurcating distally where it contains a cavity and distally ending in a fan-shaped expansion (see Table 1.4g). The gubernaculum is absent.

Host: Red deer (*Cervus elaphus*)

Spiculoptera asymmetrica

Synonyms: *Ostertagia asymmetrica*, *Apteragia asymmetrica*, *Rinadia asymmetrica*, *Mazamostrongylus asymmetrica*

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: Males measure 4.5–6 mm. Spicules are distally asymmetrical and pointed, with a T-shaped offshoot near the distal end of the right spicule. The gubernaculum is small and boat-shaped.

Hosts: Fallow deer (*Dama dama*), roe deer (*Capreolus capreolus*)

Apteragia quadrispiculata

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: Males measure 6–8.5 mm. Spicules possess four branches distally.

Hosts: Roe deer (*Capreolus capreolus*), red deer (*Cervus elaphus*), sika deer (*Cervus nippon*), fallow deer (*Dama dama*), moose (*Alces alces*), reindeer (*Rangifer tarandus*)

Spiculoptergia bohmi

Synonyms: *Apteragia bohmi*, *Rinadia bohmi*

Morph species: *Spiculoptergia mathevossiani*, *Rinadia mathevossiani*

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: Considered to be a polymorphic species with two male morphs, *Spiculoptergia bohmi* and *Spiculoptergia mathevossiani*. Males measure 6–7 mm.

- *Spiculoptergia bohmi*. Spicules of equal size but asymmetrical. The right spicule divides into three branches and the left spicule into two branches (see Table 1.4h). The gubernaculum is absent.
- *Spiculoptergia mathevossiani*. The spicules have asymmetrical distal thirds each ending in three branches. The gubernaculum is absent.

Hosts: Red deer (*Cervus elaphus*), roe deer (*Capreolus capreolus*), sika deer (*Cervus nippon*), fallow deer (*Dama dama*), moose (*Alces alces*), reindeer (*Rangifer tarandus*)

Deer can be infected with other species of abomasal nematodes found in cattle and sheep (Table 14.3). Detailed descriptions of these nematode species can be found in Chapter 1 or in Chapters 8 and 9.

Pathogenesis: Worm burdens in deer are generally light with lesions in the abomasum resembling those of ostertagiosis in cattle. Clinical disease is uncommon in free-ranging deer and occurs uncommonly in captive animals.

Table 14.3 Cattle and sheep nematodes found in the abomasa of deer.

| Species | Superfamily | Hosts | Geographical distribution |
|---|---------------------|--|---|
| <i>Ostertagia ostertagi</i> <i>Ostertagia lyrata</i> | Trichostrongyloidea | Cattle, deer and occasionally goat | Worldwide |
| <i>Teladorsagia circumcincta</i> | Trichostrongyloidea | Sheep, goat, deer, camel, llama | Worldwide |
| <i>Haemonchus contortus</i> | Trichostrongyloidea | Sheep, goat, cattle, deer, camel, llama | Worldwide |
| <i>Trichostrongylus axei</i> | Trichostrongyloidea | Cattle, sheep, goat, deer, horse, donkey, pig and occasionally human | Worldwide |
| <i>Parabronema skrjabini</i> | Spiruroidea | Sheep, goat, cattle, camel | Central and East Africa, Asia, and some Mediterranean countries, notably Cyprus |

Treatment and control: Both benzimidazoles and macrocyclic lactones have been shown to be effective against gastrointestinal nematodes in deer. For most anthelmintics, the dose rate in deer is that recommended for cattle or higher.

Intestines

A number of intestinal species have been reported in deer (Table 14.4) but are generally of little clinical significance. The majority of these are parasites of cattle or sheep and are described in more detail in Chapters 8 and 9 for these hosts.

A range of protozoa similar to those present in domesticated ruminants is found in the intestine of deer. Similarly, several species of *Eimeria* have been reported in various species of deer but their significance is not known (Table 14.5). Reported species of *Eimeria* may be synonymous and host specificity between species is unknown due to lack of cross-transmission studies.

Parasites of the respiratory system

Cephenemyia trompe

Common name: Reindeer throat bot

Predilection site: Nasopharynx

Class: Insecta

Family: Oestridae

Description, gross: The adult is bee-like in appearance, 14–16 mm in length and covered in long yellowish and black hairs overlying a shining black body. Developing larvae are white, while fully developed larvae are about 25–40 mm long and yellow–brown. The entire larval body is covered by bands of short spines on both sides and narrows posteriorly.

Hosts: Reindeer, deer, moose and caribou

Geographical distribution: Throughout the northern Holarctic region including Europe and North America

Pathogenesis: Although the larvae occasionally cause death from suffocation, their general effect is loss of condition. The adult flies cause disturbance and avoidance responses, which reduce feeding and result in loss of condition. In summer, keratitis and blindness may occur in reindeer if larvae are deposited in the eye.

Clinical signs: There are few external signs of the presence of deer nose bots, although there may be some nasal discharge. Occasionally, heavy infections may cause death by suffocation. Behaviour such as snorting and lowering or shaking of the head may indicate the migration of mature larvae within the nasal passages or oviposition activity of the adult fly.

Diagnosis: Occasionally a larva may be found on the ground after a severe sneezing attack, but often a positive diagnosis can only be made at necropsy.

Pathology: The retropharyngeal pouch may be enlarged and the epithelium of the pouch may be pitted or eroded and become partly detached, necrotic and oedematous in infected deer.

Table 14.4 Intestinal parasites in deer.

| Species | (Super)family | Hosts | Geographical distribution |
|---|---------------------|---|---|
| Small intestine | | | |
| <i>Trichostrongylus vitrinus</i> | Trichostrongyloidea | Sheep, goat, deer and occasionally pig and human | Mainly temperate regions of the world |
| <i>Trichostrongylus longispicularis</i> | Trichostrongyloidea | Cattle, sheep, goat, deer, camel, llama | Ruminants in Australia; and cattle in America and parts of Europe |
| <i>Nematodirus spathiger</i> | Trichostrongyloidea | Sheep, goat, occasionally cattle and other ruminants | Cosmopolitan, but more prevalent in temperate zones |
| <i>Nematodirus filicollis</i> | Trichostrongyloidea | Sheep, goat, occasionally cattle and deer | Cosmopolitan, but more prevalent in temperate zones |
| <i>Cooperia curticei</i> | Trichostrongyloidea | Sheep, goat, deer | Worldwide |
| <i>Cooperia onchophora</i> | Trichostrongyloidea | Cattle, sheep, goat, deer | Worldwide |
| <i>Cooperia punctata</i> | Trichostrongyloidea | Cattle, deer | Worldwide |
| <i>Cooperia pectinata</i> | Trichostrongyloidea | Cattle, deer | Worldwide |
| <i>Bunostomum trigonocephalum</i> | Ancylostomatoidea | Sheep, goat, camel, deer | Worldwide |
| <i>Capillaria bovis</i> (syn. <i>C. brevipes</i>) | Trichuroidea | Cattle, sheep, goat, deer | Worldwide |
| <i>Moniezia benedeni</i> | Anoplocephalidae | Cattle, red deer, roe deer, camel Intermediate hosts: forage mites | Worldwide |
| Large intestine | | | |
| <i>Oesophagostomum venulosum</i> | Strongyloidea | Sheep, goat, deer, camel | Worldwide |
| <i>Oesophagostomum columbianum</i> | Strongyloidea | Sheep, goat, deer, camel | Worldwide; more important in tropical and subtropical areas |
| <i>Chabertia ovina</i> | Strongyloidea | Sheep, goat, occasionally deer, cattle and other ruminants | Worldwide but more prevalent in temperate regions |
| <i>Trichuris ovis</i> | Trichuroidea | Sheep, goats, occasionally cattle and other ruminants | Worldwide |
| <i>Trichuris globulosa</i> | Trichuroidea | Cattle, occasionally sheep, goats, camels and other ruminants | Worldwide |
| <i>Trichuris capreoli</i> | Trichuroidea | Deer | ? |
| <i>Skrjabinema parva</i> | Oxyuroidea | Deer (white-tailed) | North America |

Epidemiology: *Cephenemyia trompe* is considered a serious problem in domestic reindeer management in Scandinavia. It is estimated that in Sweden the losses due to *C. trompe* and the warble fly *Oedemagena tarandi* equate to approximately 15% of the income from reindeer production.

Treatment: Nose bots are generally well tolerated in wild hosts and treatment is not usually required.

Other species of bot flies in deer are listed in Table 14.6.

Dictyocaulus viviparus

Predilection site: Bronchi, trachea

Phylum: Nematoda

Table 14.5 *Eimeria* spp. of deer.

| Roe deer (<i>Capreolus capreolus</i>) | Red deer/wapiti (<i>Cervus elaphus</i>) | Reindeer (<i>Rangifer tarandus</i>) |
|---|---|---------------------------------------|
| <i>Eimeria capreoli</i> | <i>Eimeria asymmetrica</i> | <i>Eimeria arctica</i> |
| <i>Eimeria catubrina</i> | <i>Eimeria austriaca</i> | <i>Eimeria mayeri</i> |
| <i>Eimeria panda</i> | <i>Eimeria cervi</i> | <i>Eimeria tarandi</i> |
| <i>Eimeria patavina</i> | <i>Eimeria elaphi</i> | |
| <i>Eimeria ponderosa</i> | <i>Eimeria robusta</i> | |
| <i>Eimeria rotunda</i> | <i>Eimeria sordida</i> | |
| <i>Eimeria superba</i> | <i>Eimeria wapiti</i> | |

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: The adults are slender thread-like worms; males measure around 4.0–5.5 cm and females 6–8 cm in length. The buccal ring is triangular in shape. First-stage larvae are 300–360 µm with the intestinal cells containing numerous chromatin granules (see Fig. 1.36).

Hosts: Cattle, buffalo, deer (red deer) and camel

Geographical distribution: Worldwide, but especially important in temperate climates with a high rainfall

Pathogenesis: Larval migration produces only a mild inflammatory response in the lungs. Thus, larger numbers of immature worms

Table 14.6 Other species of bot flies (Family Oestridae) in deer.

| Genus | Species | Host (s) | Region |
|---------------------|-------------------|---|-----------------------|
| <i>Pharyngomyia</i> | <i>picta</i> | Red deer (<i>Cervus elaphus</i>), sika deer (<i>Cervus nippon</i>), fallow deer (<i>Dama dama</i>), roe deer (<i>Capreolus capreolus</i>) | Europe, Central Asia |
| <i>Cephenemyia</i> | <i>auribarbis</i> | Red deer (<i>Cervus elaphus</i>), fallow deer (<i>Dama dama</i>), mule deer, white-tailed deer (<i>Odocoileus</i> spp.) | Europe, North America |
| | <i>phobifer</i> | Mule deer (<i>Odocoileus hemionus</i>) | North America |
| | <i>jellisoni</i> | Moose (<i>Alces alces</i>), elk (<i>Cervus elaphus</i>) | North America |
| | <i>stimulator</i> | Roe deer (<i>Capreolus capreolus</i>) | Eurasia |

reach the pulmonary bronchi and heavy burdens of mature worms are well tolerated.

Clinical signs: In contrast with *D. viviparus* infection in cattle, coughing is not a common sign of affected red deer. Clinical signs commonly associated with lungworm infection are loss of condition, dull coat as well as inappetence, reduced weight gains, fever, tachycardia and tachypnoea, dyspnoea and death in severe cases.

Diagnosis: Presumptive diagnosis of infection can be made on clinical signs if young susceptible deer develop respiratory problems or inappetence. On postmortem examination, the diagnosis is confirmed by finding large numbers of lungworms and mucus in pulmonary airways and pneumonic changes in the lungs. Mature *D. viviparus* infection can be detected by recovery of first-stage larvae from faecal samples by the Baermann technique (see Chapter 4).

Pathology: Gross pathological changes in lungs include consolidation of the dorsal portion of the diaphragmatic lobes, excess mucus and lungworms in the trachea, bronchi and bronchioles, and enlarged bronchial lymph nodes. Death results from asphyxiation due to obstruction of the trachea and bronchi with adult lungworms and mucus.

Epidemiology: Clinical disease is more prevalent in autumn in deer calves kept under intensive conditions. The prepatent period in red deer is 20–24 days and larvae are excreted for approximately 25 days.

Treatment: Benzimidazole anthelmintics and macrocyclic lactones are generally effective at increased dose rates.

Control: The importance and widespread occurrence of *D. viviparus* infection in farmed red deer has prompted a number of recommendations for its control. Clinical disease is exacerbated by stressors such as malnutrition and transport and is often associated with high stocking densities. These conditions should be avoided as should allowing deer to graze pasture previously grazed by cattle. Any introduced deer should be treated on arrival and then 3 and 6 weeks later. Live lungworm vaccine has been used as a preventive.

Dictyocaulus eckerti

Synonym: *Dictyocaulus noerneri*

Predilection site: Bronchi, trachea

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: Similar to *D. viviparus*. The mouth opening is elongate and the buccal ring is kidney-shaped.

Hosts: Roe deer (*Capreolus capreolus*), fallow deer (*Dama dama*) and various other deer

Geographical distribution: Worldwide, but especially important in temperate climates with high rainfall

Dictyocaulus capreolus

Predilection site: Bronchi, trachea

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: Similar to *D. eckerti*. This species is distinguished from *D. eckerti* on the basis of the morphology of the buccal capsule and the bursa.

Hosts: Roe deer (*Capreolus capreolus*), moose (*Alces alces*)

Geographical distribution: Europe

Varestrongylus sagittatus

Synonym: *Bicaulus sagittatus*

Common name: Small lungworm

Predilection site: Lung

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description: Adult worms are slender small worms, 14–34 mm long.

Final hosts: Red deer (*Cervus elaphus*), fallow deer (*Dama dama*)

Intermediate hosts: Slugs and snails

Geographical distribution: Europe

Pathogenesis and clinical signs: Infection can cause pulmonary oedema, emphysema and inflammation of the lungs. Secondary bacterial infection can lead to pneumonia, emaciation and death.

Diagnosis: *Varestrongylus* first-stage larvae have a dorsal, posteriorly directed spine.

Treatment: Treatment with fenbendazole or mebendazole given over 3–5 days has been reported to be effective.

Varestrongylus capreoli

Synonym: *Capreocaulus capreoli*

Predilection site: Lung

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Final hosts: Roe deer (*Capreolus capreolus*)

All other details similar to *V. sagittatus*.

The following metastrongylid parasites have also been reported in the lungs of various deer hosts. Control is impractical and rarely, if ever, indicated. For more details of these species see Chapter 9.

Protostrongylus rufescens

Common name: Small lungworm

Predilection site: Small bronchioles

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description: Male worms are up to 4.5 cm and females up to 6.5 cm. In the male, the bursa is well developed but small and reinforced by two chitinous plates. The dorsal ray is thick and globular in shape with six papillae on the ventral side. The tubular spicules are almost straight; the distal ends bear two membraneous alae. The gubernaculum has two boot-shaped prolongations bearing several knobs posteriorly. A telamon is also present. In the female, the vulva is close to the conoid tail.

Final hosts: Sheep, goat, deer and wild small ruminants

Intermediate hosts: Snails (*Helicella*, *Theba*, *Abida*, *Zebrina*, *Arianta*)

Muellerius capillaris

Common name: Nodular lungworms

Predilection site: Lung

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description: Males are 12–14 mm and females 19–25 mm long. The posterior end of the adult male is spirally coiled and the bursa is very small and folded inwards. The curved spicules consist of a proximal alate region and two distal serrated arms, which terminate in points. Two sclerotised rods represent the gubernaculum.

Final hosts: Sheep, goat, deer and wild small ruminants

Intermediate hosts: Snails (*Helix*, *Succinea*) and slugs (*Limax*, *Agriolimax*, *Arion*)

Cystocaulus ocreatus

Common name: Small lungworm

Predilection site: Lung

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description: Male worms are around 4–5 cm and females up to 9 cm long. In the male, the bursa is small; the spicules consist of a proximal cylindrical region joined distinctly to a distal lance-shaped region. The gubernaculum has a complex structure, with the posterior part consisting of two pointed boot-shaped structures. In the female, the vulva is protected by a bell-shaped expansion of the cuticle.

Final hosts: Sheep, goat, deer and wild small ruminants

Intermediate hosts: Snails (*Helicella*, *Helix*, *Theba*, *Cepaea*, *Monacha*)

Geographical distribution: Worldwide

Echinococcus granulosus

For more details see Parasites of the liver.

Parasites of the liver

Fascioloides magna

Common name: Large American liver fluke

Predilection site: Liver and bile ducts

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description: Flukes are large and thick and measure up to 10 by 2.5 cm. The flukes are oval, with a rounded posterior end. They possess no anterior cone and when fresh are flesh-coloured (see Fig. 1.72). In deer, adult *F. magna* occur in cysts which communicate with the bile ducts.

Description, microscopic: Eggs are large, operculate, measure 109–168 by 75–96 µm and have a protoplasmic appendage at the pole opposite the operculum.

Final hosts: Deer (particularly white-tailed deer), cattle, sheep, goat, pig, horse, llama

Intermediate hosts: A variety of freshwater snails: *Fossaria* spp., *Lymnaea* spp., *Stagnicola* spp.

Geographical distribution: Mainly occurs in North America, central, eastern and southwestern Europe, South Africa and Mexico

Pathogenesis: In deer (and cattle), the flukes are frequently encapsulated in thin-walled fibrous cysts in the liver parenchyma and this restricted migration results in low pathogenicity.

Clinical signs: In deer and cattle the parasites can cause hepatic damage on reaching the liver but the flukes rapidly become encapsulated by the host reaction and clinical signs are minimal.

Diagnosis: This is based primarily on clinical signs. The presence of cysts and the large flukes are usually seen on postmortem examination. Faecal examination for the presence of fluke eggs is a useful aid to diagnosis.

Pathology: In deer, encapsulated thin-walled fibrous cysts are found in the liver parenchyma.

Epidemiology: The various snail intermediate hosts tend to occur in stagnant semi-permanent water that contains large amounts of dead or dying vegetation, swamp areas, or pools and streams. *Fascioloides magna* is indigenous to North America and is common in Canada and the Great Lake areas where the white-tailed deer and the elk are commonly infected.

Treatment: For cattle and sheep, the commonly used flukicides such as triclabendazole, closantel, clorsulon and albendazole are effective. Mature *F. magna* are susceptible to oxiclosanide.

Control: Elimination of the snail intermediate hosts is difficult due to their varied habitats.

Notes: *Fascioloides magna* is primarily a parasite of deer (Cervidae) and is commonly found in white-tailed deer, elk and moose.

Fasciola hepatica**Common name:** Liver fluke**Predilection site:** Liver**Phylum:** Platyhelminthes**Class:** Trematoda**Family:** Fasciolidae

Description: Adult fluke are leaf-shaped (being broader anteriorly than posteriorly), grey-brown in colour and are around 2.5–3.5 cm in length and 1.0 cm in width (see Fig. 1.70a). The anterior end is conical and marked off by distinct shoulders from the body. The tegument is covered with backwardly projecting spines. An oral and ventral sucker, situated at the level of the shoulders, may be readily seen. The intestinal caeca have many branches and extend a considerable distance posteriorly. The testes and ovary are multi-branched. The uterus is positioned anterior to the testes. The cirrus is well developed. Immature fluke at the time of entry into the liver are 1.0–2.0 mm in length and lancet-like.

Final hosts: Sheep, cattle, goat, horse, deer, human and other mammals**Intermediate hosts:** Snails of the genus *Galba* (*Lymnaea*). The most common, *Galba* (syn. *Lymnaea*) *truncatula*, is an amphibious snail with a wide distribution throughout the world.**Geographical distribution:** Worldwide***Fasciola gigantica*****Common name:** Tropical large liver fluke**Predilection site:** Liver**Phylum:** Platyhelminthes**Class:** Trematoda**Family:** Fasciolidae

Description: The adult fluke is larger than *F. hepatica*, the body is more transparent, and can reach 7.5 cm in length and 1.5 cm in breadth (see Fig. 1.70b). The shape is more leaf-like, the conical anterior end is very short and the shoulders, characteristic of *F. hepatica*, are barely perceptible.

Final hosts: Cattle, buffalo, sheep, goat, pig, camel, deer, human**Intermediate hosts:** Snails of the genus *Galba* (syn. *Lymnaea*); in southern Europe it is *L. auricularia*, which is also the important species in the southern USA, the Middle East and the Pacific Islands.**Geographical distribution:** Africa, Asia, Europe, USA***Dicrocoelium dendriticum*****Synonym:** *Dicrocoelium lanceolatum***Common name:** Small lanceolate fluke**Predilection site:** Liver**Phylum:** Platyhelminthes**Class:** Trematoda**Family:** Dicrocoeliidae

Description: Adult fluke are 6–12 mm long and 1.5–2.5 mm wide, distinctly lanceolate and semi-transparent/translucent, allowing the internal organs to be readily seen (see Fig. 1.74). They are almost symmetrical in shape and the cuticle is smooth. The oral sucker is smaller than the ventral sucker and is located in close proximity. The gut is simple, consisting of two branches and resembles a tuning fork. Behind the ventral sucker the lobed testes lie in tandem with the ovary immediately posterior. The uterus is usually dark brown and convoluted, filling the space behind the genital gland. The cirrus is small. There are no spines on the cuticle (cf. *Fasciola*).

Final hosts: Sheep, goat, cattle, deer and rabbit, occasionally horse and pig**Intermediate hosts:** Two are required:

- 1 Land snails of many genera, principally *Cionella lubrica* in North America and *Zebrina detrita* in Europe. Some 29 other species have been reported to serve as first intermediate hosts of the genera *Abida*, *Theba*, *Helicella* and *Xerophila*.
- 2 Brown ants of the genus *Formica*, frequently *F. fusca*.

Geographical distribution: Worldwide except for South Africa and Australia. In Europe the prevalence is high but in the British Isles prevalence is low, being confined to small foci throughout the country.***Dicrocoelium hospes*****Predilection site:** Liver**Phylum:** Platyhelminthes**Class:** Trematoda**Family:** Dicrocoeliidae**Hosts:** Cattle and deer**Geographical distribution:** Parts of Africa**Notes:** Details are essentially similar to *D. dendriticum*.***Stilesia hepatica*****Predilection site:** Bile ducts**Phylum:** Platyhelminthes**Class:** Cestoda**Family:** Anoplocephalidae

Description: The adult tapeworm measures 20–50 cm long by 2–3 mm in width. The neck is narrow and the scolex is large with prominent suckers. The genital organs are single and the opening pores alternate irregularly. There are 10–12 testes on either side lying dorsal to the ventral canal. The proglottids are short.

Final hosts: Sheep, deer and other ruminants**Intermediate hosts:** The intermediate host is probably an oribatid mite.**Geographical distribution:** Africa and Asia

For more details of these species see Chapters 8 and 9.

Taenia hydatigena

Synonyms: *Taenia marginata*, *Cysticercus tenuicollis*

Predilection site: Abdominal cavity, liver (intermediate hosts); small intestine (definitive hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description: The mature metacestode (*Cysticercus tenuicollis*) is about 5–8 cm in diameter and contains a single invaginated scolex (bladderworm) with a long neck.

Final hosts: Dog, fox, weasel, stoat, polecat, wolf, hyena

Intermediate hosts: Sheep, cattle, deer, pig, horse

Echinococcus granulosus

Common names: Dwarf dog tapeworm, hydatidosis

Predilection site: Mainly liver and lungs (intermediate hosts); small intestine (definitive host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description: Hydatid cysts are large fluid-filled vesicles 5–10 cm in diameter, with a thick concentrically laminated cuticle and an internal germinal layer (see Figs 9.44 and 9.45).

Final hosts: Dog and many wild canids

Intermediate hosts: Domestic and wild ruminants, deer, human and primates, pig and lagomorphs; horses and donkeys are resistant.

Geographical distribution: Worldwide

For more details of these species see Chapter 9.

Parasites of the circulatory system***Babesia bovis***

Synonym: *Babesia argentina*

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: *Babesia bovis* is a small pleomorphic babesia, typically identified as a single body, as small round bodies, or as paired pear-shaped bodies joined at an obtuse angle within the centre of the mature erythrocyte. The round forms measure 1–1.5 µm and the pear-shaped bodies 1.5 by 2.4 µm in size. Vacuolated signet-ring forms are especially common.

Hosts: Cattle, buffalo, deer (roe deer, red deer)

Geographical distribution: Australia, Africa, Central and South America, Asia and southern Europe

For more details see Chapter 8.

Babesia jakimovae

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: *Babesia jakimovae* is round and pyriform and measures 2.6 by 1.5 µm in size.

Hosts: Cattle, deer (roe deer, elk, reindeer)

Geographical distribution: Northern Europe (Siberia)

Theileria cervi

Synonym: *Theileria tarandi*

Predilection site: Blood, lymph nodes

Phylum: Apicomplexa

Class: Aconoidasida

Family: Theileriidae

Hosts: Fallow deer, red deer, sika deer, white-tailed deer, reindeer

Notes: Little information is available on this species.

Anaplasma marginale

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: In Giemsa-stained blood films the organisms of *A. marginale* are seen as small, round, dark-red ‘inclusion bodies’ approximately 0.3–1.0 µm within the red cell (see Fig. 8.39). Often there is only one organism in a red cell and characteristically this lies at the outer margin; however, these two features are not constant.

Hosts: Cattle, wild ruminants

Geographical distribution: Africa, southern Europe, Australia, South America, Asia, former Soviet States and USA

Anaplasma centrale

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: As for *A. marginale*, except that the organisms are commonly found in the centre of the erythrocyte.

Hosts: Cattle, deer, wild ruminants, and perhaps sheep, may act as reservoirs of infection.

Geographical distribution: Africa, southern Europe, Australia, South America, Asia, former Soviet States and USA

For more details of these species see Chapter 8.

Parasites of the nervous system

Elaphostrongylus cervi

Synonym: *Elaphostrongylus rangiferi*

Predilection site: Connective tissue, central nervous system (CNS)

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description: The mature worms are long and slender. Males are up to 40 mm and females up to 60 µm long. First-stage larvae have a dorsal spine on the tail and measure 395–440 µm in length.

Final hosts: Red deer (*Cervus elaphus*), roe deer (*Capreolus capreolus*), sika deer (*Cervus nippon*)

Intermediate hosts: Various land and freshwater snails and slugs

Life cycle: Female worms lay eggs that either hatch *in situ* or are carried to the lungs via the bloodstream and then hatch. Larvae migrate through the lungs to the airways and are then swallowed and pass out in the faeces. The larvae may survive in the environment for up to 2 years before infecting a molluscan intermediate host. The parasites develop through the second-stage larvae to the infective third-stage larvae in the mollusc within 27–50 days and can retain their infectivity for up to another 2 years. Deer become infected when they ingest snails containing infective larvae. After ingestion, the larvae burrow through the gut wall and migrate to the final tissue site, at the same time developing into adult worms. The prepatent period is about 112 days.

Geographical distribution: *Elaphostrongylus cervi* is present in most countries of northern and central Europe and the CIS states. It is also present in New Zealand.

Pathogenesis: The severity of clinical disease is very much influenced by the level of infection and location in the body. Light infections are usually subclinical. Three clinical syndromes are described:

- acute disease characterised by hindlimb paralysis and perhaps blindness resulting from damage to the CNS;
- chronic ill-thrift, resulting from connective tissue damage;
- verminous pneumonia, resulting from larval migration.

Additionally, there may be economic losses through trimming, downgrading or condemnation of carcasses.

Clinical signs: Most infections are inapparent. Clinical signs include exercise intolerance, hindlimb incoordination and nervous disorders.

Diagnosis: Diagnosis is based on finding the infective larvae in faeces using the Baermann method. The first-stage larvae have a characteristic dorsal spine on their tails and look very like the protostrongylid larvae of *Muellerius* spp. that infest sheep.

Pathology: Connective tissue lesions are most likely to be found in the muscles of the neck, shoulders, flanks and loins. These consist of green discoloration of fascial sheets, and chronic granulomas with encapsulated degenerated worms. Similar lesions may be seen in regional lymph nodes. Worms associated with CNS lesions are most likely to be seen in the subdural and subarachnoid spaces. Pulmonary lesions consist of a diffuse interstitial pneumonia with focal emphysema and consolidation.

Epidemiology: This parasite affects a number of deer species and the prevalence of infection is generally high in both wild and farmed deer.

Treatment and control: Fenbendazole given on three consecutive days has been reported to be effective. Control is difficult given the ubiquitous nature of the intermediate hosts.

Parelaphostrongylus tenuis

Synonyms: *Odocoileostrongylus tenuis*, *Elaphostrongylus tenuis*

Common names: Cerebrospinal nematodosis, meningeal worm, moose sickness, moose disease

Predilection site: Veins and venous sinuses of cranial meninges, CNS

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description: The mature worms are long and thread-like; males are up to 40 mm and females up to about 90 mm long. First-stage larvae have a dorsal spine on the tail and measure about 350 µm.

Final hosts: White-tailed deer (*Odocoileus virginianus*) is the principal host but moose (*Alces alces*), wapiti (*Cervus canadensis*), other deer species, llama, guanaco, alpaca and camels can be infected. *Parelaphostrongylus tenuis* has been reported rarely in sheep and goats.

Intermediate hosts: Snails and slugs

Life cycle: Unembryonated eggs are released into the bloodstream and travel to the lungs where they lodge in the capillaries and complete their development to L₁ before moving to the alveoli from where they are coughed up and swallowed and passed in the faeces. To develop further they must penetrate or be eaten by a slug or snail. In the foot of the snail the larvae develop through the second-stage larvae to the infective third-stage larvae. Deer become infected when they accidentally ingest slugs or snails containing infective larvae. After ingestion, the larvae burrow through the gut wall and migrate to the CNS via the spinal nerves and spinal cord, at the same time developing into adult worms. The prepatent period is about 82–137 days.

Pathogenesis: In the white-tailed deer the parasite causes little clinical effect but in other cervids and camelids (and in sheep and goats) can cause debilitating neurological signs and in North America is the causative agent of ‘moose sickness’. Llamas and their relatives are susceptible to *P. tenuis*.

Clinical signs: Signs of infection are rare in white-tailed deer. Infected moose may show swaying, paraparesis, torticollis, circling, blindness, ataxia, paresis, difficulty in standing, weight loss and death. In red deer (wapiti), there is progressive neurological disease and death.

Diagnosis: Diagnosis is based on finding adult worms in the CNS. *Parelaphostrongylus tenuis* does not normally mature in the abnormal hosts and larvae will not be present in faeces.

Epidemiology: *Parelaphostrongylus tenuis* is a common parasite of white-tailed deer in North America. Infection occurs in moose that share the same range as white-tailed deer.

Treatment and control: Not practical. Strict management of national and international deer translocations should be practised wherever possible.

Parasites of the reproductive/urogenital system

No parasites of veterinary significance reported.

Parasites of the locomotory system

Taenia ovis

Synonyms: *Taenia cervi*, *Taenia krabbei*, *Taenia hyenae*, *Cysticercus ovis*, *Cysticercus cervi*, *Cysticercus tarandi*, *Cysticercus dromedarii*, *Cysticercus cameli*

Predilection site: Small intestine (definitive host); muscle (intermediate host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description: Each cysticercus occurs within a small cyst measuring about 4 mm or less in length.

Final hosts: Dog, fox, wild carnivores

Intermediate hosts: Sheep, goat (*Cysticercus ovis*); deer (*Cysticercus cervi*); reindeer (*Cysticercus tarandi*); camel (*Cysticercus dromedarii*, *Cysticercus cameli*)

Life cycle: Wild canids are infested by consuming the cysticercus in the intermediate host. The intermediate host is infected through the ingestion of tapeworm eggs that hatch in the intestine.

Geographical distribution: Worldwide

Pathogenesis: Cysticerci may cause economic loss through condemnation at meat inspection.

Clinical signs: Infected intermediate hosts do not usually show clinical signs of disease.

Diagnosis: Diagnosis is through the identification of cysts at postmortem.

Pathology: The mature, ovoid, white cysticerci are grossly visible in the muscle, heart, lung, liver and brain.

Epidemiology: Deer are infected by grazing pasture and forages contaminated with carnivore faeces harbouring taenid eggs.

Treatment and control: Control is not practical.

Notes: The correct nomenclature for the intermediate host stage is ‘metacestode stage of *Taenia ovis*’ rather than ‘*Cysticercus ovis*’. It is now thought that *Taenia cervi*, which is found mainly in red deer and roe deer, and *Taenia krabbei*, found mainly in reindeer, are synonymous with *T. ovis*, and that they are one and the same species present in different hosts.

Sarcocystosis

Several species of *Sarcocystis* have been reported in deer (Table 14.7). Specific descriptions are outwith the scope of this book. As with cattle and sheep, infections are only diagnosed at postmortem or on histology when the sarcocysts in muscle are discovered (Fig. 14.1).

Table 14.7 *Sarcocystis* species found in deer.

| Species | Deer host(s) | Final hosts | Distribution |
|----------------------------------|---|--|-----------------------|
| <i>Sarcocystis cervicanis</i> | Red deer (<i>Cervus elaphus</i>) | Dog | Europe |
| <i>Sarcocystis grueneri</i> | Red deer (<i>Cervus elaphus</i>), reindeer (<i>Rangifer tarandus</i>) | Dog, fox (<i>Vulpes vulpes</i>), coyote (<i>Canis latrans</i>) | Eurasia |
| <i>Sarcocystis wapiti</i> | Red deer (<i>Cervus elaphus</i>), roe deer (<i>Capreolus capreolus</i>) | Dog, coyote (<i>Canis latrans</i>) | North America |
| <i>Sarcocystis sybillensis</i> | Red deer (<i>Cervus elaphus</i>), roe deer (<i>Capreolus capreolus</i>) | Dog | North America |
| <i>Sarcocystis hofmani</i> | Red deer (<i>Cervus elaphus</i>), roe deer (<i>Capreolus capreolus</i>), fallow deer (<i>Dama dama</i>), sika deer (<i>Cervus nippon</i>) | Dog, raccoon dog (<i>Nyctereutes procyonoides</i>) | Eurasia |
| <i>Sarcocystis capreolicanis</i> | Roe deer (<i>Capreolus capreolus</i>) | Dog, fox (<i>Vulpes vulpes</i>) | Europe |
| <i>Sarcocystis gracilis</i> | Roe deer (<i>Capreolus capreolus</i>) | Dog, fox (<i>Vulpes vulpes</i>) | Eurasia |
| <i>Sarcocystis rangi</i> | Reindeer (<i>Rangifer tarandus</i>) | Dog | Europe |
| <i>Sarcocystis tarandivulpis</i> | Reindeer (<i>Rangifer tarandus</i>) | Dog, fox (<i>Vulpes vulpes</i>), raccoon dog (<i>Nyctereutes procyonoides</i>) | Europe |
| <i>Sarcocystis tarandi</i> | Reindeer (<i>Rangifer tarandus</i>) | Unknown | Europe |
| <i>Sarcocystis rangiferi</i> | Reindeer (<i>Rangifer tarandus</i>) | Unknown | Europe |
| <i>Sarcocystis alceslatrans</i> | Moose (<i>Alces alces</i>) | Dog, coyote (<i>Canis latrans</i>) | North America, Europe |
| <i>Sarcocystis jorrini</i> | Fallow deer (<i>Dama dama</i>) | | Europe |

Fig. 14.1 Sarcocysts in the heart muscle of a red deer (*Cervus elaphus*).

Parasites of the connective tissue

Elaeophora schneideri

Common names: Filarial dermatosis, 'sore head'

Predilection site: Blood vessels

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description: Slender worms; males are around 5–8 cm and females up to 12 cm long with a very long oesophagus. The tail of the male is coiled and the spicules are long, slender and unequal.

Final hosts: Sheep, goat, deer (elk, moose, mule deer)

Intermediate hosts: Tabanid flies

Geographical distribution: Western and southern USA

Pathogenesis: It is thought that the natural hosts of *E. schneideri* are deer, in which the infection is asymptomatic.

For more details see Chapter 9.

Hypoderma diana

Common name: Warble fly

Predilection site: Subcutaneous skin

Class: Insecta

Family: Oestridae

Description, adults: Adult female *Hypoderma diana* are about 15 mm in length and bee-like in appearance; the abdomen is covered with yellow–orange hairs with a broad band of black hairs around the middle. The adults have no functioning mouthparts.

Description, larvae: The mature larvae are thick and somewhat barrel-shaped, tapering anteriorly. When mature they are 25–30 mm in length and most segments bear short spines. Larvae are dirty white in colour when newly emerged from the host, but rapidly turn dark brown. The pupa is almost black. The larvae are relatively host-specific and live as subcutaneous parasites of deer.

Hosts: Deer, occasionally horse, sheep

Geographical distribution: Northern hemisphere

Pathogenesis: The fly is most active in May and June, but it is not recognised as a cause of 'gadding' in deer. The mature larvae occur subcutaneously along the back, and hide damage occurs with linear perforations.

Clinical signs: Except for poor growth in severe cases, the hosts show no symptoms until the larvae appear along the back, when the swellings can be seen and felt. The larval migration is not usually noticed clinically, but heavy infestations may reduce growth. Occasionally the pressure of larvae on the spinal cord can cause paralysis. When the larvae reach the skin on the animal's back, large, soft, painful swellings of up to 3 mm in diameter develop. The larvae lie in cysts containing yellow purulent fluid.

Diagnosis: The presence of the larvae under the skin of the back of deer allows diagnosis of warble flies. The eggs may also be found on the hairs of the animals in the summer.

Pathology: Warble larvae induce a pronounced tissue inflammation. The cellular reaction is predominantly eosinophilic and lymphocytic. The presence of the larvae also induces the production of a thickened connective-tissue lined cavity, surrounding the larva, filled with inflammatory cells, particularly eosinophils.

Epidemiology: *Hypoderma diana* is present in a great variety of habitats, overlapping the territory of its hosts. It is spread throughout Europe and Asia, from 30° to 60° N, living in several different ecological zones, such as mixed, deciduous and coniferous forests, wooded steppes and wetlands. The adult fly is most active in May and June, particularly on warm sunny days. The main factors influencing the flight and oviposition of female flies are ambient air temperature and light, as a result of which they are most active at midday. As in other species, the extent of parasitism and prevalence are higher in younger animals, possibly due to a measure of resistance in adults built up through repeated contact with the parasite. The degree of parasitism in male deer is usually higher than in females and castrated animals.

Treatment: Like other species, *H. diana* is highly susceptible to systemically active organophosphate insecticides and to the macrocyclic lactones ivermectin, doramectin, eprinomectin and moxidectin.

Control: For farm-raised deer a control programme may be implemented, with regular treatment timed in relation to the local population dynamics of *Hypoderma*. Animals may be given some protection by being herded into corrals, shelters or shaded areas to reduce the risk of infestation when adult flies are active.

It is more difficult to develop effective control measures for diseases in wild and semi-wild deer. Here it is important that any attempted parasite controls do not have an effect on the environment in which the animals live. For free-range deer that cannot be captured, food may be supplemented with oral forms of antiparasitic preparations. However, care must be taken in selecting a suitable food medium for the antiparasitic agent, since it cannot be freely distributed around the environment because it may be eaten by other animals; neither can the volume ingested be controlled.

Notes: With the success of control measures against warbles in cattle it is important to realise that *H. diana*, although capable of infecting many species of deer, will not infect cattle. As a consequence of this, even in areas where (as is commonly the case) almost all the deer carry the parasitic larvae, cattle are not at risk.

Hypoderma tarandi

Synonym: *Oedemagena tarandi*

Common name: Reindeer warble

Predilection site: Subcutaneous connective tissue

Class: Insecta

Family: Oestridae

Description: Large hairy flies with reddish-yellow hairy abdomens. Mature, third-stage larvae are approximately 25 mm in length.

Hosts: Reindeer, musk ox and caribou

Geographical distribution: Circum-arctic and sub-arctic regions of Europe, Asiatic Russia and America

Pathogenesis: The adult flies cause gadding, and the newly hatched larvae may cause dermatitis with local oedema when they penetrate the skin. However, the main importance of this genus is economic, from damage to hides by the L₃. In Sweden this loss can amount to one-fifth of the total income from reindeer herds. Up to 200 holes may be found in typically infested reindeer skins in Russia.

Clinical signs: Except for poor growth in severe cases, the hosts show no symptoms until the larvae appear along the back, when the swellings can be seen and felt. The larval migration is not usually noticed clinically, but heavy infestations may reduce growth. Occasionally the pressure of larvae on the spinal cord can cause paralysis. When the larvae reach the skin on the animal's back, large, soft, painful swellings may be observed. The larvae lie in cysts containing yellow purulent fluid. Attacks by warble flies laying eggs can cause irritation to reindeer. Host animals may injure themselves as a result.

Diagnosis: The presence of the larvae under the skin of the back allows diagnosis of warble flies. The eggs may also be found on the hairs of the animals in the summer.

Pathology: Warble larvae induce a pronounced tissue inflammation. The cellular reaction is predominantly eosinophilic and lymphocytic. The presence of the larvae also induces the production of a thickened connective tissue-lined cavity surrounding the larva, filled with inflammatory cells, particularly eosinophils.

Epidemiology: Fawns and yearlings are most affected by this parasite, which produces large oedematous swellings. These swellings may suppurate and attract blowflies, which then oviposit in the wound.

Treatment: Injectable ivermectin, doramectin, eprinomectin or moxidectin administered between November and January is extremely effective in eliminating these parasites.

Control: In control schemes a single annual treatment in autumn is usually recommended before the larvae have reached the back and perforated the hide.

Notes: Limited geographical distribution but of local veterinary importance.

Parasites of the integument

Besnoitia tarandi

Predilection site: Skin, conjunctiva

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Final host: Unknown

Intermediate hosts: Reindeer, caribou

Geographical distribution: Arctic regions of Europe and America

ECTOPARASITES

Lice

Lice infestations are frequently encountered in deer. It is beyond the scope of this book to provide detailed descriptions of all the species of lice that may be encountered on deer throughout the world. Some of the more common species that may be encountered are provided in Table 14.8.

Treatments with insecticides, such as carbaryl, cypermethrin, deltamethrin, diazinon, lindane and malathion, are usually effective in controlling lice on deer. Insecticidal dust bags or 'back rubbers' can be used as self-dosing rubbing stations for deer and other ungulates. Because louse populations on most temperate ungulates increase during the cooler months, insecticides should ideally be administered to them in the autumn/winter. Avermectins are generally less effective against chewing lice but may be effective against sucking lice. Animals destined to be introduced into established herds should be quarantined and where necessary treated.

Mites

Sarcoptes scabiei

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Sarcoptidae

Hosts: Red deer, roe deer, moose, reindeer

For more details see Chapters 3 and 11.

A number of non-obligate ectoparasites are found on deer and these are listed in the host–parasite checklists at the end of this chapter. More detailed descriptions of these parasites can be found in Chapter 17.

CAMELS

ENDOPARASITES

Parasites of the digestive system

Gongylonema pulchrum

Common name: Gullet worm

Predilection site: Oesophagus, rumen

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description: A long, slender, whitish worm, the males being about 5.0 cm and the females up to about 14.0 cm in length. Asymmetrical cervical alae are prominent and the anterior end has longitudinal rows of cuticular plaques. The tail of the male has asymmetrical alae with 10 pairs of papillae. The left spicule is long and slender whereas the right spicule is short and stout. The male has a gubernaculum.

Final host: Sheep, goat, cattle, pig, buffalo, horse, donkey, deer, camel, camelids, human

Intermediate host: Coprophagous beetles, cockroaches

Geographical distribution: Probably worldwide

For more details see Chapter 9.

Gongylonema verrucosum

Common name: Rumen gullet worm

Predilection site: Rumen, reticulum, omasum

Phylum: Nematoda

Class: Secernentea

Table 14.8 Lice on deer.

| Lice | Family | Host(s) | Region |
|--------------------------------|----------------|---|----------------------------------|
| <i>Solenopotes tarandi</i> | Linognathidae | Reindeer, Caribou (<i>Rangifer tarandus</i>) | Eurasia, North America |
| <i>Solenopotes binipilosus</i> | Linognathidae | White-tailed deer, Black-tailed deer, Mule deer (<i>Odocoileus</i> spp.) | North, Central and South America |
| <i>Solenopotes burmeisteri</i> | Linognathidae | Elk (<i>Cervus elaphus</i>) | Eurasia |
| <i>Solenopotes burmeisteri</i> | Linognathidae | Red deer (<i>Cervus elaphus</i>), Sika deer (<i>Cervus nippon</i>) | Eurasia |
| <i>Solenopotes capreoli</i> | Linognathidae | Roe deer (<i>Capreolus capreolus</i>) | Eurasia |
| <i>Solenopotes ferrisi</i> | Linognathidae | Black-tailed deer (<i>Odocoileus</i> spp.) | North America |
| <i>Solenopotes muntiacus</i> | Linognathidae | Muntjac (<i>Muntiacus reevesi</i>) | South Asia |
| <i>Bovicola forficula</i> | Trichodectidae | Muntjac (<i>Muntiacus muntjak</i>) | Asia |
| <i>Bovicola longicornis</i> | Trichodectidae | Red deer (<i>Cervus elaphus</i>) | Europe |
| <i>Bovicola maai</i> | Trichodectidae | Sika deer (<i>Cervus nippon</i>) | Eurasia |
| <i>Bovicola meyeri</i> | Trichodectidae | Roe deer (<i>Capreolus capreolus</i>) | Eurasia |
| <i>Bovicola tibialis</i> | Trichodectidae | Fallow deer (<i>Dama dama</i>) | Europe |
| <i>Tricholipeurus indicus</i> | Philopteridae | Muntjac (<i>Muntiacus reevesi</i>) | Asia |

Superfamily: Spiruroidea

Description: Long slender worms, reddish when fresh. The males are about 3.5 cm and the females 7.0–9.5 cm in length. The adult worms have a festooned cervical ala and cuticular bosses only on the left side of the body. The males' spicules are unequal in length, with the left spicule considerably longer than the right.

Final host: Cattle, sheep, goat, deer, camel

Intermediate hosts: Coprophagous beetles and cockroaches

For more details see Chapter 9.

Studies on the helminth parasites of camels are few, and published information consists mainly of case reports and lists of reported helminths. Many of the species reported are accidental infections with parasite species of domestic ruminants and their significance and pathogenicity are generally not known. The most important species, against which treatment is targeted, is the camel stomach worm *Haemonchus longistipes*. This nematode, either alone or in mixed infections with *Trichostrongylus* spp., may cause a debilitating and sometimes fatal condition. Limited information is available on the efficacy of anthelmintics against gastrointestinal nematodes in camels. Benzimidazoles and ivermectin given at cattle dose rates have reported efficacy against a number of gastrointestinal nematode species found in camels. Ivermectin has been reported as less effective against *Nematodirus* and *Trichuris* spp.

Monthly treatments of young animals during the rainy season can help reduce parasitic burdens. Removal of faeces around watering points and keeping these areas dry can also reduce numbers of infective larvae.

Abomasum

Haemonchus longistipes

Common name: Camel stomach worm

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: Relatively small worms; males are 10–20 mm and females 18–30 mm long. Females have a reduced knob-like vulvar flap (cf. *H. contortus* which has a well-developed linguiform vulvar flap).

Hosts: Camel and sheep

Geographical distribution: Africa, Middle East

Pathogenesis and clinical signs: *Haemonchus longistipes* is a voracious blood-sucker, producing symptoms similar to those of *H. contortus* in domestic ruminants. Infection has been reported to cause anaemia, oedema, emaciation and death.

Epidemiology: The epidemiology is similar to that reported with haemonchosis in domestic ruminants. The prevalence of this parasite varies from region to region and from season to season in the same region. Higher prevalence rates have been reported during the rainy season with a drop in prevalence during the dry season.

Camelostrongylus mentulatus

Predilection site: Abomasum, small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: *Camelostrongylus mentulatus* is similar in size to *Ostertagia ostertagi*. Males are 6.5–7.5 mm and females 8–10 mm long. The bursa possesses two large lateral lobes and the spicules are narrow, long, denticulated and of equal length. Eggs measure about 75–85 by 40–50 μm .

Hosts: Camel, llama, sheep, goat

Geographical distribution: Common in the Middle East and Australia; South America

Pathogenesis: Generally of low pathogenicity and considered of little importance.

Pathology: Heavy infections can produce gastric hyperplasia and increase in abomasal pH, similar to that seen in *Ostertagia* infection.

Impalaia tuberculata

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: Males are 7–9 mm and females 14–18 mm long. The cervical cuticle is studded with papillae. Eggs measure about 60 by 32 μm .

Hosts: Wild ruminants, camel

Geographical distribution: India

Impalaia nudicollis

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: Males are 7.5–8.2 mm and females 14.8–16.7 mm long. Males have long spicules and a long gubernaculum. Eggs measure about 60 by 32 μm .

Hosts: Wild ruminants, camel

Geographical distribution: Africa, India

Physocephalus sexalatus

Predilection site: Abomasum

Phylum: Nematoda

Table 14.9 Cattle and sheep parasites found in the abomasa of camels.

| Species | (Super)family | Hosts | Geographical distribution |
|-----------------------------------|---------------------|--|--|
| <i>Teladorsagia circumcincta</i> | Trichostrongyloidea | Cattle, sheep, goat, deer, camel, llama | Worldwide |
| <i>Ostertagia leptospicularis</i> | Trichostrongyloidea | Deer (roe deer), cattle, sheep, goat, camel | Many parts of the world, particularly Europe and New Zealand |
| <i>Haemonchus contortus</i> | Trichostrongyloidea | Sheep, goat, cattle, deer, camel, llama | Worldwide |
| <i>Marshallagia marshalli</i> | Trichostrongyloidea | Sheep, goat and wild small ruminants | Tropics and subtropics including southern Europe, USA, South America, India and Russia |
| <i>Trichostrongylus axei</i> | Trichostrongyloidea | Cattle, sheep, goat, deer, horse, donkey, pig and occasionally human | Worldwide |
| <i>Parabronema skrjabini</i> | Spiruroidea | Sheep, goat, cattle, camel | Central and East Africa, Asia, and some Mediterranean countries, notably Cyprus |

Class: Secernentea

Superfamily: Spiruroidea

Description: Small slender worms, the males measuring about 10–12 mm and the females up to 22 mm long. The wall of the pharynx contains a single spiral support. The cervical papillae are asymmetrically located. Eggs are small, an elongated ellipse, thick-shelled, measure around 34–39 by 15–17 µm and are embryonated when passed.

Final hosts: Pig, camel; occasionally rabbit, hare

Intermediate hosts: Coprophagous beetles

Notes: Reported in dromedary camels in Iran. *Physocephalus sexalatus* may be synonymous with *P. cristatus*, which has also been reported in camels.

Other parasites of cattle or sheep and wild ruminants have been reported in the abomasum of camels (Table 14.9). More details of these species can be found in Chapters 8 and 9.

Small intestine

Species of nematodes and cestodes reported in the small intestines of camels are generally of little clinical significance and only brief details are listed below. Cattle or sheep parasites found in the small intestine are listed in Table 14.10, and those of the large intestine are given in Table 14.11. Further details of these parasites can be found in Chapters 8 and 9. A more detailed list of helminth species found in camels is provided in the parasite checklist at the end of the chapter.

Table 14.10 Cattle and sheep parasites found in the small intestines of camels.

| Species | (Super)family | Hosts | Geographical distribution |
|---|---------------------|---|---|
| Nematodes | | | |
| <i>Trichostrongylus longispicularis</i> | Trichostrongyloidea | Cattle, sheep, goat, deer, camel, llama | Ruminants in Australia; and cattle in America and parts of Europe |
| <i>Trichostrongylus vitrinus</i> | Trichostrongyloidea | Sheep, goat, deer, camel, occasionally pig and human | Mainly temperate regions of the world |
| <i>Trichostrongylus colubriformis</i> | Trichostrongyloidea | Sheep, goat, cattle, camel and occasionally pig and human | Worldwide |
| <i>Trichostrongylus probolorus</i> | Trichostrongyloidea | Sheep, camel, human | ? |
| <i>Nematodirus spathiger</i> | Trichostrongyloidea | Sheep, goat, occasionally cattle and other ruminants | Cosmopolitan, but more prevalent in temperate zones |
| <i>Nematodirus helvetianus</i> | Trichostrongyloidea | Cattle, occasionally sheep, goat and other ruminants | |
| <i>Nematodirus abnormalis</i> | Trichostrongyloidea | Sheep, goat, camel | Europe, Asia, North America, Australia and Russia |
| <i>Cooperia oncophora</i> | Trichostrongyloidea | Cattle, sheep, goat, deer | Worldwide |
| <i>Cooperia surnabada</i> (syn. <i>Cooperia mcmasteri</i>) | Trichostrongyloidea | Cattle, sheep, camel | Parts of Europe, North America and Australia |
| <i>Bunostomum trigonocephalum</i> | Ancylostomatoidea | Sheep, goat, camel | Worldwide |
| <i>Strongyloides papillosus</i> | Rhabditoidea | Sheep, cattle, other ruminants and rabbits | Worldwide |
| Cestodes | | | |
| <i>Moniezia benedeni</i> | Anoplocephalidae | Cattle, red deer, roe deer, camel Intermediate hosts: forage mites | Worldwide |
| <i>Moniezia expansa</i> | Anoplocephalidae | Sheep, goat, occasionally cattle Intermediate hosts: forage mites | Worldwide |
| <i>Thysaniezia ovilla</i> (syn. <i>Thysaniezia giardia</i>) | Anoplocephalidae | Cattle, sheep, goat, camel and wild ruminants Intermediate hosts: oribatid mites and psocids | Southern Africa |
| <i>Avitellina centripunctata</i> (syn. <i>Avitellina woodlandi</i>) | Anoplocephalidae | Sheep and other ruminants Intermediate hosts: oribatid mites or psocid lice | Europe, Africa and Asia. Widespread in camels in Asia and Africa |
| <i>Stilesia globipunctata</i> | Anoplocephalidae | Sheep, cattle and other ruminants Intermediate hosts: oribatid mites or psocid lice | Southern Europe, Africa and Asia |

Table 14.11 Cattle and sheep parasites found in the large intestine of camels.

| Species | (Super)family | Hosts | Geographical distribution |
|---|---------------|---|---|
| <i>Oesophagostomum venulosum</i> (syn. <i>Oesophagostomum virginimembrum</i>) | Strongyloidea | Sheep, goat, deer, camel | Worldwide |
| <i>Oesophagostomum columbianum</i> | Strongyloidea | Sheep, goat, deer, camel | Worldwide; more important in tropical and subtropical areas |
| <i>Chabertia ovina</i> | Strongyloidea | Sheep, goat, occasionally deer, cattle and other ruminants | Worldwide but more prevalent in temperate regions |
| <i>Trichuris ovis</i> | Trichuroidea | Sheep, goat, occasionally cattle and other ruminants | Worldwide |
| <i>Trichuris globulosa</i> | Trichuroidea | Cattle, occasionally sheep, goat, camel and other ruminants | Worldwide |

Nematodirus mauritanicus

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: Females are 21–24 mm and males 13–15 mm long. Male spicules are joined for part of their length with the tips enclosed in a thin lanceolate membrane.

Host: Camel

Nematodirella dromedarii

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: The anterior of the worm is narrow and is similar to *Nematodirus*. Males are 10–15 mm and females 10–30 mm long. The very long spicules can measure up to half the body length and are equal in size (see Fig. 1.35). Eggs are large, measuring about 250 by 125 µm.

Hosts: Dromedary camel

Life cycle: This is thought to be similar to that of *Nematodirus* spp. (not *N. battus*).

Geographical distribution: Presumed throughout the host range of Asia and North Africa

Nematodirella cameli

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: Males are 16–17 mm and females 21–25 mm in size. In the males, the spicules are asymmetrical, thin and extremely long, adjoining each other closely over their entire length and

forming rounded swellings distally from which branch off spine-shaped distal extremities.

Hosts: Bacterian camel, reindeer, elk

Geographical distribution: Russia and CIS countries

Stilesia vittata

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description: The tapeworm is around 18–23 cm long. The scolex is 0.5–0.6 mm in size; mature proglottids contain five to seven testes lying lateral to the ventral canal.

Host: Camel

Coccidia

Eimeria bactriani

Synonym: *Eimeria nolleri*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Camel (Bactrian, dromedary)

Description: The oocysts are spherical to ellipsoidal, pale yellow–brown, smooth, 21–34 by 20–28 µm, with a micropyle but without micropylar cap and oocyst residuum. Sporocysts are spherical or elongate, 8–9 by 6–9 µm with a residuum. Meronts in the small intestine are 16 by 10 µm and contain 20–24 merozoites; mature microgamonts are 25 by 20 µm.

Life cycle: The life cycle is typically coccidian with endogenous stages found in the small intestine, although the number of merogony stages is unknown. Sporulation time is 9–15 days.

Geographical distribution: Germany, Russia and former Soviet states

Pathogenesis and clinical signs: Not reported

Diagnosis: Diagnosis is based on clinical signs and the demonstration of oocysts in diarrhoeic faeces.

Epidemiology: Unknown

Treatment and control: Little is known about treatment but, by analogy with other hosts, one of the sulphonamide drugs should be tried if disease is suspected. Prevention is based on good management, avoidance of overcrowding and stress, and attention to hygiene, particularly watering areas, which should be protected from faecal contamination.

Notes: There is controversy regarding the specific name of this organism. In some texts it is referred to as *Eimeria nollerii*.

Eimeria cameli

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Camel (Bactrian, dromedary)

Description: The oocysts are large, pyriform, 80–100 by 55–94 μm , have a rough brown wall, with a micropyle, with or without a micropylar cap, and without an oocyst residuum. Sporocysts are elongate or ellipsoidal, pointed at both ends, 30–50 by 14–20 μm without a Stieda body but with a residuum. Sporozoites are comma-shaped, lie lengthwise head to tail in the sporocyst, and have a clear globule at the large end. Giant meronts in the small intestine are up to 350 μm and contain many merozoites.

Life cycle: Giant meronts are found in the small intestine and gamonts are found in the ileum and occasionally the caecum. Sporulation time is 9–15 days.

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Infections can produce severe enteritis leading to progressive weight loss and emaciation. Watery diarrhoea, sometimes containing blood, has been found in heavy infections. Diarrhoea and secondary bacterial infections may aggravate the condition leading to death in young camels.

Pathology: Presence of the parasite may cause inflammatory lesions in the small intestine and giant meronts may be visible with the naked eye. Cystic structures containing oocysts may be seen in the mucosa on histopathology.

Epidemiology: Young camels are much more susceptible to infection.

Treatment and control: As for *E. bactriani*.

Notes: This is the most frequently encountered *Eimeria* species in camels in North Africa.

Eimeria dromedarii

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Camel (Bactrian, dromedary)

Description: The oocysts are ovoid, 23–33 by 20–25 μm , have a brown wall, with a micropylar cap, but without a polar granule or oocyst residuum (Fig. 14.2). Sporocysts are ovoid or spherical, 8–11 by 6–9 μm , without a Stieda body or residuum. Sporozoites are comma-shaped, with one to two clear globules.

Life cycle: Giant meronts are found in the small intestine and gamonts are found in the ileum and occasionally the caecum. Sporulation time is 15–17 days.

Geographical distribution: Worldwide

Pathogenesis and clinical signs: As for *E. cameli*.

Notes: This species is found frequently, often together with *E. cameli*.

Eimeria pellerdyi

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Camel (Bactrian)

Description: The oocysts are ovoid or ellipsoidal, smooth, colourless, 22–24 by 12–14 μm , without a micropyle, polar granule or oocyst residuum. Sporocysts are ovoid, 9–11 by 4–6 μm , with a small

Fig. 14.2 Oocyst of *Eimeria dromedarii*.

Stieda body and a residuum. Sporozoites are club-shaped, 8–10 by 1–3 μm , with a clear globule at the large end.

Life cycle: Unknown

Geographical distribution: Unknown

Pathogenesis and clinical signs: Unknown

Eimeria rajasthani

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Camel (dromedary)

Description: The oocysts are ellipsoidal, light yellowish-green, 34–39 by 25–27 μm , with a micropylar cap, but without a polar granule or oocyst residuum. Sporocysts are ovoid, 14–15 by 8–11 μm , with a Stieda body and a residuum. Sporozoites are elongate, 10–14 by 3–4 μm , with two or more clear globules.

Life cycle: Unknown

Geographical distribution: Unknown

Pathogenesis and clinical signs: Unknown

Cystispora orlovi

Synonym: *Isoospora orlovi*

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Host: Camel

Description: Oocysts contain two sporocysts each with four sporozoites. The oocysts are ellipsoidal, oval, cylindrical or figure-of-eight-shaped, smooth, 27–35 by 15–20 μm , without a polar granule, micropyle or residuum. Sporocysts are ellipsoidal, ovoid (15–20 \times 13–17 μm) or spherical (13–15 μm diameter) without a Stieda body but with a residuum.

Life cycle: Unknown

Geographical distribution: Russia, former Soviet states

Pathogenesis and clinical signs: Unknown

Notes: Another species, *Isoospora cameli*, has been reported in India. It is not clear if these species are valid.

Cryptosporidium parvum

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Description: Oocysts are ovoidal or spheroidal, 5.0 by 4.5 μm in size (range 4.6–5.4 \times 3.8–4.7 μm), with a length/width ratio of 1.19.

For more details see Chapter 8.

Large intestine

Buxtonella sulcata

Predilection site: Large intestine

Phylum: Ciliophora

Class: Litostomatea

Family: Pycnotrichidae

Description: The body is ovoid, 100 by 72 μm , and uniformly ciliated with a prominent curved groove bordered by two ridges running from end to end with a cyathostome at the anterior end, and an oval or bean-shaped macronucleus 28 by 14 μm in size.

Geographical distribution: Worldwide

Entamoeba wenyoni

Predilection site: Small intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites are 12 by 9 μm with granular protoplasm. The cysts are spherical, 7 μm in diameter, and contain eight nuclei.

Hosts: Goat, camel

Geographical distribution: Unknown

Parasites of the respiratory system

Cephalopina titillator

Synonym: *Cephalopsis titillator*

Common name: Camel nasal bot fly

Predilection site: Nasal cavity

Class: Insecta

Family: Oestridae

Description, adult: The adult fly measures 8–10 mm in length. It is relatively robust and has a powdery grey appearance. The head is large, orange above and yellow below. The eyes are broadly separated, especially in the female. The thorax is reddish-brown, with a black pattern. The abdomen has irregular black blotches and white hairs. The legs are yellow.

Description, larvae: The first-stage larvae are about 0.7 mm in length and have long spines on the lateral edges of the segments.

L₂ are about 15 mm in length and the L₃ 25–35 mm in length, the latter being characterised by smooth fleshy lobes on each segment and large mouth hooks.

Hosts: Camels

Geographical distribution: Occurs over entire range of both species of camel: sub-Saharan Africa, Middle East, Australia and Asia

Pathogenesis: The larvae irritate and damage the mucosa. Camels snort, sneeze and are restless, and may even stop feeding, especially during the emergence of mature larvae from the nostrils. When large numbers of larvae are present the animals' breathing and working capacity may be severely impaired. Unlike many oestrids, adult *Cephalopina* do not panic the animals, and large numbers are often seen resting on the head and around the nostrils.

Clinical signs: Snorting, sneezing, increased grooming, nasal discharge, bleeding from the nostrils, coughing and reduced milk production and body weight.

Diagnosis: The adult flies may be visible and recognisable on the host. The eggs are also easily identifiable on the host. Larvae present in the pharynx may be seen on direct inspection.

Pathology: The larval phase usually occupies about 11 months, and is associated with inflammation, sometimes purulent, of the nasopharyngeal mucosa.

Epidemiology: Infestation of up to 90% of camel herds has been recorded.

Treatment: Macrocytic lactones, rafoxanide, trichlorphon and nitroxylnil have all been reported to be effective against the larvae of *Cephalopina titillator*.

Control: The most effective means of control of this parasite is to remove the eggs from the host's coat. This requires, where possible, daily examination of the animal, paying particular attention to the area around the nostrils.

Oestrus ovis

Common name: Sheep nasal bot

Predilection site: Nasal passages

Class: Insecta

Family: Oestridae

Description: Greyish-brown flies about 12 mm long, with small black spots on the abdomen and a covering of short brown hairs (see Figs 3.44 and 9.41). The head is broad, with small eyes, and the frons, scutellum and dorsal thorax bear small wart-like protruberances. The segments of the antennae are small and the arista bare. The mouthparts are reduced to small knobs.

Mature larvae in the nasal passages are about 30 mm long, yellowish-white and taper anteriorly. Each segment has a dark transverse band dorsally (see Fig. 3.45). They have large black oral hooks, connected to an internal cephalopharyngeal skeleton. The ventral surface bears rows of small spines.

Hosts: Primarily sheep and goat, but also ibex, camel and humans

For more details see Chapter 9.

Dictyocaulus filaria

Predilection site: Lungs

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Hosts: Sheep, goat, camel and a few wild ruminants

Description: The worms are white with the intestine visible as a dark band. Males measure around 4–8 cm and the females 6–10 cm in length. In the bursa the posterolateral and the mediolateral rays are fused together, except at their extremities. The dark-brown spicules are stout and shaped like a boot. The vulva is located just posterior to the middle of the worm.

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Severe infections cause depression, coughing, dyspnoea and loss of condition.

Epidemiology: *Dictyocaulus filaria* is found in the respiratory tract of camels in Africa.

Treatment and control: Benzimidazoles, levamisole and avermectins are all reported to be effective against this species in camels.

For more details see Chapter 9.

Dictyocaulus viviparus

Synonym: *Dictyocaulus cameli*

Predilection site: Lungs

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: The adults are slender thread-like worms; males measure around 4.0–5.5 cm and females 6–8 cm in length. The buccal ring is triangular in shape. They are very similar to *D. filaria* but the posterolateral and mediolateral rays are entirely fused together.

Hosts: Cattle, deer, camel

Geographical distribution: Worldwide

Pathogenesis and clinical signs: As for *D. filaria*.

For more details see Chapter 8.

Echinococcus granulosus

For more details see Parasites of the liver.

Parasites of the liver

Fasciola hepatica

Common name: Liver fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description: Adult fluke are leaf-shaped (being broader anteriorly than posteriorly), grey–brown in colour and around 2.5–3.5 cm in length and 1.0 cm in width (see Fig. 1.70a). The anterior end is conical and marked off by distinct shoulders from the body. The tegument is covered with backwardly projecting spines. An oral and ventral sucker, situated at the level of the shoulders, may be readily seen. The intestinal caeca have many branches and extend a considerable distance posteriorly. The testes and ovary are multi-branched. The uterus is positioned anterior to the testes. The cirrus is well developed. Immature fluke at the time of entry into the liver are 1.0–2.0 mm in length and lancet-like.

Final hosts: Sheep, cattle, goat, horse, deer, human and other mammals

For more details see Chapter 9.

Fasciola gigantica

Common name: Tropical large liver fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description: The adult fluke is larger than *F. hepatica*, the body is more transparent, and can reach 7.5 cm in length and 1.5 cm in breadth (see Fig. 1.70b). The shape is more leaf-like, the conical anterior end is very short and the shoulders, characteristic of *F. hepatica*, are barely perceptible. The gut caeca are more highly branched than in *F. hepatica*.

Final hosts: Cattle, buffalo, sheep, goat, pig, camel, deer, human

For more details see Chapter 8.

Echinococcus granulosus

Predilection site: Mainly liver and lungs (intermediate hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description: Hydatid cysts are large fluid-filled vesicles 5–10 cm in diameter, with a thick concentrically laminated cuticle and an internal germinal layer (see Figs 9.44 and 9.45). The germinal layer produces numerous small vesicles or brood capsules each containing up to 40 scolices, invaginated into their neck portions and attached to the wall by stalks. Brood capsules may become detached from the wall of the vesicle and float freely in the vesicular fluid and form ‘hydatid sand’.

Final hosts: Dog and many wild canids

Intermediate hosts: Domestic and wild ruminants, human and primates, pig and lagomorphs

For more details see Chapter 9.

Parasites of the pancreas

Eurytrema pancreaticum

Synonyms: *Distoma pancreaticum*, *Eurytrema ovis*

Common name: Pancreatic fluke

Predilection site: Pancreatic ducts

Phylum: Platyhelminthes

Class: Trematoda

Family: Dicrocoeliidae

Description: Oval, leaf-shaped, reddish-brown flukes measuring around 8–16 by 5–8.5 mm. The body is thick and the juvenile flukes are armed with spines which are often absent by the adult stage. The oral sucker is larger than the ventral sucker and the pharynx and oesophagus are short. The testes are positioned horizontally just behind the ventral sucker. A tubular cirrus sac is present. The uterus completely occupies the posterior body. Eggs measure around 40–50 by 25–35 µm and are similar to those of *Dicrocoelium*.

Final hosts: Cattle, buffalo, sheep, goat, pig, camel and human

Intermediate hosts: Two are required. Host 1: land snails, particularly of the genus *Bradybaena*. Host 2: grasshoppers of the genus *Conocephalus* or tree crickets (*Oecanthus*).

Geographical distribution: South America, Asia and Europe

Parasites of the circulatory system

Elaeophora schneideri

Common names: Filarial dermatosis, ‘sore head’

Predilection site: Blood vessels

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description: Slender worms; males are around 5–8 cm and females up to 12 cm long with a very long oesophagus. The tail of the male is coiled and the spicules are long, slender and unequal.

Final hosts: Sheep, goat, deer, (elk, moose, mule deer), camel

For more details see Chapter 9.

Dipetalonema evansi

Synonym: *Deraiphoronema evansi*

Common name: Subcutaneous filarioidosis

Predilection site: Heart, arteries and veins, pulmonary arteries, spermatic arteries, lymph nodes

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Fairly large filarial worms; adult males are 8–11 cm and adult females 14.5–18.5 cm.

Description, microscopic: Microfilariae are ensheathed, 200–315 µm in length and found in the peripheral blood.

Final host: Camel

Intermediate hosts: Mosquitoes of the genus *Aedes*

Life cycle: The life cycle has not been described in detail but *Aedes* mosquitoes are thought to act as intermediate hosts. Following ingestion of a blood meal the microfilariae develop to infective larvae in the intermediate host. Larvae pass to the host when the intermediate host next feeds.

Geographical distribution: North Africa, Asia, eastern Russia, Australia

Pathogenesis: Light infections are inapparent. Heavy infections can cause emaciation, arteriosclerosis and heart insufficiency and parasitic orchitis in the spermatic vessels.

Clinical signs: Emaciation, lethargy, orchitis

Diagnosis: Filarial nematodes within arteries cannot be detected clinically. The identification of the microfilariae in the blood (samples ideally taken in the early evening) is aided by concentrating the parasites following lysis, filtration and then staining with methylene blue or May–Grunwald Giemsa. Alternatively, one part of blood and nine parts of formalin are centrifuged and the sediment mixed with a blue stain and examined as a microscopic smear.

Pathology: The presence of the parasites in an artery or vein leads to inflammation of the vessel wall and thrombosis may occur. Fibrosis leads to a granulomatous arteritis or phlebitis, and possible occlusion of the vessel lumen. Aneurysms may occur in the spermatic vessels.

Epidemiology: Infection is presumably common in areas where the parasite and intermediate hosts coexist. In the eastern former Soviet states, infection may occur in up to 80% of camels.

Treatment: Stibophen 0.5 mg/kg i.v. is effective both therapeutically and prophylactically during the periods of mosquito activity.

Control: Mosquito control methods, such as the use of insect repellents, may limit exposure. Stibophen used prophylactically as described may help limit infection. Ivermectin 200 µg/kg can be used to eliminate microfilariae.

Onchocerca armillata

Common name: Aortic filariosis

Predilection site: Aorta

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description: Slender whitish worms; males are about 7 cm and females up to 70 cm long. Microfilariae are unsheathed and measure 346–382 µm.

Final hosts: Cattle, rarely camel, sheep, goat

Intermediate hosts: Midges (*Culicoides*), blackflies (*Simulium*)

Geographical distribution: Africa, Middle East, India

Schistosomes

Schistosomes are flukes found in the circulatory system. The sexes are separate, the small adult female lying permanently in a longitudinal groove, the gynaecophoric canal, in the body of the male. The genus has been divided into four groups – *haematobium*, *indicum*, *mansoni* and *japonicum* – but the genus as currently defined is paraphyletic so revisions are likely.

Haematobium group

Schistosoma bovis

Common names: Blood fluke, bilharziosis

Predilection site: Portal and mesenteric veins, urogenital veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description: The males are 9–22 mm long and 1–2 mm wide, and the female 12–28 mm long. In the male the suckers and the tegument behind the suckers are armed with minute spines, while the dorsal surface of the tegument bears small cuticular tubercles. The slender female worm lies permanently in a ventral groove in the broad flat body of the male.

Final hosts: Cattle, sheep, goat, camel (dromedary)

Intermediate hosts: Snails (*Bulinus contortus*, *B. truncatus*, *Physopsis africana*, *P. nasuta*)

Geographical distribution: Africa, Middle East, southern Asia, southern Europe

Schistosoma mattheei

Predilection site: Portal, mesenteric and bladder veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Final hosts: Cattle, sheep, goat, camel, rodents, human

Intermediate hosts: Snails (*Physopsis* spp.)

Geographical distribution: South and Central Africa, Middle East

Notes: Thought to be synonymous with *S. bovis* but differs on morphological and pathological grounds and is restricted to the alimentary canal.

Indicum group

Schistosoma indicum

Predilection site: Portal, pancreatic, hepatic and mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description: The sexes are separate; the males are 5–19 mm and the females 6–22 mm long. The eggs are oval with a terminal spine and measure 57–140 by 18–72 μm .

Final hosts: Cattle, sheep, goat, horse, donkey, camel

Intermediate hosts: Snails (*Indoplanorbis*)

Geographical distribution: India

Other schistosomes

Schistosoma turkestanica

Synonym: *Orientobilharzia turkestanicum*

Predilection site: Mesenteric veins and small veins of the pancreas and liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description: Small species, the male measuring around 4.2–8 mm and the female 3.4–8 mm in length. The spirally coiled ovary is positioned in the anterior part of the body. In the male there are around 70–80 testes. The female uterus is short and contains only one egg at a time, which measures 72–77 by 16–26 μm with a terminal spine and a short appendage at the opposite end.

Final hosts: Cattle, buffalo, sheep, goat, camel, horse, donkey, mule and cat

Intermediate hosts: Snail (*Lymnaea euphratica*)

Geographical distribution: Asia, Middle East and parts of Europe

Trypanosomes

Trypanosoma brucei brucei

Common name: Nagana

Predilection site: Blood. *Trypanosoma brucei brucei* is also found extravascularly in, for example, the myocardium, CNS and reproductive tract.

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Trypanozoon*

Description: *Trypanosoma brucei brucei* is pleomorphic in form and ranges from long and slender, up to 42 μm (mean 29 μm), to short and stumpy, 12–26 μm (mean 18 μm), the two forms often being present in the same blood sample. The undulating membrane is conspicuous, the kinetoplast is small and subterminal and the posterior end is pointed. In the slender form the kinetoplast is up to 4 μm from the posterior end, which is usually drawn out, tapering almost to a point, and has a well-developed free flagellum; in the stumpy form the flagellum is either short or absent and the posterior end is broad and rounded with the kinetoplast almost terminal. Intermediate forms average 23 μm long and have a blunt posterior end and moderately long flagellum (see Fig. 2.6). A fourth form with a posterior nucleus may be seen in laboratory animals. In fresh unfixed blood films, the organism moves rapidly within small areas of the microscope field.

Hosts: Cattle, horse, donkey, zebu, sheep, goat, camel, pig, dog, cat, wild game species, particularly antelope

Geographical distribution: Approximately 10 million km² of sub-Saharan Africa between latitudes 14° N and 29° S.

Treatment: The two drugs in common use in camels are diminazene aceturate and suramin. Treatment should be followed by surveillance since reinfection, followed by clinical signs and parasitaemia, may occur within a week or two.

Notes: Antelope are the natural host species and are reservoirs of infection for domestic animals. Horses, mules and donkeys are very susceptible, and the disease is very severe in sheep, goats, camels and dogs (see respective hosts).

For more details see Chapter 8.

Trypanosoma brucei evansi

Synonyms: *Trypanosoma evansi*, *Trypanosoma equinum*

Common name: Surra, el debab, mbori, murrina, mal de Caderas, doukane, dioufar, thaga

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Trypanozoon*

Hosts: Horse, donkey, camel, cattle, zebu, goat, pig, dog, water buffalo, elephant, capybara, tapir, mongoose, ocelot, deer and other wild animals. Many laboratory and wild animals can be infected experimentally.

Geographical distribution: North Africa, Central and South America, central and southern Russia, parts of Asia (India, Burma, Malaysia, southern China, Indonesia, Philippines)

Treatment and control: Suramin or quinapyramine (Trypacide) are the drugs of choice for treatment and also confer a short period of prophylaxis. For more prolonged protection a modified quinapyramine known as Trypacide Pro-Salt is also available. Unfortunately, drug resistance, at least to suramin, is not uncommon. Currently in camels, isometamidium is administered intravenously because of local tissue reactions.

Notes: The original distribution of this parasite coincided with that of the camel, and is often associated with arid deserts and semi-arid steppes.

For more details see Chapter 10.

Trypanosoma congolense

Common names: Nagana, paranagana, Gambia fever, ghindi, gobial

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Nannomonas*

Description: *Trypanosoma congolense* is small, monomorphic in form and 8–20 µm long. The undulating membrane is inconspicuous, the medium-sized kinetoplast is marginal and the posterior end is blunt. There is no free flagellum (see Fig. 2.5). In fresh blood films the organism moves sluggishly, often apparently attached to red cells.

Hosts: Cattle, sheep, goat, horse, camel, dog, pig. Reservoir hosts include antelope, giraffe, zebra, elephant and warthog.

Geographical distribution: Widely distributed in tropical Africa between latitudes 15° N and 25° S.

Pathogenesis: With *T. congolense*, there are many strains that differ markedly in virulence. The signs caused by this species are similar to those caused by other trypanosomes, but the CNS is not affected.

Treatment and control: Isometamidium is the drug of choice but is administered intravenously because of local tissue reactions. Diminazene is contraindicated in the camel.

For more details see Chapter 8.

Trypanosoma vivax vivax

Common names: Nagana, souma

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Duttonella*

Description: *Trypanosoma vivax vivax* is monomorphic, ranging from 20 to 27 µm. The undulating membrane is inconspicuous, the large kinetoplast is terminal and the posterior end is broad and rounded. A short free flagellum is present (see Fig. 2.4). In fresh blood films, *T. vivax* moves rapidly across the microscope field.

Hosts: Cattle, sheep, goat, camel, horse, antelope and giraffe are reservoirs.

Geographical distribution: Central Africa, West Indies, Central and South America (Brazil, Venezuela, Bolivia, Colombia, Guyana, French Guiana), Mauritius

For more details see Chapter 8.

Theileriosis

Theileria camelensis

Predilection site: Blood, lymph nodes

Phylum: Apicomplexa

Class: Aconoidasida

Family: Theileriidae

Description: Trophozoite forms in the erythrocyte are predominantly rounded.

Host: Camel

Life cycle: Not described although probably similar to *Theileria* spp. in cattle and sheep.

Geographical distribution: North Africa

Pathogenesis and clinical signs: Non-pathogenic

Diagnosis: Presence of erythrocytic forms in blood smears

Pathology: No associated pathology

Epidemiology: Transmitted by *Hyalomma dromedarii*.

Treatment and control: Not required

Notes: The validity of this species is questionable.

Theileria dromedari

Predilection site: Blood, lymph nodes

Phylum: Apicomplexa

Class: Aconoidasida

Family: Theileriidae

Description: Trophozoite forms in the erythrocyte are predominantly round.

Host: Camel

Rickettsiosis

Although *Rickettsia* are now considered to be in the kingdom Bacteria, for historical reasons they are included within parasitological texts and for this reason mention is made to some genera and species of importance.

Anaplasma marginale

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: In Giemsa-stained blood films the organisms of *A. marginale* are seen as small, round, dark-red ‘inclusion bodies’ approximately 0.3–1.0 µm within the red cell (see Fig. 8.39). Often there is only one organism in a red cell and characteristically this lies at the outer margin, although these two features are not constant.

Hosts: Cattle, sheep, goat, camel, wild ruminants

Geographical distribution: Africa, southern Europe, Australia, South America, Asia, former Soviet states and USA

For more details see Chapter 8.

Anaplasma centrale

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: As for *A. marginale*, except that the organisms are commonly found in the centre of the erythrocyte.

Hosts: Cattle, wild ruminants, and perhaps sheep, may act as reservoirs of infection.

Geographical distribution: Africa, southern Europe, Australia, South America, Asia, former Soviet states and USA

For more details see Chapter 8.

Parasites of the nervous system

Thelazia rhodesi

Common name: Cattle eye worm

Predilection site: Eye, conjunctival sac, lacrimal duct

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description: Small, thin, yellowish-white worms 1.0–2.0 cm long. Males are 8–12 mm and females 12–20 mm in length. The cuticle has prominent striations at the anterior end. The male worms have about 14 pairs of pre-cloacal and three pairs of post-cloacal papillae.

Final hosts: Cattle, buffalo, occasionally sheep, goat, camel

Intermediate host: Muscid flies, particularly *Fannia* spp.

For more details see Chapter 8.

Thelazia leesi

Common name: Eye worm

Predilection site: Conjunctival sac

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Final host: Camel

Intermediate host: Muscid flies

Geographical distribution: Africa, Asia, Russia

Pathogenesis and clinical signs: Heavy infections may cause irritation and keratitis with epiphora.

Taenia multiceps

Synonyms: *Multiceps multiceps*, *Coenurus cerebralis*

Common names: Gid, sturdy, staggers, coenurosis

Predilection site: Brain and spinal cord (intermediate hosts); small intestine (final hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description: When mature the *Coenurus cerebralis* cyst is readily recognised as a large fluid-filled transparent bladder up to 5 cm or more in diameter (Fig. 1.88). The coenurus bears clusters of several hundred protoscolices on its internal wall.

Final hosts: Dog, fox, coyote, jackal

Intermediate hosts: Sheep, cattle, deer, pig, horse, camel, human

Geographical distribution: Worldwide

For more details see Chapter 9.

Parasites of the locomotory system

Taenia ovis

Synonyms: *Taenia cervi*, *Taenia krabbei*, *Taenia hyenae*, *Cysticercus cervi*, *Cysticercus tarandi*, *Cysticercus dromedarii*, *Cysticercus cameli*

Predilection site: Small intestine (definitive host); muscle (intermediate host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description: Each cysticercus occurs within a small cyst measuring about 4 mm or less in length.

Final hosts: Dog, fox, wild carnivores (hyena)

Intermediate hosts: Sheep, goat (*Cysticercus ovis*); deer (*Cysticercus cervi*); reindeer (*Cysticercus tarandi*); camel (*Cysticercus dromedarii*, *Cysticercus cameli*)

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Infection is usually asymptomatic.

Sarcocystis

Several species of *Sarcocystis* have been reported in camels. Further general details on nomenclature, diagnosis and epidemiology are given in Chapter 2.

Sarcocystis cameli

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: In the camel, the tissue cysts are compartmented, up to 12 mm long with striated walls and are found in oesophageal, skeletal and cardiac muscle.

Final host: Dog

Intermediate hosts: Camel (Bactrian and dromedary)

Geographical distribution: North Africa (Egypt, Morocco, Sudan), Asia

Pathogenesis and clinical signs: The pathogenic significance is unknown. The parasite is widespread within its endemic range, with a high percentage of camels found to be infected at slaughter. Myocardial lesions and emaciation have both been attributed to infection.

Diagnosis: Antemortem diagnosis is difficult and most cases of *Sarcocystis* infection are only revealed at postmortem when the grossly visible sarcocysts in the muscle are discovered.

Pathology: The tissue cysts may be visible to the naked eye but are more likely to be detected on histopathology.

Epidemiology: Little is known of the epidemiology, but from the high prevalence of symptomless infections observed in abattoirs it is clear that where dogs are kept in close association with camels or their feed, then transmission is likely.

Treatment and control: Treatment is not usually indicated. The only control measures possible are those of simple hygiene. Dogs should not be fed raw or uncooked camel meat.

Sarcocystis ippeni

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Final host: Unknown

Intermediate hosts: Camel (dromedary)

Toxoplasma gondii

Predilection site: Muscle, lung, liver, reproductive system, CNS

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

For more details see Chapter 11.

Parasites of the connective tissue

In camels, three species of filarial worms have been reported to cause skin nodules, 0.5–4 cm in diameter, on various parts of the body. The intermediate hosts are various species of biting flies.

Onchocerca gutturosa

Predilection site: Connective tissue, ligamentum nuchae

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description: Slender whitish worms; males range from 2 to 6 cm, while females are up to 60 cm in length or longer and are coiled in fibrous tissues. The cuticle possesses spiral thickenings to aid attachment.

Final host: Cattle, camel

Intermediate hosts: Blackflies (*Simulium*)

Onchocerca fasciata

Predilection site: Connective tissue, ligamentum nuchae

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Final host: Camel

Intermediate hosts: Unknown

Geographical distribution: Africa

ECTOPARASITES

Microthoracius cameli

Common name: Camel sucking louse

Predilection site: Skin

Class: Insecta

Order: Phthiraptera

Family: Microthoraciidae

Description: *Microthoracius cameli* has a very characteristic elongated spindle-shaped head, which is almost as long as its swollen rounded abdomen (Fig. 14.3). The entire body is 1–2 mm in length.

Host: Camel

Fig. 14.3 *Microthoracius* spp. (Courtesy of K. Floate and R. Spooner, Agriculture and Agri-Food Canada.)

Geographical distribution: Worldwide, in association with its host

Pathogenesis: These lice are blood-feeders and heavy infestations can significantly reduce weight gain and milk production.

Clinical signs: The signs of infestation are variable. Light infestation may have no obvious effects, but pruritis, dermatitis and hair loss are usually evident at heavier parasite loads.

Diagnosis: The lice and their eggs can be seen on the skin of the host animal when the hair is parted.

Epidemiology: Infection occurs after direct contact with an infested host animal. Cross-contamination between different host species is possible if the animals have physical contact.

Treatment and control: Macrocytic lactones, such as moxidectin, in a repeated treatment programme of 7–10 days may be effective.

Notes: Microthoraciidae contains four species in the genus *Microthoracius*; three species parasitise llamas. The fourth species, *Microthoracius cameli*, is parasitic on camels. The closely related *Microthoracius mazzai* is an economically important parasite of alpacas (see host section in this chapter).

Hippobosca camelina

Common name: Camel fly

Predilection site: Skin

Class: Insecta

Order: Diptera

Family: Hippoboscidae

Description: Adult flies are approximately 10 mm in length and are generally pale reddish-brown with yellow spots on the indistinctly segmented abdomen. They have one pair of wings, the veins of which are crowded together towards the anterior margin. Both sexes of adult are blood feeders. The mature larvae are rarely seen and measure about 5 mm in length.

Host: Camels

Geographical distribution: Sub-Saharan Africa

Pathogenesis: This species is primarily a nuisance and a cause of disturbance. There is no evidence that it plays any role in the transmission of camel trypanosomiasis.

Clinical signs: The adult flies are clearly visible when feeding on the host animal. Irritation at the feeding sites may be observed.

Diagnosis: Observation of adult flies on the host animal.

Epidemiology: The adult flies are most abundant on the host during the summer months.

Treatment and control: This is best achieved by topical application of insecticides, preferably those with some repellent and residual effect, such as the synthetic pyrethroids permethrin and deltamethrin.

Sarcoptes scabiei

Subspecies: *cameli*

Common names: Camel mange, jarab

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Sarcoptidae

Description: The adult of this species has a round, ventrally flattened, dorsally convex body (see Fig. 3.89). Adult females are 0.3–0.6 mm long and 0.25–0.4 mm wide, while males are smaller, typically up to 0.3 mm long and 0.1–0.2 mm wide. The posterior two pairs of limbs do not extend beyond the body margin. In both sexes, the pretarsi of the first two pairs of legs bear empodial claws and a sucker-like pulvillus, borne on a long stalk-like pretarsus. The sucker-like pulvilli help the mite grip the substrate as it moves. The third and fourth pairs of legs in the female and the third pair of legs in the male end in long setae and lack stalked pulvilli. The mouthparts have a rounded appearance. These mites have no eyes or stigmata. The dorsal surface of the body of *S. scabiei* is covered with transverse ridges, but also bears a central patch of triangular scales. The dorsal setae are strong and spine-like. The anus is terminal and only slightly dorsal. There are a number of host-adapted varieties of *S. scabiei* that differ subtly in their morphology.

Host: Camel

Geographical distribution: Africa, Asia

Pathogenesis and clinical signs: Host reaction starts on the head, neck, mammary glands, prepuce and flanks. The first lesions appear as erythema, papules and intense pruritis with hair loss, which becomes reddened and moist. The lesions may become generalised with hyperkeratosis on the neck and legs, with intense pruritis leading to loss of appetite, weight loss and emaciation.

Epidemiology: New hosts are infected by contact with infected individuals, presumably by the transfer of larvae, which are commonly present more superficially on the skin surface. Transmission occurs between mature animals and also from mother to offspring at birth.

Treatment and control: Spray treatments of lindane or organophosphates repeated after 1–2 weeks and ivermectin given twice at 2-week intervals been reported to be effective. It is important to treat the whole herd and new introductions.

Notes: Sarcoptic mange is one of the most important diseases of camels and can also be transmitted to humans.

Chorioptes bovis

Synonyms: *Chorioptes ovis*, *Chorioptes equi*, *Chorioptes caprae*, *Chorioptes cuniculi*

Predilection site: Skin; particularly the legs, feet, base of tail and upper rear surface of the udder

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Psoroptidae

Description: In the adult female, tarsi I, II and IV have short-stalked pretarsi and tarsi III have a pair of long, terminal, whip-like setae. The first and second pairs of legs are stronger than the others and the fourth pair has long slender tarsi. In the male, all legs possess short-stalked pretarsi and pulvilli. However, the fourth pair is extremely short, not extending beyond the body margin. Male *C. bovis* are characterised by a very long opisthosomal seta 1 (ae) and short spatulate setae 2 (l4 and d5), on well-developed posterior lobes (see Fig. 3.93). The mouthparts are distinctly rounder, and the abdominal tubercles of the male are noticeably more truncate than those of *Psoroptes*.

Hosts: Cattle, sheep, horse, goat, camel, llama, rabbit

Notes: Has been reported in dromedary camels in zoos.

For more details see Chapter 8.

Hyalomma dromedarii

Common name: Camel tick

Predilection site: All over the body but especially the axilla, inguinal region, face and ears

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: *Hyalomma dromedarii* is usually inornate but with banded legs; eyes are present and festoons are sometimes present. The second segment of the palps is usually less than twice as long as the third segment, and the scutum has no pattern.

Hosts: Camels, but may also be of veterinary significance in ruminants and horses

Geographical distribution: India to Africa

For more details see Chapter 17.

A number of non-obligate ectoparasites are found on camels and these are listed in the host–parasite checklists at the end of this chapter. More detailed descriptions of these parasites can also be found in Chapter 17.

LLAMAS, ALPACAS, GUANACOS, VICUÑAS

Several species of parasites are unique to camelids, for example coccidia and lice. However, there are a number of parasites

for which camelids are an alternate or aberrant host. Parasites unique to these hosts are covered in detail in this chapter; others which are parasites of cattle or sheep will be mentioned or briefly described, and are covered in greater detail under their respective host chapters.

ENDOPARASITES

Parasites of the digestive system

Gongylonema pulchrum

Common name: Gullet worm

Predilection site: Oesophagus, rumen

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description: A long, slender whitish worm, the males being about 5.0 cm and the females up to about 14.0 cm in length. Asymmetrical cervical alae are prominent and the anterior end has longitudinal rows of cuticular plaques. The tail of the male has asymmetrical alae with 10 pairs of papillae. The left spicule is long and slender whereas the right spicule is short and stout. The male has a gubernaculum.

Final hosts: Sheep, goat, cattle, pig, buffalo, horse, donkey, deer, camel, camelids, human

Intermediate hosts: Coprophagous beetles, cockroaches

Geographical distribution: Probably worldwide

For more details see section Deer, and Chapter 9.

Abomasum

The following nematode species have been reported in the abomasum of camelids in their country of origin, Peru. Their pathogenicities are unknown.

Graphinema aucheniae

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: Male worms measure about 5.5–8.0 mm and females 9–12 mm in length. These worms have a small buccal capsule, a claviform oesophagus and cervical papillae. The male bursa has a small anteroventral ray and a widely divergent posteroventral ray. The dorsal ray bifurcates near the distal tip, with each branch dividing distally. The spicules are long and pointed.

Hosts: Alpaca, llama and vicuña

Spiculoptera peruvianus**Predilection site:** Abomasum**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Trichostrongyloidea**Description:** Males measure 6.5–8.0 mm and females 8.5–10 mm in length.**Hosts:** Alpaca, llama and vicuña***Camelostrogylus mentulatus*****Predilection site:** Abomasum, small intestine**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Trichostrongyloidea**Description:** *Camelostrogylus mentulatus* is similar in size to *Ostertagia ostertagi*. Males are 6.5–7.5 mm and females 8–10 mm long. The bursa possesses two large lateral lobes and the spicules are narrow, long, denticulated and of equal length. Eggs measure about 75–85 by 40–50 µm.**Hosts:** Camel, llama, sheep, goat**Geographical distribution:** Common in the Middle East and Australia; South America**Pathogenesis:** Generally of low pathogenicity and considered of little importance.**Pathology:** Heavy infections can produce gastric hyperplasia and increase in abomasal pH, similar to that seen in *Ostertagia* infection.

Additionally, several cattle and sheep nematode species have been reported in farmed camelids (Table 14.12).

Small intestine

Intestinal species reported in camelids are generally of little clinical significance. Many of the species listed are parasites of cattle or sheep and are described in more detail under the chapters for these hosts.

Lamanema chavezii**Predilection site:** Small intestine, with immature stages in the liver and lungs**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Trichostrongyloidea**Description, gross:** Small worms, males 9–11 mm and females 14–18 mm long.**Description, microscopic:** Shallow buccal capsule with dorsal tooth and two small lateroventral teeth at the base. In the male, the lateral lobes are large; the dorsal lobe is small. There are short spicules and large gubernaculum.**Hosts:** Alpaca (*Lama pacos*), vicuña (*Vicugna vicugna*)**Geographical:** South America**Clinical signs:** Large infections can cause respiratory and hepatic failure.**Pathology:** The penetration and migration of larvae through the wall of the intestine can cause catarrhal haemorrhagic enteritis with localised necrosis. Areas of congestion may be present in the lungs with petechial haemorrhages and necrosis in the hepatic tissue. These liver lesions can calcify following re-migration of larvae to the intestine.***Nematodirus lamae*****Predilection site:** Small intestine**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Trichostrongyloidea**Description:** Small worms, males 10–13 mm and females 14–20 mm long. Male worms have a deeply emarginated dorsal lobe with two distinct lobules; there are long spicules with enlarged distal ends terminating in two distinct bifurcated medioventral processes.**Hosts:** Alpaca (*Lama pacos*), llama, vicuña (*Vicugna vicugna*)**Geographical distribution:** South America**Pathogenicity:** Not reported**Table 14.12** Cattle and sheep parasites found in the abomasa of camelids.

| Species | (Super)family | Hosts | Geographical distribution |
|-----------------------------------|---------------------|--|--|
| <i>Teladorsagia circumcincta</i> | Trichostrongyloidea | Cattle, sheep, goat, deer, camel, llama | Worldwide |
| <i>Ostertagia leptospicularis</i> | Trichostrongyloidea | Deer (roe deer), cattle, sheep, goat, camel | Many parts of the world, particularly Europe and New Zealand |
| <i>Haemonchus contortus</i> | Trichostrongyloidea | Sheep, goat, cattle, deer, camel, llama | Worldwide |
| <i>Marshallagia marshalli</i> | Trichostrongyloidea | Sheep, goat and wild small ruminants | Tropics and subtropics including southern Europe, USA, South America, India and Russia |
| <i>Trichostrongylus axei</i> | Trichostrongyloidea | Cattle, sheep, goat, deer, horse, donkey, pig and occasionally human | Worldwide |

Table 14.13 Cattle and sheep parasites found in the small intestine of camelids.

| Species | (Super)family | Hosts | Geographical distribution |
|--|---------------------|---|--|
| Nematodes | | | |
| <i>Trichostrongylus vitrinus</i> | Trichostrongyloidea | Sheep, goat, deer, llama and occasionally pig and human | Worldwide |
| <i>Trichostrongylus colubriformis</i> | Trichostrongyloidea | Sheep, goat, cattle, camel and occasionally pig and human | Worldwide |
| <i>Trichostrongylus longispicularis</i> | Trichostrongyloidea | Cattle, sheep, goat, deer, camel, llama | Australia, America and parts of Europe |
| <i>Nematodirus helvetianus</i> | Trichostrongyloidea | Cattle, occasionally sheep, goat and other ruminants | Worldwide |
| <i>Nematodirus battus</i> | Trichostrongyloidea | Sheep, goat, camelids, occasionally cattle | UK, Norway, Sweden, Netherlands, Canada |
| <i>Cooperia surnabada</i> (syn. <i>Cooperia mcmasteri</i>) | Trichostrongyloidea | Cattle, sheep, camel | Parts of Europe, North America and Australia |
| <i>Bunostomum trigonocephalum</i> | Ancylostomatoidea | Sheep, goat, camel | Worldwide |
| <i>Strongyloides papillosus</i> | Rhabditoidea | Sheep, cattle, other ruminants and rabbits | Worldwide |
| Cestodes | | | |
| <i>Moniezia expansa</i> | Anoplocephalidae | Sheep, goats, occasionally cattle Intermediate hosts: forage mites | Worldwide |

Table 14.13 lists parasites of cattle or sheep which have been reported in the small intestine of camelids.

The following species of *Eimeria* have been described from the faeces of alpacas in their native country of Peru. Details of their life cycle, pathogenicity, etc. are not known.

Eimeria lamae

Predilection site: Unknown

Phylum: Apicomplexa

Class: Aconoidasida

Family: Eimeriidae

Description: The oocysts are ellipsoidal to ovoid, smooth, bluish to greenish yellow, 30–40 by 21–30 μm , with a micropyle and micropylar cap, with or without a polar granule, but without an oocyst residuum (Fig. 14.4). Sporocysts are elongate ovoid, 13–16 by 8–10 μm , with a Stieda body and a residuum. Sporozoites are elongate, with one to three clear globules.

Host: Alpaca

Eimeria alpaca

Predilection site: Unknown

Phylum: Apicomplexa

Class: Aconoidasida

Family: Eimeriidae

Description: The oocysts are ellipsoidal, rarely ovoid, pale green-blue, smooth, 22–26 by 18–21 μm , with a micropyle and micropylar cap, with or without polar granules and without an oocyst residuum. Sporocysts are ovoid, 10–13 by 7–8 μm , with a faint Stieda body and a residuum. Sporozoites are elongate and lie lengthwise head to tail in the sporocyst with one to three clear granules.

Host: Alpaca

Eimeria punoensis

Predilection site: Unknown

Phylum: Apicomplexa

Class: Aconoidasida

Fig. 14.4 Oocyst of *Eimeria lamae*.

Family: Eimeriidae

Description: Oocysts are ellipsoidal, smooth, 17–22 by 14–19 μm (mean $19.9 \times 16.4 \mu\text{m}$), with a micropyle, micropylar cap and polar granules. Sporocysts are elongate, 9.2 by 6.1 μm , with a faint Stieda body and a sporocyst residuum.

Host: Alpaca

Eimeria macusaniensis

Predilection site: Unknown

Phylum: Apicomplexa

Class: Aconoidasida

Family: Eimeriidae

Description: The oocysts are ovoid, sometimes pyriform, brown with a thick wall, 81–107 by 61–80 μm , with a micropyle and micropylar cap, but without a polar granule or oocyst residuum. Sporocysts are elongate ovoid, 33–40 by 16–20 μm , with a faint Stieda body and a residuum. Sporozoites are elongate, with a clear globule at the large end and a small one at the small end.

Host: Alpaca

Cryptosporidium parvum

For more details see Chapter 8.

Giardia intestinalis

Synonyms: *Giardia duodenalis*, *Giardia lamblia*, *Lamblia lamblia*

Predilection site: Small intestine

Phylum: Fornicata

Class: Treponomadea

Family: Giardiidae

Description: The trophozoite has a pyriform to ellipsoidal, bilaterally symmetrical body, 12–15 μm long by 5–9 μm wide. The dorsal side is convex and there is a large sucking disc on the ventral side (see Fig. 2.21). There are two anterior nuclei, two slender axostyles, eight flagellae in four pairs and a pair of darkly staining median bodies. The median bodies are curved bars resembling the claws of a hammer. Cysts are ovoid, 8–12 by 7–10 μm , and contain four nuclei.

Hosts: Human, cattle, sheep, goat, pig, horse, alpaca, dog, cat, guinea pig, chinchilla

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Infections in alpacas are considered non-pathogenic.

For more details see Chapter 8.

Large intestine

See Table 14.14 for the cattle and sheep parasites found in the large intestine of camelids.

Parasites of the respiratory system

Cephenemyia spp.

Common name: Deer nasopharyngeal/throat bot

Predilection site: Nasopharynx

Class: Insecta

Family: Oestridae

Host: Llama

Clinical signs: As the llama is an aberrant host the signs of infection can be more marked and a granulomatous swelling may occur in the nasal cavity and the nasopharynx, with coughing and sneezing present. Breathing can become impaired.

For more details see section Deer.

Dictyocaulus filaria

Predilection site: Lungs

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: The worms are white with the intestine visible as a dark band. Males measure around 4–8 cm and the females 6–10 cm in length. In the bursa the posterolateral and the mediolateral rays are fused together, except at their extremities. The dark-brown spicules are stout and shaped like a boot. The vulva is located just posterior to the middle of the worm.

Hosts: Sheep, goat, camelids and a few wild ruminants

Geographical distribution: Worldwide

Table 14.14 Cattle and sheep parasites found in the large intestine of camelids.

| Species | (Super)family | Hosts | Geographical distribution |
|------------------------------------|---------------|---|---|
| <i>Oesophagostomum venulosum</i> | Strongyloidea | Sheep, goat, deer, camel | Worldwide |
| <i>Oesophagostomum columbianum</i> | Strongyloidea | Sheep, goat, deer, camel | Worldwide; more important in tropical and subtropical areas |
| <i>Chabertia ovina</i> | Strongyloidea | Sheep, goat occasionally deer, cattle and other ruminants | Worldwide but more prevalent in temperate regions |
| <i>Trichuris ovis</i> | Trichuroidea | Sheep, goat, occasionally cattle and other ruminants | Worldwide |
| <i>Skryabinema ovis</i> | Oxyuroidea | Sheep, goat, guanaco | Worldwide |

Pathogenesis and clinical signs: Severe infections cause depression, coughing, dyspnoea and loss of condition.

Epidemiology: *Dictyocaulus filaria* is found in the respiratory tract of camelids in many areas of the world.

Treatment and control: Benzimidazoles, levamisole and avermectins are all reported to be effective against this species in camels.

For more details of these species see Chapter 9.

Dictyocaulus viviparus

Synonym: *Dictyocaulus cameli*

Predilection site: Lungs

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: The adults are slender thread-like worms; males measure around 4.0–5.5 cm and females 6–8 cm in length. The buccal ring is triangular in shape. They are very similar to *D. filaria* but the posterolateral and mediolateral rays are entirely fused together.

Hosts: Cattle, deer, camel, camelids

Geographical distribution: Worldwide

Pathogenesis and clinical signs: As for *D. filaria*.

For more details see Chapter 8.

Parasites of the liver

Fasciola hepatica

Common name: Liver fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description: Adult fluke are leaf-shaped (being broader anteriorly than posteriorly), grey–brown in colour and around 2.5–3.5 cm in length and 1.0 cm in width (see Fig. 1.70a). The anterior end is conical and marked off by distinct shoulders from the body. The tegument is covered with backwardly projecting spines. An oral and ventral sucker, situated at the level of the shoulders, may be readily seen. The intestinal caeca have many branches and extend a considerable distance posteriorly. The testes and ovary are multi-branched. The uterus is positioned anterior to the testes. The cirrus is well developed. Immature fluke at the time of entry into the liver are 1.0–2.0 mm in length and lancet-like.

Final hosts: Sheep, cattle, goat, horse, deer, llama, human and other mammals

For more details see Chapter 9.

Fasciola gigantica

Common name: Tropical large liver fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description: The adult fluke is larger than *F. hepatica*, the body is more transparent and it can reach 7.5 cm in length and 1.5 cm in breadth. The shape is more leaf-like, the conical anterior end is very short and the shoulders, characteristic of *F. hepatica*, are barely perceptible (see Fig. 1.70b). The gut caeca are more highly branched than in *F. hepatica*.

Final hosts: Cattle, buffalo, sheep, goat, pig, camel, deer, llama, human

For more details see Chapter 8.

Dicrocoelium dendriticum

Synonym: *Dicrocoelium lanceolatum*

Common name: Small lanceolate fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Dicrocoeliidae

Description: Adult fluke are 6–12 mm long and 1.5–2.5 mm wide, distinctly lanceolate and semi-transparent/translucent, allowing the internal organs to be readily seen (see Fig. 1.74). Fluke are almost symmetrical in shape and the cuticle is smooth. The oral sucker is smaller than the ventral sucker and is located in close proximity. The gut is simple, consisting of two branches and resembles a tuning fork. Behind the ventral sucker the lobed testes lie in tandem with the ovary immediately posterior. The uterus is usually dark brown and convoluted, filling the space behind the genital gland. The cirrus is small. There are no spines on the cuticle (cf. *Fasciola*).

Final hosts: Sheep, goat, cattle, deer, llama and rabbit; occasionally horse and pig

Geographical distribution: Worldwide except for South Africa and Australia

For more details see Chapter 9.

Echinococcus granulosus

Predilection site: Mainly liver and lungs (intermediate hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description: Hydatid cysts are large fluid-filled vesicles 5–10 cm in diameter, with a thick concentrically laminated cuticle and an internal germinal layer (see Figs 9.44 and 9.45). The germinal layer

produces numerous small vesicles or brood capsules each containing up to 40 scolices, invaginated into their neck portions and attached to the wall by stalks. Brood capsules may become detached from the wall of the vesicle and float freely in the vesicular fluid and form ‘hydatid sand’.

Final hosts: Dog and many wild canids

Intermediate hosts: Domestic and wild ruminants, human and primates, pig, camelids and lagomorphs

For more details see Chapter 9.

Parasites of the nervous system

Parelaphostrongylus tenuis

Synonyms: *Odocoileostrongylus tenuis*, *Elaphostrongylus tenuis*

Common names: Cerebrospinal nematodosis, meningeal worm, moose sickness, moose disease

Predilection site: Veins and venous sinuses of cranial meninges, CNS

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description: Males measure around 40 mm and females up to 90 mm in length.

Final hosts: White-tailed deer (*Odocoileus virginianus*), moose (*Alces alces*), wapiti (*Cervus canadensis*), other deer species, llama, guanaco, alpaca

Intermediate hosts: Snails and slugs

Pathogenesis: The parasite is well adapted to its normal definitive host but in an aberrant host such as the llama the migration of the larvae in the spinal cord can cause neurological symptoms which relate to their exact location.

Clinical signs: These include ataxia, circling, lameness, paraplegia, hypermetria and blindness.

Control: Management procedures such as fencing to protect farmed camelids from white-tailed deer can be effective. Where applicable a molluscicide may be used to reduce the numbers of snails and slugs.

For more details see section Deer.

Parasites of the reproductive/urogenital system

No parasites of veterinary significance reported.

Parasites of the locomotory system

Toxoplasma gondii

See section Camels.

Table 14.15 *Sarcocystis* species found in camelids.

| Species | Camelid host(s) | Final host | Distribution |
|---|---------------------------|------------|---------------|
| <i>Sarcocystis aucheniae</i> (syn. <i>Sarcocystis tiopodi</i> , <i>Sarcocystis guanicoensis</i>) | Llama, guanaco, alpaca | Dog | South America |
| <i>Sarcocystis lamacensis</i> | Llama | Unknown | South America |

Sarcocystosis

Several species of *Sarcocystis* have been reported in camelids (Table 14.15). Specific descriptions are outwith the scope of this book. Further general details on nomenclature, diagnosis and epidemiology are given in Chapter 2.

ECTOPARASITES

Microthoracius mazzai

Common name: Llama louse

Predilection site: Hair, particularly around the face

Class: Insecta

Order: Phthiraptera

Suborder: Anoplura

Family: Microthoraciidae

Description: *Microthoracius mazzai* has a very characteristic elongated spindle-shaped head, which is almost as long as its swollen rounded abdomen (see Fig. 14.3). The entire body is 1–2 mm in length.

Hosts: Alpaca, llama

Geographical distribution: Worldwide, in association with its host

Pathogenesis: These lice are blood-feeders and heavy infestations can significantly reduce weight gain and milk production.

Clinical signs: The signs of infestation are variable. Light infestation may have no obvious effects, but pruritis, dermatitis and hair loss are usually evident at heavier parasite loads. Anaemia may be seen in young animals with heavy infestations.

Diagnosis: The lice can be seen in the hair of the host animal when the hair is parted. The eggs (nits) may be seen glued to hair shafts.

Epidemiology: Infection usually occurs after direct contact with an infested host animal. Cross-contamination between different host species is possible if the animals have physical contact. Transfer may occur from a contaminated environment or grooming equipment as the lice can survive for short periods off the host.

Treatment and control: Dips, dusts and sprays containing coumaphos, malathion or permethrin may be effective, particularly if applied after shearing. Macrocyclic lactones, such as ivermectin, doramectin and moxidectin, given in a repeated treatment programme of 7–10 days may also be highly effective.

Psoroptes ovis

Synonyms: *Psoroptes communis* var. *ovis*, *Psoroptes cuniculi*, *Psoroptes cervinus*, *Psoroptes bovis*, *Psoroptes equi*, *Psoroptes aucheniae*

Common name: Scab mite

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Psoroptidae

Description: Mites of the genus *Psoroptes* are non-burrowing mites, up to 0.75 mm in length and oval in shape (see Fig. 3.92). All the legs project beyond the body margin. Its most important recognition features are the pointed mouthparts and the three-jointed pretarsi (pedicels) bearing funnel-shaped suckers (pulvilli) (see Fig. 3.87). Adult females have jointed pretarsi and pulvilli on the first, second and fourth pairs of legs and long whip-like setae on the third pair. In contrast, the smaller adult males, which are recognisable by their copulatory suckers and paired posterior lobes, have pulvilli on the first three pairs of legs and setae on the fourth pair. The legs of adult females are approximately the same length, whereas in males the fourth pair is extremely short.

Hosts: Sheep, cattle, goat, horse, rabbit, camelids

Geographical distribution: Worldwide, particularly Europe and South America

For more details see Chapter 9.

Chorioptes bovis

Synonyms: *Chorioptes ovis*, *Chorioptes equi*, *Chorioptes caprae*, *Chorioptes cuniculi*

Predilection site: Skin; particularly the legs, feet, base of tail and upper rear surface of the udder

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Psoroptidae

Description: In the adult female, tarsi I, II and IV have short-stalked pretarsi and tarsi III have a pair of long, terminal, whip-like setae. The first and second pairs of legs are stronger than the others and the fourth pair has long slender tarsi. In the male, all legs possess short-stalked pretarsi and pulvilli. However, the fourth pair is extremely short, not extending beyond the body margin. Male *C. bovis* are characterised by a very long opisthosomal seta 1 (ae) and short spatulate setae 2 (l4 and d5), on well-developed posterior lobes (see Fig. 3.93). The mouthparts are distinctly rounder, and the abdominal tubercles of the male are noticeably more truncate than those of *Psoroptes*.

Hosts: Cattle, sheep, horse, goat, camel, llama, rabbit

For more details see Chapter 8.

Sarcoptes scabiei

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Sarcoptidae

Description: The adult of this species has a round, ventrally flattened, dorsally convex body. Adult females are 0.3–0.6 mm long and 0.25–0.4 mm wide, while males are smaller, typically up to 0.3 mm long and 0.1–0.2 mm wide. The posterior two pairs of limbs do not extend beyond the body margin. In both sexes, the pretarsi of the first two pairs of legs bear empodial claws and a sucker-like pulvillus, borne on a long stalk-like pretarsus. The sucker-like pulvilli help the mite grip the substrate as it moves. The third and fourth pairs of legs in the female and the third pair of legs in the male end in long setae and lack stalked pulvilli. The mouthparts have a rounded appearance. These mites have no eyes or stigmata. The dorsal surface of the body of *S. scabiei* is covered with transverse ridges, but also bears a central patch of triangular scales. The dorsal setae are strong and spine-like. The anus is terminal and only slightly dorsal. There are a number of host-adapted varieties of *S. scabiei* that differ subtly in their morphology.

Hosts: Llama, guanaco, alpaca, vicuña

For more details see Chapter 11.

A number of non-obligate ectoparasites are found on camelids and these are listed in the host–parasite checklists at the end of this chapter. More detailed descriptions of these parasites can be found in Chapter 17.

WATER BUFFALO

The water buffalo, or domestic Asian water buffalo (*Bubalus bubalis*), is a large buffalo found on the Indian subcontinent. Buffalo breeds and populations have been established in countries throughout Europe, the Middle East, Asia, North and South America, China and Australia.

ENDOPARASITES**Parasites of the digestive system*****Gongylonema pulchrum***

Common name: Gullet worm

Predilection site: Oesophagus, rumen

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description: A long, slender, whitish worm, the males being about 5.0 cm and the females up to about 14.0 cm in length. Asymmetrical cervical alae are prominent and the anterior end has longitudinal rows of cuticular plaques. The tail of the male has asymmetrical alae

Table 14.16 Rumen fluke found in buffalo.

| Species | Hosts | Site | Intermediate hosts |
|--|--|------------------|---|
| Paramphistomatidae | | | |
| <i>Paramphistomum cervi</i> (syn. <i>Paramphistomum explanatum</i>) | Cattle, sheep, goat, deer, buffalo, antelope | Rumen | Freshwater snails (<i>Bulinus</i> spp., <i>Planorbis</i> spp.) |
| <i>Paramphistomum microbothrium</i> | Cattle, sheep, goat, deer, buffalo, antelope | Rumen | Freshwater snails (<i>Fossaria</i> spp., <i>Bulinus</i> spp.) |
| <i>Cotylophorum cotylophorum</i> (syn. <i>Paramphistomum cotylophorum</i>) | Sheep, goats, cattle and wild ruminants | Rumen, reticulum | Freshwater snails (<i>Bulinus</i> spp.) |
| <i>Calicophoron calicophorum</i> (syn. <i>Paramphistomum calicophorum</i>) | Cattle, sheep, other ruminants | Rumen, reticulum | Water snails |
| <i>Carmyerius gregarius</i> | Cattle, buffalo | Rumen | Water snails |
| Gastrothylacidae | | | |
| <i>Gastrothylax crumenifer</i> | Cattle, buffalo, zebu, sheep and other ruminants | Rumen, reticulum | Freshwater snails |
| <i>Fischoederius elongatus</i> | Cattle, buffalo, zebu, sheep and other ruminants; rarely human | Rumen, duodenum | Freshwater snails |
| <i>Fischoederius cobboldi</i> | Cattle, buffalo, zebu, sheep and other ruminants | Rumen, duodenum | Freshwater snails |

with 10 pairs of papillae. The left spicule is long and slender whereas the right spicule is short and stout. The male has a gubernaculum.

Final hosts: Sheep, goat, cattle, pig, buffalo, horse, donkey, deer, camel, camelids, human and primates

Intermediate hosts: Coprophagous beetles, cockroaches

Geographical distribution: Probably worldwide

For more details see section Deer, and Chapter 9.

Rumen and reticulum

Several species of rumen fluke belonging to the genera of the families Paramphistomatidae and Gastrothylacidae are found in buffalo and are summarised in Table 14.16. For more details on these rumen fluke species refer to Chapters 1, 8 and 9.

Abomasum

Mecistocirrus digitatus

Predilection site: Abomasum

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: To the naked eye, the worm is indistinguishable from *Haemonchus contortus*, although it is closely related to *Nematodirus*. The white ovary is wrapped around the red blood-filled intestine giving it a 'barbers pole' appearance. The males measure up to around 30 mm and the females 42 mm in length.

Description, microscopic: The male is distinguishable from *Haemonchus* by the presence of long narrow spicules that are fused together for the majority of their length and the tips are enclosed in a spindle-shaped appendage (in *Haemonchus* the spicules are thicker, separate and barbed at the tips). The dorsal ray is symmetrically located in the bursa, whereas in *Haemonchus* the dorsal ray is asymmetrical. The female differs from *Haemonchus* in that the

slit-shaped vulva is positioned nearer to the tip of the tail and there is no vulval flap. The cuticle contains many longitudinal ridges and the cervical papillae are readily apparent. The small buccal capsule is armed with a lancet. The eggs are large and unlike *Nematodirus*, typically strongylate and measure around 100 µm in length.

Hosts: Cattle, buffalo, zebu, sheep and goat; occasionally the stomach of the pig and rarely human

Geographical distribution: Tropical and subtropical regions, particularly Central America and parts of Asia

The nematode species listed in Table 14.17 have been reported in the abomasum of water buffalo in various countries in which they are found. Their pathogenicities are unknown.

Intestines

Toxocara vitulorum

Synonym: *Neoascaris vitulorum*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: This is a very large whitish nematode. The adult male is up to 25 cm and the female up to 30 cm in length.

Table 14.17 Cattle parasites found in the abomasa of water buffalo.

| Species | Superfamily | Hosts | Geographical distribution |
|------------------------------|---------------------|--|---------------------------|
| <i>Ostertagia ostertagi</i> | Trichostrongyloidea | Cattle, deer and occasionally goat | Worldwide |
| <i>Haemonchus contortus</i> | Trichostrongyloidea | Sheep, goat, cattle, deer, camel, llama | Worldwide |
| <i>Trichostrongylus axei</i> | Trichostrongyloidea | Cattle, sheep, goat, deer, horse, donkey, pig and occasionally human | Worldwide |

Table 14.18 Cattle parasites found in the intestines of water buffalo.

| Species | (Super)family | Hosts | Geographical distribution |
|---|---------------------|--|---|
| Small intestine | | | |
| <i>Trichostrongylus longispicularis</i> | Trichostrongyloidea | Cattle, sheep, goat, deer, camel, llama | Ruminants in Australia; cattle in America and parts of Europe |
| <i>Nematodirus helvetianus</i> | Trichostrongyloidea | Cattle, occasionally sheep, goat and other ruminants | Worldwide |
| <i>Cooperia oncophora</i> | Trichostrongyloidea | Cattle, sheep, goat, deer | Worldwide |
| <i>Bunostomum phlebotomum</i> | Ancylostomatoidea | | Worldwide |
| <i>Agriostomum vryburgi</i> | Ancylostomatoidea | Cattle, buffalo, ox and zebu | |
| <i>Strongyloides papillosus</i> | Rhabditoidea | Sheep, cattle, other ruminants, rabbit | Worldwide |
| <i>Capillaria bovis</i> | Trichuroidea | Cattle, sheep, goat | Worldwide |
| <i>Moniezia benedeni</i> | Anoplocephalidae | Cattle, buffalo | Worldwide |
| <i>Avitellina centripunctata</i> | Anoplocephalidae | Sheep and other ruminants | Europe, Africa and Asia |
| Large intestine | | | |
| <i>Oesophagostomum radiatum</i> | Strongyloidea | Cattle, buffalo | Worldwide |
| <i>Trichuris discolor</i> | Trichuroidea | Cattle, buffalo, occasionally sheep, goat | Europe, Asia, USA |

Description, microscopic: The cuticle is less thick than other ascarids and somewhat soft and translucent. There are three lips, broad at the base and narrowing anteriorly. The oesophagus is 3–4.5 mm long and has a posterior granular ventriculus. The tail of the male usually forms a small spike-like appendage. There are about five pairs of post-cloacal papillae; the anterior pair is large and double. Pre-cloacal papillae are variable in number. The vulva is situated about one-eighth of the body length from the anterior end. The medium-sized egg of *T. vitulorum* is subglobular, with a thick finely pitted albuminous shell, is almost colourless and measures 75–95 by 60–74 µm. The egg is unsegmented and the granular contents frequently only occupy part of the internal volume.

Hosts: Cattle, buffalo and zebu, rarely sheep and goats

Geographical distribution: Africa, India, Asia

Epidemiology: Infection is highly prevalent in water buffalo calves between 2 weeks and 3 months of age and can be responsible for high morbidity and mortality rates in calves, resulting in serious economic losses. Infection can be transmitted by the transplacental and transmammary routes. Peak egg output occurs between 30 and 45 days post infection. Following peak infection around 4 months of age, the onset of immunity results in a rapid decline in faecal egg output.

Clinical signs: The presence of adult worms in the small intestine of young calves results in growth reduction and diarrhoea.

Treatment and control: Adult worms are sensitive to a wide range of anthelmintics and young calves should be treated at 3–6 weeks of age.

Homalogaster paloniae

Predilection site: Large intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Gastrodiscidae

Description, gross: The body is divided into two with a large anterior region and small cylindrical posterior region.

Hosts: Buffalo and cattle

Intermediate hosts: Water snails

Geographical distribution: Asia, Australasia

Pathogenesis: Generally considered to be non-pathogenic.

Treatment and control: Not required

A number of intestinal helminths of cattle have been reported in water buffalo (Table 14.18). These parasites are described in more detail in Chapter 8.

Several species of *Eimeria* have been described and appear specific to water buffalo. In addition, species found in cattle have also been reported in water buffalo but their significance is not known (Table 14.19).

Eimeria ankarensis

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Table 14.19 Cattle coccidia reported in the intestines of water buffalo.

| Species | Site | Distribution |
|------------------------------|---------------------------|-----------------------------------|
| <i>Eimeria alabamensis</i> | Small and large intestine | Presumed worldwide, mainly Europe |
| <i>Eimeria auburnensis</i> | Small intestine | Worldwide |
| <i>Eimeria bovis</i> | Small and large intestine | Worldwide |
| <i>Eimeria brasiliensis</i> | Unknown | Worldwide |
| <i>Eimeria bukidonensis</i> | Small and large intestine | Worldwide |
| <i>Eimeria canadensis</i> | Unknown | Worldwide |
| <i>Eimeria cylindrica</i> | Unknown | Worldwide |
| <i>Eimeria ellipsoidalis</i> | Small intestine | Worldwide |
| <i>Eimeria subspherica</i> | Unknown | Worldwide |
| <i>Eimeria wyomingensis</i> | Unknown | Worldwide |
| <i>Eimeria zuernii</i> | Small and large intestine | Worldwide |

Description: Oocysts are ovoid, 32–43 by 25–29 μm (mean $37.5 \times 27 \mu\text{m}$), with a micropyle and thick yellowish-brown wall. Sporocysts are elongate, almost ellipsoidal, with a Stieda body and residuum, with sporozoites that are elongate and comma-shaped with two clear globules. Sporulation time is 3–4 days.

Geographical distribution: Turkey

Eimeria bareillyi

Synonym: *Eimeria bubalis*

Predilection site: Jejunum

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are pyriform, 24–35 by 15–25 μm (mean $29.5 \times 20 \mu\text{m}$), with a micropyle and residuum and with a smooth brown wall. Sporocysts are lemon-shaped, with a Stieda body and residuum, and with sporozoites that are banana-shaped with a clear globule at the large end and sometimes one to two smaller ones.

Geographical distribution: Asia, Europe

Eimeria gokaki

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, 22–31 by 18–25 μm (mean $26.5 \times 21.5 \mu\text{m}$), with an orange wall and micropyle but without a residuum. Sporocysts are elongate.

Geographical distribution: India

Eimeria ovoidalis

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, 32–40 by 20–28 μm (mean $36 \times 24 \mu\text{m}$), with a pinkish-orange wall and micropyle but without a residuum. Sporocysts are ovoid with a Stieda body and residuum. The sporulation time is 4–5 days.

Geographical distribution: India

Eimeria thianethi

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, 34–49 by 20–28 μm (mean $44 \times 26 \mu\text{m}$), with a greyish-yellow wall and distinct micropyle but without a residuum. Sporocysts are lemon-shaped with a pointed end and residuum.

Geographical distribution: Georgia, India

Cryptosporidium parvum

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Description: Mature oocysts are ovoidal or spheroidal, 5.0 by 4.5 μm in size (range $4.6\text{--}5.4 \times 3.8\text{--}4.7 \mu\text{m}$), with a length/width ratio of 1.19.

Hosts: Cattle, sheep, goat, horse, deer, human

Geographical distribution: Worldwide

Epidemiology: *Cryptosporidium* oocysts have been found in buffalo faeces from all countries where they are bred.

Parasites of the respiratory system

Mammomonogamus laryngeus

Synonym: *Syngamus laryngeus*

Common name: Gapeworm

Predilection site: Larynx

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: The worms are reddish in appearance and about 0.5–2 cm long. The females and males are found in permanent copulation. The buccal capsule lacks a cuticular crown.

Description, microscopic: Eggs are ellipsoid, 42–45 by 75–85 μm , with no operculum at either end.

Hosts: Cattle, buffalo, goat, sheep, deer, rarely human

Geographical distribution: Asia, Central Africa, South America and Caribbean islands

Pathogenesis and clinical signs: Infections are usually asymptomatic.

Dictyocaulus viviparus

Predilection site: Bronchi, trachea

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description: The adults are slender thread-like worms, males measuring around 4.0–5.5 cm and females 6–8 cm in length. The buccal ring is triangular in shape. First-stage larvae are 300–360 µm with the intestinal cells containing numerous chromatin granules.

Hosts: Cattle, buffalo, deer (red deer) and camel

Geographical distribution: Worldwide, but especially important in temperate climates with a high rainfall

Parasites of the liver

Fasciola gigantica

Common name: Tropical large liver fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description: The adult fluke is larger than *F. hepatica*, the body is more transparent, and it can reach 7.5 cm in length and 1.5 cm in breadth. The shape is more leaf-like, the conical anterior end is very short and the shoulders, characteristic of *F. hepatica*, are barely perceptible (see Fig. 1.70b).

Final hosts: Cattle, buffalo, sheep, goat, pig, camel, deer, human

Intermediate hosts: Snails of the genus *Galba* (syn. *Lymnaea*); in southern Europe it is *L. auricularia*, which is also the important species in the southern USA, the Middle East and the Pacific Islands.

Geographical distribution: Africa, Asia, Europe, USA

Epidemiology: Infection can have a huge economic impact as water buffalo are the main beasts of labour in rice fields in some countries, and important for meat and milk production. In India and Pakistan, young calves acquire infection during early winter and suffer an acute condition leading to death.

Clinical signs: Fluke infections in buffalo are usually chronic, leading to weight loss and poor performance.

Diagnosis: Diagnosis is based on clinical signs or the presence of eggs in faeces.

Fasciola hepatica

Common name: Liver fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Description, gross: The young fluke at the time of entry into the liver is 1.0–2.0 mm in length and lancet-like. When it has become

fully mature in the bile ducts it is leaf-shaped, grey–brown in colour and is around 2.5–3.5 cm in length and 1.0 cm in width. The anterior end is conical and marked off by distinct shoulders from the body (see Fig. 1.70a).

Description, microscopic: The tegument is covered with backwardly projecting spines. An oral and ventral sucker may be readily seen.

Final hosts: Sheep, cattle, goat, horse, deer, human and other mammals

Intermediate hosts: Snails of the genus *Galba* (*Lymnaea*)

Gigantocotyle explanatum

Synonyms: *Explanatum explanatum*, *Paramphistomum explanatum*

Predilection site: Liver, intrahepatic ductules, bile ducts, gallbladder, duodenum

Phylum: Platyhelminthes

Class: Trematoda

Family: Paramphistomatidae

Description, gross: These are conical pinkish flukes when fresh. Adult flukes are 8–10 mm in length by 4.7–5.7 mm in width.

Description, microscopic: The body tapers anteriorly and is curved ventrally with no tegumental papillae. The acetabulum is very large and the genital pore is bifurcal. The oval eggs measure 180–200 by 110–130 µm, are colourless and have an operculum.

Final hosts: Cattle, buffalo and other ruminants

Intermediate hosts: Snails

Geographical distribution: Indian subcontinent, Southeast Asia, tropical and subtropical regions of the Middle East and Africa

Pathogenesis: Large numbers of immature flukes can cause amphistomosis with enteritis which in some cases, particularly young buffaloes, can be fatal to the host. The flukes can cause connective tissue proliferation and haemorrhages at the site of attachment.

Clinical signs: General wasting of body condition, diarrhoea and loss of weight.

Pathology: There is extensive fibrosis and hyperplasia of the bile ducts and multifocal granulomatous nodules occur over their luminal surface.

Echinococcus granulosus

Common names: Dwarf dog tapeworm, hydatidosis

Predilection site: Mainly liver and lungs (intermediate hosts); small intestine (definitive hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: Hydatid cysts are large fluid-filled vesicles 5–10 cm in diameter, with a thick concentrically laminated cuticle and an internal germinal layer (see Figs 9.44 and 9.45).

Description, microscopic: The germinal layer produces numerous small vesicles or brood capsules each containing up to 40 scolices, invaginated into their neck portions and attached to the wall by stalks. Brood capsules may become detached from the wall of the vesicle and float freely in the vesicular fluid and form ‘hydatid sand’.

Final hosts: Dog and many wild canids

Intermediate hosts: Cattle, sheep, camel, pig, buffalo, deer, human

Parasites of the pancreas

Eurytrema pancreaticum

Synonyms: *Distoma pancreaticum*, *Eurytrema ovis*

Common name: Pancreatic fluke

Predilection site: Pancreatic ducts

Phylum: Platyhelminthes

Class: Trematoda

Family: Dicrocoeliidae

Description: Oval, leaf-shaped, reddish-brown flukes measuring around 8–16 by 5–8.5 mm. The body is thick and the juvenile flukes are armed with spines which are often absent by the adult stage. The oral sucker is larger than the ventral sucker and the pharynx and oesophagus are short. The testes are positioned horizontally just behind the ventral sucker. A tubular cirrus sac is present. The uterus completely occupies the posterior body. Eggs measure around 40–50 by 25–35 µm and are similar to those of *Dicrocoelium*.

Final hosts: Cattle, buffalo, sheep, goat, pig, camel and human

Intermediate hosts: Two are required. Host 1: land snails, particularly of the genus *Bradybaena*. Host 2: grasshoppers of the genus *Conocephalus* or tree crickets (*Oecanthus*).

Geographical distribution: South America, Asia and Europe

Pathogenesis: Low to moderate infections cause little effect on the host. A general weight loss may occur in heavy infections.

Epidemiology: Buffalo are commonly infected with pancreatic fluke in Southeast Asia and Brazil.

Parasites of the circulatory system

Elaeophora poeli

Common name: Large aortic filariasis

Predilection site: Blood vessels

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Slender worms, males measuring around 4–7 cm and females up to 30 cm.

Description, microscopic: There are no lips and the oesophagus is very long. The tail of the male bears five to seven pairs of papillae, two pairs being pre-cloacal. Microfilariae are 340–360 µm.

Final hosts: Cattle, buffalo, zebu

Intermediate hosts: Not known, possibly tabanid flies

Geographical distribution: Parts of Africa, Asia and the Far East

Schistosomes

Indicum group

Schistosoma nasalis

Synonym: *Schistosoma nasalae*

Common name: Snoring disease

Predilection site: Veins of nasal mucosa

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The sexes are separate. The male, which is broad and flat and about 0.6–1 cm long, carries the female in the hollow of its inwardly curved body. The flukes closely resemble those of *S. spindale*.

Description, microscopic: The eggs measure 350–380 by 50–80 µm and are boomerang-shaped, with a terminal spine.

Final hosts: Cattle, goat, sheep, buffalo, horse

Intermediate hosts: Snails (*Lymnaea luteola*, *L. acuminata*, *Indoplanorbis exustus*)

Geographical distribution: India, Pakistan, Southeast Asia

Indicum group

Schistosoma indicum

Predilection site: Portal, pancreatic, hepatic and mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The sexes are separate; the males are 5–19 mm and the females 6–22 mm long.

Description, microscopic: The eggs are oval with a terminal spine and measure 57–140 by 18–72 µm.

Final hosts: Cattle, sheep, goat, horse, donkey, camel, buffalo

Intermediate hosts: Snails (*Indoplanorbis*)

Geographical distribution: India

Schistosoma spindale

Predilection site: Mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The sexes are separate. The male, which is broad and flat and up to about 16 mm long, carries the female in the hollow of its inwardly curved body.

Description, microscopic: The eggs are spindle-shaped, measure 200–300 by 70–90 μm and have a lateral or terminal spine. There is no operculum.

Hosts: Cattle, buffalo, horse, pig and occasionally dog

Intermediate hosts: Snails (*Planorbis*, *Indoplanorbis* spp., *Lymnaea* spp.)

Geographical distribution: Parts of Asia and the Far East

Other schistosomes

Schistosoma turkestanica

Synonym: *Orientobilharzia turkestanicum*

Predilection site: Mesenteric veins and small veins of the pancreas and liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description: Small species, the male measuring around 4.2–8 mm and the female 3.4–8 mm in length. The spirally coiled ovary is positioned in the anterior part of the body. In the male there are around 70–80 testes. The female uterus is short and contains only one egg at a time, which measures 72–77 by 16–26 μm with a terminal spine and a short appendage at the opposite end.

Final hosts: Cattle, buffalo, sheep, goat, camel, horse, donkey, mule and cat

Intermediate hosts: Snail (*Lymnaea euphratica*)

Geographical distribution: Asia, Middle East and parts of Europe

Trypanosomes

Trypanosoma brucei evansi

Synonyms: *Trypanosoma evansi*, *Trypanosoma equinum*

Common name: Surra, el debab, mbori, murrina, mal de Caderas, doukane, dioufar, thaga

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Trypanozoon*

Hosts: Horse, donkey, camel, cattle, zebu, goat, pig, dog, water buffalo, elephant, capybara, tapir, mongoose, ocelot, deer and other wild animals. Many laboratory and wild animals can be infected experimentally.

Geographical distribution: North Africa, Central and South America, central and southern Russia, parts of Asia (India, Burma, Malaysia, southern China, Indonesia, Philippines)

Epidemiology: Surra is widely prevalent on the Indian subcontinent and parts of Southeast Asia. Buffalo can be considered reservoir hosts, although clinical signs may manifest if animals are stressed or through the presence of intercurrent diseases. Infection is also widespread in North Africa and South America.

Pathogenesis: Surra is a chronic infection in water buffaloes, characterised by weight loss, infertility and abortion.

Clinical Signs: In buffaloes, disease is characterised by enlargement of the lymph nodes, mucous discharge from the eyes, emaciation, hindlimb weakness and recumbency.

Treatment and control: The drug of choice in buffaloes is 10% quinapyrimine sulphate 5 mg/kg subcutaneously.

For more details see Chapter 10.

Trypanosoma theileri

Predilection site: Blood

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Megatrypanum*

Description: Large trypanosome, 60–70 μm in length, although may be up to 120 μm , with posterior end long and pointed (see Figs 2.7 and 8.31). There is a medium-sized kinetoplast with a prominent undulating membrane and a free flagellum. Both trypomastigote and epimastigote forms may appear in the blood.

Host: Cattle, buffalo

Intermediate hosts: Tabanid flies

Geographical distribution: Worldwide

Pathogenesis: Infections are usually asymptomatic.

Babesiosis

Babesia bovis

Synonym: *Babesia argentina*

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: *Babesia bovis* is a small pleomorphic babesia, typically identified as a single body, as small round bodies, or as paired pear-shaped bodies joined at an obtuse angle within the centre of the mature erythrocyte. The round forms measure 1–1.5 μm and the pear-shaped bodies are 1.5 by 2.4 μm in size. Vacuolated signet-ring forms are especially common.

Hosts: Cattle, buffalo, deer (roe deer, red deer)

Geographical distribution: Australia, Africa, Central and South America, Asia and southern Europe

Babesia bigemina

Common name: Texas fever

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: *Babesia bigemina* is a large pleomorphic organism but characteristically is seen and identified by the pear-shaped bodies joined at an acute angle within the mature erythrocyte (see Fig. 8.32). Round forms measure 2 µm and the pear-shaped elongated ones are 4–5 µm.

Hosts: Cattle, buffalo

Geographical distribution: Australia, Africa, North, Central and South America, Asia and southern Europe

For more details on these species see Chapter 8.

Babesia orientalis

Common name: Buffalo babesiosis

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: *Babesia orientalis* is a small babesia similar in appearance to *B. bovis* but smaller, measuring 1.3 by 2.2 µm.

Host: Buffalo

Geographical distribution: China

Pathogenesis: Infection is characterised by fever, icterus, haemoglobinuria and high mortality.

Epidemiology: The parasite is found in water buffalo only, and is transmitted by *Rhipicephalus haemaphysaloides* ticks.

Theileriosis

Theileria parva

Subspecies: *Theileria parva parva*, *Theileria parva lawrencei*

Common name: East Coast fever, corridor fever

Predilection site: Blood and lymphatics

Phylum: Apicomplexa

Class: Aconoidasida

Family: Theileriidae

Description: Trophozoite forms in the erythrocyte are predominantly rod-shaped (1.5–2.0 × 0.1–1.0 µm), but may also be round, oval and comma-shaped (see Fig. 8.36). Koch bodies are present in the lymphocytes and endothelial cells of the spleen or lymph nodes where they are very numerous and average 8 µm but can range up to 12 µm or more. Two types have been described: macroschizonts containing chromatin granules 0.4–2.0 µm in diameter (see Fig. 8.37); these divide further to become microschizonts that contain chromatin granules 0.3–0.8 µm in diameter and produce merozoites 0.7–1 µm in diameter.

Hosts: Cattle, buffalo

Geographical distribution: East and Central Africa

Epidemiology: Occurs in some regions of Africa where cattle and buffaloes share the same pasture. Infection is transmitted by the tick *Rhipicephalus appendiculatus*. *Theileria parva lawrencei* is transmitted from the African buffalo and becomes indistinguishable in its behaviour from *Theileria parva parva* following several passages in cattle.

Theileria annulata

Common names: Mediterranean theileriosis, Mediterranean coast fever

Predilection site: Blood and lymphatics

Phylum: Apicomplexa

Class: Aconoidasida

Family: Theileriidae

Description: Trophozoite forms in the erythrocyte are predominantly round (0.5–2.7 µm) to oval (2 × 0.6 µm), but may also be rod-shaped or comma-shaped (1.2 × 0.5 µm). Division by binary fission may form two or four daughter cells, the latter in the shape of a cross. Koch bodies are present in the lymphocytes of the spleen or lymph nodes or even free in these organs. They average 8 µm but can be up to 27 µm. Two types have been described: macromeronts containing chromatin granules 0.4–1.9 µm in diameter; these divide further to become micromeronts that contain chromatin granules 0.3–0.8 µm in diameter and produce merozoites 0.7–1 µm in diameter.

Hosts: Cattle, domestic buffalo

Geographical distribution: Mediterranean countries (Portugal and Spain, the Balkans), the Middle East, Indian subcontinent and China

***Theileria orientalis* complex**

Synonyms: *Theileria mutans*, *Theileria buffeli*, *Theileria sergenti*

Common name: Benign theileriosis

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Theileriidae

Description: Trophozoite forms in erythrocytes are round (1–2 µm diameter), oval (1.5 × 0.6 µm), pyriform, or comma-shaped (see Fig. 8.38). Binary fission produces two or four daughter cells. There are relatively few Koch bodies (8–20 µm) in the lymphocytes of the spleen and lymph nodes, which contain 1–80 chromatin granules (1–2 µm in diameter).

Hosts: Cattle, buffalo

Geographical distribution: Southern Europe, Middle East, Asia, Australia

For more details on *Theileria* species see Chapter 8.

Ehrlichia ruminantium

Synonym: *Cowdria ruminantium*

Common names: Heartwater, cowdriosis, malkopsiekte (Afrikaans)

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Family: Anaplasmataceae

Description: Organisms are seen as close-packed colonies consisting of less than ten to many hundred cocci. The organism varies in size from 0.2 µm to greater than 1.5 µm. The diameter of individual organisms in a given cluster is rather uniform but groups are very pleomorphic. The small granules tend to be coccoid, with larger ones looking like rings, horseshoes, rods and irregular masses.

Hosts: Cattle, sheep, goat, buffalo and wild ruminants

Geographical distribution: Africa south of the Sahara, Caribbean (Guadeloupe, Marie-Galante and Antigua)

Parasites of the nervous system

Thelazia rhodesi

Common name: Cattle eye worm

Predilection site: Eye, conjunctival sac, lacrimal duct

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description: Small, thin, yellowish-white worms 1.0–2.0 cm long. Males are 8–12 mm and females 12–20 mm in length. The cuticle has prominent striations at the anterior end. The male worms have about 14 pairs of pre-cloacal and three pairs of post-cloacal papillae.

Final hosts: Cattle, buffalo, occasionally sheep, goat, camel

Intermediate hosts: Muscid flies, particularly *Fannia* spp.

For more details see Chapter 8.

Parasites of the reproductive/urogenital system

No parasites of veterinary significance reported.

Parasites of the locomotory system

There is uncertainty as to the number of distinct *Sarcocystis* species that occur in water buffalo because studies have shown that some species are capable of developing in more than one intermediate host. Morphological similarities have been reported for *Sarcocystis sinensis* found in buffalo, and *S. hominis* in cattle, and it appears that cattle and water buffalo can each serve as a competent intermediate host for each species.

Sarcocystis sinensis

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: In buffalo, sarcocysts are approximately 1250 by 100 µm with a wall of about 6 µm in thickness.

Intermediate host: Buffalo

Final host: Unknown

Geographical distribution: Unknown

Parasites of the connective tissue

Parafilaria bovicola

Common names: Summer 'bleeding disease', verminous nodules

Predilection site: Subcutaneous and intermuscular connective tissue

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Slender white worms 3.0–6.0 cm in length. Males are 2–3 cm and females 4–6 cm.

Description, microscopic: Anteriorly, there are numerous papillae and circular ridges in the cuticle. In the female the vulva is situated anteriorly near the simple mouth opening. Small embryonated eggs, 45 by 30 µm, have a thin flexible shell and are laid on the skin surface where they hatch to release the microfilariae or L₁, which are about 200 µm in length.

Final hosts: Cattle, buffalo

Intermediate hosts: Muscid flies; *Musca autumnalis* in Europe

Geographical distribution: Africa, Asia, southern Europe and Sweden

Setaria labiato-papillosa

Synonym: *Setaria cervi*

Common name: Bovine abdominal filariosis

Predilection site: Peritoneum, pleural cavity

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Long slender whitish worms, up to 12.0 cm in length, with the posterior end spirally coiled. The site and gross appearance are sufficient for generic identification (see Fig. 8.46). Males are 40–60 mm and females 60–120 mm in length.

Description, microscopic: The tail of the female ends in a marked button, which is divided into a number of papillae. Microfilariae are sheathed and measure 240–260 µm.

Final hosts: Cattle, buffalo, bison, yak, and various deer and antelope, rarely sheep

Intermediate hosts: Mosquitoes (*Aedes*, *Culex*)

Geographical distribution: Worldwide

Setaria digitatus

Common name: Kumri

Predilection site: Peritoneum, pleural cavity

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: As for *S. labiato-papillosa*. The male is 40–60 mm and the female 60–120 mm in length.

Description, microscopic: The tail of the female ends in a simple button.

Final hosts: Cattle, buffalo

Intermediate hosts: Mosquitoes (*Armigeres*, *Aedes*, *Anopholes*, *Culex*)

Geographical distribution: Asia

Parasites of the integument***Stephanofilaria zaheeri***

Predilection site: Skin

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Final hosts: Buffalo and cattle

Intermediate hosts: Muscid flies

Geographical distribution: India

Clinical signs: With *S. zaheeri*, lesions occur mainly on the head, legs and teats of cattle and buffalo.

ECTOPARASITES***Haematopinus tuberculatus***

Common name: Buffalo louse

Class: Insecta

Order: Phthiraptera

Suborder: Anoplura

Family: Haematopinidae

Description: A large louse measuring about 5.5 mm in length, with prominent ocular points but without eyes.

Hosts: Cattle, buffalo

Pathogenesis: Populations build up during the winter when the animal's coat is longer and thicker but it is not generally considered of any great clinical importance.

Notes: Known originally to infest buffalo but now found to infest cattle in Africa.

Sarcoptes scabiei

Common name: Scabies

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Sarcoptidae

Description: Adult mites have a round, ventrally flattened, dorsally convex body. Adult females are 0.3–0.6 mm long and 0.25–0.4 mm wide, while males are smaller, typically up to 0.3 mm long and 0.1–0.2 mm wide. The posterior two pairs of limbs do not extend beyond the body margin. In both sexes, the pretarsi of the first two pairs of legs bear empodial claws and a sucker-like pulvillus, borne on a long stalk-like pretarsus. The sucker-like pulvilli help the mite grip the substrate as it moves. The third and fourth pairs of legs in the female and the third pair of legs in the male end in long setae and lack stalked pulvilli. The mouthparts have a rounded appearance. These mites have no eyes or stigmata. The dorsal surface of the body of *S. scabiei* is covered with transverse ridges, but also bears a central patch of triangular scales. The dorsal setae are strong and spine-like. The anus is terminal and only slightly dorsal.

Psoroptes natalensis

Predilection site: Skin; particularly the legs, feet, base of tail and upper rear surface of the udder

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Psoroptidae

Description: Very similar to *P. ovis* but it is believed that *P. natalensis* can be distinguished morphologically by the length and spatulate shape of the fourth outer opisthosomal seta of the male. However, the precise species status of *P. natalensis* has yet to be confirmed.

Hosts: Primarily buffalo but it has been reported on cattle.

For treatment and pathogenesis see *P. ovis*.

HOST-PARASITE CHECKLISTS

In the following checklists, the codes listed below apply:

Helminths

N, nematode; T, trematode; C, cestode; A, acanthocephalan.

Arthropods

F, fly; L, louse; S, flea; M, mite; Mx, maxillopod; Ti, tick.

Protozoa

Co, coccidia; Bs, blood sporozoa; Am, amoeba; Fl, flagellate; Ci, ciliate.

Miscellaneous 'protozoal organisms'

B, blastocyst; Mi, microsporidian; My, *Mycoplasma*; P, Pneumocystidomycete; R, *Rickettsia*.

Parasites of laboratory animals

RABBITS

ENDOPARASITES

Parasites of the digestive system

Helminth infections are rarely seen in domestic rabbits unless they are kept in conditions that expose them to the infective stages resultant from contact with wild rabbits. The following species, with the exception of *Passalurus*, are therefore generally only found in wild rabbits and treatment of domesticated rabbits for many of these parasites is therefore rarely indicated. When treatment is required, fenbendazole and mebendazole are effective. In-feed medication with flubendazole can also be given over 10 days.

A more detailed list of helminth species found in both domesticated and wild rabbits is provided in the parasite checklist at the end of the chapter.

Graphidium strigosum

Common name: Rabbit strongyle

Predilection site: Stomach, small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are reddish worms when fresh, with 40–60 longitudinal lines and fine transverse striations. The male is 8–16 mm and female 11–20 mm long.

Description, microscopic: The male bursa has large lateral lobes and a small dorsal lobe. Spicules are long, slender and each ends distally in several points. The medium-sized eggs are typically trichostrongyle, ovoid and measure 98–106 by 50–58 μm (see Fig. 4.8). The egg contains a large number of blastomeres or may contain an L₁ larva. The eggs are larger than those of *Trichostrongylus*.

Hosts: Rabbit, hare

Geographical distribution: Europe

Pathogenesis and clinical signs: Light infections cause little effect, but heavy infections cause destruction of the gastric mucosa, diarrhoea, anaemia, emaciation and sometimes death if untreated.

Diagnosis: This is based on identification of the eggs in the faeces or adult worms in the stomach on postmortem.

Obeliscoides cuniculi

Predilection site: Stomach

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are brownish-red worms; the male is 10–16 mm and female 15–18 mm long.

Description, microscopic: The male spicules are brown, and bifurcated at the distal end. The body of the female is tapered over the posterior 20% of its length. Eggs are typically trichostrongyle, ovoid and measure 76–86 by 44–45 μm (see Fig. 4.8).

Hosts: Rabbit, hare and occasionally white-tailed deer

Geographical distribution: USA

Pathogenesis and clinical signs: Similar to *G. strigosum*.

Diagnosis: This is based on identification of the eggs in the faeces or adult worms in the stomach on postmortem.

Epidemiology: The parasite can undergo hypobiosis on some occasions.

Trichostrongylus retortaeformis

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are small, white and hair-like, usually less than 7.0 mm long and difficult to see with the naked eye.

Description, microscopic: In the male, the ventro-ventral ray tends to be disparate from the other rays and spicules are stout, unequal in length and terminate in a barb-like tip (see Table 1.3h). The females possess double ovejectors. The medium-sized eggs are an irregular ellipse with dissimilar poles. One of the side walls may be

slightly flattened (see Fig. 4.8). Eggs measure about 85–91 by 46–56 μm . The thin chitinous shell has a smooth surface and contains 16–32 blastomeres.

Hosts: Rabbit, hare

Geographical distribution: Worldwide

Pathogenesis and clinical signs: The parasites penetrate into the mucosa, causing desquamation and, in heavy infections, inflammation of the intestine with excess mucous exudate.

Diagnosis: This is based on clinical signs, seasonal occurrence of disease and, if possible, lesions at postmortem examination. Faecal egg counts are a useful aid to diagnosis, although faecal cultures are necessary for generic identification of larvae.

Trichostrongylus calcaratus

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adults are small, white and hair-like, usually less than 7.0 mm long.

Description, microscopic: Male worms have an asymmetrical dorsal ray and two short nearly equal spicules.

Hosts: Rabbit, hare

Geographical distribution: USA

Nematodirus leporis

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: Male worms are 8–15 mm and female worms 16–20 mm in length.

Description, microscopic: The bursa has rounded lobes with parallel posterolateral and mediolateral bursal rays and the spicules are long. The eggs are large (250 \times 100 μm).

Hosts: Rabbit, hare

Pathogenesis: Clinical signs become noticeable with severe infestations, leading to diarrhoea and loss of weight. Necropsy shows that the large numbers of worms form clumps resembling cottonwool and are usually intertwined around the intestinal villi, causing atrophy, degeneration and necrosis of the surface enterocytes.

Tapeworms

Gross: Tapeworms of the genus *Cittotaenia* are up to 80 cm long and 1 cm wide.

Description, microscopic: Proglottids are broader than long and each contains two sets of genital organs. Eggs are about 64 μm in diameter and have a pyriform apparatus.

Intermediate hosts: Forage mites, mainly of the family Oribatidae

Epidemiology: Infection may occur in domesticated rabbits grazing contaminated grass.

Pathogenesis and clinical signs: Heavy infections may cause digestive disturbances, emaciation and occasionally death in affected rabbits.

Diagnosis: This is based largely on the presence of mature proglottids in the faeces.

Cittotaenia ctenoides

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, microscopic: The tapeworms can measure up to about 80 cm in length. The scolex is about 0.5 mm wide.

Final host: Rabbit

Geographical distribution: Europe

Cittotaenia denticulata

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, microscopic: Differs from *C. ctenoides* by having a wider scolex (0.8 mm) and possesses no neck.

Final host: Rabbit

Geographical distribution: Europe

Cittotaenia pectinata

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Anoplocephalidae

Description, microscopic: The scolex is smaller (0.25 mm) than that of *C. ctenoides* and also bears a short neck.

Final hosts: Rabbit, hare

Geographical distribution: Europe, Asia, America

Trichuris leporis**Common name:** Whipworms**Predilection site:** Large intestine**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Trichuroidea**Description, gross:** Adult males measure around 1.9–2.1 cm and adult females 1.7–2.1 cm in length.**Hosts:** Rabbit, hare, coypu**Oxyurid worms*****Passalurus ambiguus*****Common name:** Rabbit pinworm**Predilection site:** Caecum, colon**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Oxyuroidea**Description, gross:** Adult worms are 4–11 mm in size and semi-transparent; males are 4–5 mm and females 9–11 mm.**Description, microscopic:** The oesophagus has the typical oxyurid oesophageal bulb. Eggs are thin-walled, with slightly flattened walls on one side and measure 95–103 by 43 µm.**Hosts:** Rabbit, hare**Geographical distribution:** Worldwide**Pathogenesis:** Rabbits can harbour large numbers of oxyurid worms with no clinical signs. These worms can be a problem in rabbit colonies.**Treatment and control:** Single treatments are not very effective because of the direct life cycle and rapidity of reinfection. Fenbendazole 50 mg/kg in feed for 5 days is effective.***Dermatoxys veligera*****Predilection site:** Caecum**Phylum:** Nematoda**Class:** Secernentea**Superfamily:** Oxyuroidea**Description, gross:** Females are 16–17 mm and males 8–11 mm long.**Description, microscopic:** Males have small spicules. Females have a vulva located in the cranial half of their body.**Hosts:** Rabbit, hare**Geographical distribution:** North America**Table 15.1** Common *Eimeria* species in rabbits.

| Species | Predilection site | Prepatent period (days) |
|-----------------------------|---------------------------|-------------------------|
| <i>Eimeria flavescens</i> | Small and large intestine | 9 |
| <i>Eimeria intestinalis</i> | Small intestine | 9–10 |
| <i>Eimeria exigua</i> | Small intestine | 7 |
| <i>Eimeria perforans</i> | Small intestine | 5 |
| <i>Eimeria irrisidua</i> | Small intestine | 9 |
| <i>Eimeria media</i> | Small intestine | 5–6 |
| <i>Eimeria vej dovskiyi</i> | Small intestine | 10 |
| <i>Eimeria coecicola</i> | Large intestine | 9 |
| <i>Eimeria magna</i> | Small intestine | 7 |
| <i>Eimeria piriformis</i> | Colon | 9 |
| <i>Eimeria stiedai</i> | Liver, bile ducts | 18 |

Pathogenesis: Adult worms do not attach to the mucosa, but fourth-stage larvae may cause ulceration of the mucosa of the caecum.**Coccidiosis**

There are more than 30 species of coccidia described from lagomorphs. The more common species from domestic rabbits are given in Table 15.1. The intestinal species, *Eimeria flavescens* and *Eimeria intestinalis*, are the most pathogenic causing the destruction of crypts in the intestine and resulting in diarrhoea and emaciation, with disease commonest around weaning. Coccidial infections are seen commonly on commercial rabbit farms.

Diagnosis: As in other hosts, diagnosis is best made by a postmortem examination. Species identification is based on pathological lesions and location within the intestine. Identification is possible with oocysts recovered from faeces following sporulation. In practice, the demonstration of many oocysts in the faeces is often used as an indication that rabbits require treatment.

Treatment and control: A number of coccidiostats are available for prophylactic use, including robenidine and clopidol. Sulphonamides (sulphadimidine or sulphaquinoxaline) are used for treatment, usually given as two 7-day courses in drinking water, 1 week apart to allow for the possibility of reinfection. Control of rabbit coccidiosis involves the daily cleaning of cages, hutches or pens and the provision of clean feeding troughs. In many large units, control is achieved by rearing animals on wire floors; alternatively, coccidiostats such as amprolium, clopidol or robenidine are incorporated in the feed.

Eimeria flavescens**Predilection site:** Small and large intestine (Fig. 15.1)**Phylum:** Apicomplexa**Class:** Conoidasida**Family:** Eimeriidae**Description:** Oocysts are ovoid, 30 by 21 µm (range 25–35 × 16–21 µm), yellowish in colour, with a prominent micropyle at the broad end. There is no polar granule or oocyst residuum (Fig. 15.2; see also Fig. 4.37).

Fig. 15.1 Predilection site of *Eimeria flavescens*.

Fig. 15.2 Oocysts of *Eimeria flavescens*.

Life cycle: There are five merogony stages. The first-generation meronts are in the glands of the lower small intestine, the second- to fifth-generation meronts in the caecum and colon. The second-, third- and fourth-generation meronts are in the superficial epithelium, and the fifth-generation meronts and the gamonts are in the crypts (Figs 15.3 and 15.4). Gamonts and gametes appear about 7 days after infection, and oocysts appear in the faeces about 9 days after infection. Sporulation time is 4 days.

Fig. 15.3 Thickened and inflamed intestine due to the presence of *Eimeria flavescens*.

Fig. 15.4 Meronts of *Eimeria flavescens* within crypt epithelial cells of the caecum.

Fig. 15.5 Gamonts and oocysts of *Eimeria flavescens* in the mucosa of the large intestine.

Geographical distribution: Worldwide

Pathogenesis and clinical signs: *Eimeria flavescens* is highly pathogenic for young rabbits, causing high morbidity and mortality and is a major problem on commercial rabbit farms.

Pathology: There is thickening of the intestinal wall of the caecum and colon with petechial haemorrhages and loss of epithelium in the caecum and colon (Fig. 15.5).

Eimeria intestinalis

Predilection site: Small intestine (Fig. 15.6)

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are pyriform, 27 by 19 μm (range 22–30 \times 16–21 μm), yellowish-brown in colour, with a micropyle at the narrow end and a large oocyst residuum but no polar granule (Fig. 15.7; see also Fig. 4.37).

Life cycle: There are three merogony stages. First-generation meronts are at the base of the villi in the lower ileum. There appear

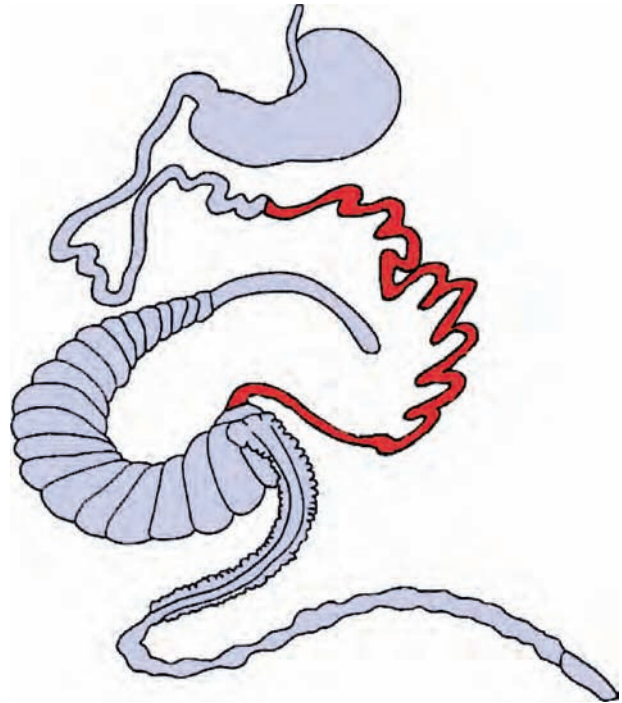

Fig. 15.6 Predilection site of *Eimeria intestinalis*.

Fig. 15.7 Oocysts of *Eimeria intestinalis*.

to be two types of second-generation meronts in the distal part of the villi, followed by third-generation meronts in the same location on the villi. Gamonts begin developing 8 days post infection, and are located above the host cell nucleus in the epithelial cells of the villi (Fig. 15.8). The prepatent period is 9–10 days and the patent period 6–10 days. Sporulation time is 3 days.

Geographical distribution: Worldwide

Fig. 15.8 Gamonts of *Eimeria intestinalis* within epithelial cells of the villi of the small intestine.

Pathogenesis and clinical signs: *Eimeria intestinalis* is highly pathogenic, causing diarrhoea and emaciation.

Pathology: There is oedema of the intestinal wall with destruction of the crypts in the ileum and lower jejunum. Greyish-white foci may coalesce forming a sticky purulent layer in the small intestine (Fig. 15.9).

Eimeria exigua

Predilection site: Small intestine (Fig. 15.10)

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are spherical or subspherical, colourless, with no micropyle, polar granule or oocyst residuum, and measure 15 by 14 μm (range 10–18 \times 11–16 μm).

Life cycle: Development takes place in the ileum and lower jejunum but details of the life cycle are unknown. The prepatent period is 7 days. The sporulation time is 1 day.

Geographical distribution: Unknown, probably worldwide

Pathogenesis and clinical signs: This species is not considered pathogenic or is only slightly pathogenic. Infections are usually asymptomatic but heavy infections may cause slight depression of growth.

Eimeria perforans

Predilection site: Small intestine (Fig. 15.11)

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal to sub-rectangular, 22 by 14 μm (range 15–27 \times 11–17 μm), smooth and colourless with a uniformly thin wall. There is an inconspicuous micropyle and an oocyst residuum but no polar granule (see Fig. 4.37).

Life cycle: The endogenous stages are found in the epithelial cells of the villi and crypts of the small intestine, especially the middle section. There are two asexual generations, followed by gametogony. The prepatent period is 5 days and the patent period 12–32 days. Sporulation time is 1.5–2 days.

Geographical distribution: Worldwide

Pathogenesis and clinical signs: *Eimeria perforans* is one of the less pathogenic intestinal coccidia of rabbits, but it may cause mild to moderate signs in a heavy infection. Symptoms are usually mild, but in heavy infections there may be anorexia, diarrhoea, weakness, weight loss and growth retardation.

Pathology: The duodenum may be enlarged and oedematous, and may appear a chalky white colour. The jejunum and ileum may contain white spots and streaks and petechiae have been observed in the caecum.

Fig. 15.9 Focal lesions associated with *Eimeria intestinalis* infection in the small intestine.

Fig. 15.10 Predilection site of *Eimeria exigua*.

Fig. 15.11 Predilection site of *Eimeria perforans*.

Fig. 15.12 Predilection site of *Eimeria irresidua*.

Eimeria irresidua

Predilection site: Small intestine (Fig. 15.12)

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid and smooth, barrel-shaped, yellowish in colour, with a wide micropyle, a residuum may be present but there are no polar granules, and measure 39 by 23 μm (range 31–44 \times 20–27 μm) (Fig. 15.13; see also Fig. 4.37).

Life cycle: There are four merogony stages. First-generation meronts are in the crypts, second-generation meronts are in the lamina

Fig. 15.13 Oocysts of *Eimeria irresidua*.

Fig. 15.14 Gamonts of *Eimeria irresidua*.

propria, and third- and fourth-generation meronts and gamonts are in the villous epithelium in the jejunum, and to a lesser extent the ileum. The prepatent period is 9 days. Sporulation time is 4 days.

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Mildly pathogenic causing a depression in weight gain and in some cases diarrhoea. During this time, there is a reduction in food and water consumption as well as faecal excretion. Occasionally causes mortality depending on the level of infection.

Pathology: Catarrhal inflammation of the small intestine, particularly the jejunum, may be seen. On postmortem there may be enteritis, with gross thickening of the intestine. Large numbers of meronts and gamonts may be found in mucosal scrapings. Histopathological examination shows a congested and thickened mucosa with villous atrophy, villous fusion and crypt hyperplasia with numerous parasite stages present within the mucosa (Fig. 15.14).

Eimeria media

Predilection site: Small intestine (Fig. 15.15)

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid or ellipsoidal, 31 by 17 μm (range 25–35 \times 15–20 μm), smooth and 'pinkish' with a micropyle with a pyramidal-shaped protruberance. There is a medium to large oocyst residuum and no polar granule (see Fig. 4.37).

Life cycle: There are two merogony stages. The endogenous stages are found above or below the host cell nuclei of the epithelial cells and submucosa of the villi of the small intestine, mainly jejunum and ileum. The prepatent period is 5–6 days and the patent period 15–18 days. Sporulation time is 2 days.

Geographical distribution: Worldwide

Pathogenesis and clinical signs: *Eimeria media* is slightly to moderately pathogenic, causing a depression in weight gain and in some cases diarrhoea. During this time there is a reduction in food and water consumption as well as faecal excretion.

Fig. 15.15 Predilection site of *Eimeria media*.

Pathology: The affected parts of the intestine, mainly the duodenum, are oedematous with greyish foci. In heavy infections, the lesions may extend into the large intestine.

Eimeria vejdoskyi

Predilection site: Small intestine (Fig. 15.16)

Phylum: Apicomplexa

Fig. 15.16 Predilection site of *Eimeria vejdoskyi*.

Fig. 15.17 Predilection site of *Eimeria coecicola*.

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are elongate or ovoid, 32 by 19 μm (range 25–38 \times 16–22 μm), a micropyle is present without collar-like protrusion and there is a medium-sized oocyst residuum.

Life cycle: Development takes place in the ileum and lower jejunum but details of the life cycle are unknown. The prepatent period is 10 days. The sporulation time is 2 days.

Geographical distribution: Unknown, probably worldwide

Pathogenesis and clinical signs: This species is considered only slightly pathogenic. Infections are usually asymptomatic but heavy infections may cause slight depression of growth.

Pathology: Lesions occur only in the ileum and distal jejunum following heavy infection.

Eimeria coecicola

Predilection site: Large intestine (Fig. 15.17)

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are smooth-walled, ellipsoidal, 34 by 20 μm (range 27–40 \times 15–22 μm), light yellow to light brown in colour, with a distinct micropyle having a slight collar-like protrusion, and with oocyst residuum but no polar granule (Fig. 15.18; see also Fig. 4.37).

Life cycle: The number of generations is unknown. The meronts are in the epithelial cells of the ileum and the gamonts in the epithelial cells of the vermiform process of the caecum. The gamonts are usually sited beneath the host cell nucleus. The prepatent

Fig. 15.18 Oocysts of *Eimeria coecicola*.

period is 9–11 days and the patent period 7–9 days. Sporulation time is 4 days.

Geographical distribution: Worldwide

Pathogenesis and clinical signs: This species is not considered pathogenic and infection is not associated with clinical signs.

Pathology: In heavy infections, lesions may be seen in the crypts of the vermiform appendix.

Eimeria magna

Predilection site: Small intestine (Fig. 15.19)

Phylum: Apicomplexa

Fig. 15.19 Predilection site of *Eimeria magna*.

Fig. 15.20 Oocysts of *Eimeria magna*.

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, 36 by 24 μm (range 31–42 \times 20–28 μm), dark yellow in colour, and truncated at the micropylar end with a marked collar-like thickening around the micropyle. There is a very large oocyst residuum but no polar granules (Fig. 15.20; see also Fig. 4.37).

Life cycle: There are two or three merogony stages. The meronts develop in the villous epithelial cells from the middle of the jejunum to the posterior end of the ileum. They lie either above or below the host cell nucleus. The prepatent period is 7 days and the patent period 12–21 days. Sporulation time is 2–3 days.

Geographical distribution: Worldwide

Pathogenesis and clinical signs: *Eimeria magna* is mildly to moderately pathogenic, causing a depression in weight gain and in some cases diarrhoea. During this time, there is a reduction in food and water consumption as well as faecal excretion. A large amount of mucus may be passed in the faeces. Mortality may occur depending on the level of infection.

Pathology: The intestinal mucosa is hyperaemic and inflamed. Epithelial sloughing may occur. Large numbers of meronts and gamonts may be found in mucosal scrapings. Histopathological examination shows a congested and thickened mucosa with villous atrophy, villous fusion and crypt hyperplasia.

Eimeria piriformis

Predilection site: Colon (Fig. 15.21)

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are pyriform, often asymmetrical, 30 by 18 μm (range 25–33 \times 16–21 μm), yellowish-brown in colour, with a prominent micropyle but no polar granule or oocyst residuum (see Fig. 4.37).

Life cycle: There are three generations of meronts found in the proximal and distal colon. The prepatent period is 9 days and the patent period is 5–10 days. Sporulation time is 4 days.

Fig. 15.21 Predilection site of *Eimeria piriformis*.

Geographical distribution: Worldwide

Pathogenesis and clinical signs: *Eimeria piriformis* is mildly to moderately pathogenic. Infection causes anorexia, diarrhoea, weakness, weight loss and growth retardation, and in heavy infections can result in death.

Pathology: The wall of the large intestine is thickened and inflamed with large numbers of endogenous parasite stages found within crypt epithelial cells on histopathology (Fig. 15.22).

Other protozoa

Entamoeba cuniculi

Predilection site: Caecum

Phylum: Amoebozoa

Class: Archamoebae

Fig. 15.22 Mucosa of the colon infected with *Eimeria piriformis*.

Family: Entamoebidae

Description: Trophozoites are 20–30 μm in diameter. The cysts are 10–33 μm in diameter and contain a single nucleus.

Host: Rabbit

Geographical distribution: Worldwide

Pathogenesis: Non-pathogenic

Retortamonas cuniculi

Synonym: *Embadomonas cuniculi*

Predilection site: Caecum

Phylum: Fornicata

Class: Retortamonadea

Family: Retortamonadorididae

Description: Trophozoites are ovoid, 7–13 by 5–10 μm , with an anterior flagellum and a posterior trailing flagellum emerging from the cytostomal groove and occasionally have a tail-like process. Cysts are pyriform or ovoid, 5–7 by 3–4 μm .

Host: Rabbit

Geographical distribution: Worldwide

Pathogenesis: Non-pathogenic

Diagnosis: Diagnosis is based on the identification of the characteristic trophozoites.

Parasites of the respiratory system

Several protostrongylid nematodes are found in the lungs of wild rabbits. These are listed in the parasite checklist at the end of the chapter.

Echinococcus granulosus

For more details see Chapter 9.

Parasites of the liver

Capillaria hepatica

Synonyms: *Callodium hepatica*, *Hepaticola hepatica*

Predilection site: Liver

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description: These are very fine filamentous worms generally measuring 10–50 mm in length.

Hosts: Rat, mouse, squirrel, rabbit and farmed mustelids; occasionally dog, cat and human

For more information see section Rats and mice.

Fasciola hepatica

Common name: Liver fluke

Predilection site: Liver

Phylum: Platyhelminthes

Class: Trematoda

Family: Fasciolidae

Final hosts: Sheep, cattle, goat, horse, deer, human and other mammals

Intermediate hosts: Snails of the genus *Galba* (*Lymnaea*). The most common, *Galba* (syn. *Lymnaea*) *truncatula*, is an amphibious snail with a wide distribution throughout the world.

Geographical distribution: Worldwide

For more details see Chapter 9.

Taenia serialis

Synonym: *Coenurus serialis*

Predilection site: Intramuscular and subcutaneous connective tissue (intermediate host); small intestine (definitive host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Final hosts: Dog, fox and other canids

Intermediate hosts: Rabbit, hare and rarely rodents, human and primates

Geographical distribution: Worldwide

For more information see Chapter 12.

Eimeria stiedai

Predilection site: Liver, bile ducts (Fig. 15.23)

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Life cycle: The sporozoites emerge from the sporocysts in the small intestine and migrate to the liver via the lymph vessels. Merogony occurs above the host cell nucleus in the epithelial cells of the bile ducts. The number of asexual generations is uncertain, but there appear to be at least six. In due course, some merozoites form macrogametes and others form microgamonts. The latter produce large numbers of comma-shaped biflagellate microgametes. These fertilise the macrogametes which lay down an oocyst wall, break out of the host cell and pass into the intestine with the bile, and then out in the faeces. The prepatent period is 18 days and the patent period 21–30 days. The sporulation time is 2–3 days.

Geographical distribution: Worldwide

Fig. 15.23 Predilection site of *Eimeria stiedai*.

Pathogenesis and clinical signs: This species, which occurs in the bile ducts, reaches the liver via the portal vein and then locates in the epithelium of the bile ducts where it results in a severe cholangitis. Grossly the liver is enlarged and studded with white nodules (Fig. 15.24). Some of the symptoms seen are due to interference with liver function. Mild cases may be asymptomatic. In more severe infections the animals become inappetent and lose weight. There may be diarrhoea, jaundice, ascites and polyuria. The symptoms may become chronic, or death may occur in 21–30 days.

Pathology: The liver may become markedly enlarged, and white circular nodules or elongated cords may be visible. These nodules are initially sharply circumscribed, but later coalesce. The bile ducts are grossly enlarged and are filled with developing parasites. There is pronounced hyperplasia of the bile duct epithelial cells, and the epithelium is thrown into folds. Each cell contains one or more parasites (Figs 15.25 and 15.26).

Other helminths found in the liver of wild rabbits are listed in the parasite checklist at the end of the chapter.

Parasites of the circulatory system

Rickettsia conorii

Common names: Boutonneuse fever, Mediterranean spotted fever, Indian tick typhus, East African tick typhus

Predilection site: Blood

Kingdom: Bacteria

Phylum: Proteobacteria

Class: Alphaproteobacteria

Order: Rickettsiales

Fig. 15.24 Rabbit liver infected with *Eimeria stiedai*.

Family: Rickettsiaceae

Description: Small, pleomorphic, Gram-negative, coccoid, obligatory intracellular organisms infecting endothelial cells of smaller blood vessels.

Hosts: Rodents, dog, cattle, sheep, goat, human

Geographical distribution: Southern Europe, Africa, India and the Oriental region

For a more detailed description see Chapter 12.

Hepatozoon cuniculi

Predilection site: Spleen

Phylum: Apicomplexa

Class: Conoidasida

Family: Hepatozoidae

Description: Merocysts may reach 4–6 mm in diameter.

Fig. 15.25 Hyperplastic bile duct epithelium with endogenous stages of *Eimeria stiedai*.

Fig. 15.26 Gamonts of *Eimeria stiedai*.

Host: Rabbit

Geographical distribution: Reported in Italy

Pathogenesis: Not known

Parasites of the nervous system

Encephalitozoon cuniculi

Synonym: *Nosema cuniculi*

Predilection site: Blood

Kingdom: Fungi

Phylum: Microsporidia

Order: Microsporida

Family: Enterocytozoonidae

Description: Microsporidia are obligate, intracellular, spore-forming protozoa. Trophozoites are 2–2.5 by 0.8–1.2 µm in tissue sections or 4 by 2.5 µm in smears. Spores are about 2 µm long and contain a spirally coiled polar filament with four to five coils.

Hosts: Rabbit, dog, red fox (*Vulpes vulpes*), blue fox (*Alopex lagopus*), silver fox, cat, mouse, rat, human, monkeys

Geographical distribution: Worldwide

Pathogenesis: In rabbits, infection is very common causing granuloma formation in the kidneys, liver and brain. Infection in the brain causes convulsions, tremors, torticollis, ataxia, urinary incontinence, coma and death.

Clinical signs: Many infected rabbits are asymptomatic, although clinical signs such as head tilt, urinary incontinence, posterior paresis and anterior uveitis have been reported.

Diagnosis: Diagnosis in the live animal is difficult and is usually based on identifying the lesions on histopathology and observation of the organisms in Giemsa, Gram or Goodpasture-carbol fuchsin stains. A serum enzyme-linked immunosorbent assay (ELISA) is available.

Pathology: In the rabbit, microscopic lesions consist of focal granulomas and pseudocysts in the brain and kidneys, with occasional severe focal interstitial nephritis.

Epidemiology: Transplacental infection occurs in rabbits and rodents, but is probably rare with most infections in these animals acquired by ingestion of spores. Evidence suggests that infection in rabbits is common in many countries.

Treatment: Treatment with benzimidazoles (fenbendazole, oxfendazole and albendazole) has been reported in rabbits. Fenbendazole 20 mg/kg for 28 days, or albendazole 10–15 mg/kg for 3 months, can be given. Corticosteroids may suppress granuloma formation, but should be used with caution.

Control: Control in rabbits depends on testing individuals, isolation and treatment. The primary source of infection is urinary excretion and ingestion of spores. Strict hygiene should therefore be followed, with raised food dishes and use of water bottles rather than bowls. Rabbits should not be housed in tiered hutches where urine contamination of cages below is common.

Notes: There are reports of *E. cuniculi* acting as a zoonosis, particularly in immunocompromised individuals. Three strains of *Encephalitozoon* have been identified: strain I ('rabbit strain'), strain II ('rodent strain') and strain III ('dog strain'). Each of the three strains has been reported in humans and infections in rabbits may therefore pose a potential zoonotic risk.

Parasites of the reproductive/urogenital system

No parasites of veterinary significance reported.

Parasites of the locomotory system

Toxoplasma gondii

Predilection site: Muscle, lung, liver, reproductive system, central nervous system (CNS)

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: Tachyzoites are found developing in vacuoles in many cell types, for example fibroblasts, hepatocytes, reticular cells and myocardial cells. In any one cell there may be 8–16 organisms, each measuring 6.0–8.0 µm. Tissue cysts, measuring up to 100 µm in diameter, are found mainly in the muscle, liver, lung and brain, and may contain several thousand lancet-shaped bradyzoites (see Fig. 9.59).

Intermediate hosts: Any mammal, including human, or birds

Final host: Cat, other felids

For more details see Chapter 9.

Sarcocystis cuniculi

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: In the rabbit, the sarcocysts are elongate, compartmented and up to 5 by 5 mm. The cyst wall has numerous fine projections up to 11 µm long, packed into a tight pile. Metrocytes are 4–5 µm in diameter.

Final host: Cat

Intermediate host: Rabbit

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Non-pathogenic

Diagnosis: Diagnosis is made by microscopic identification of the characteristic cysts. They may be sometimes visible macroscopically.

Epidemiology: Little is known of the epidemiology, but it is clear that where cats are able to hunt or catch rabbits then transmission is likely. The longevity of the sporocysts shed in the faeces is not known.

Treatment and control: Not necessary

Pelecitus scapiceps

Synonyms: *Dirofilaria scapiceps*, *Loaina scapiceps*

Predilection site: Synovial sheaths of the feet

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description: Male worms are 11–16 mm in length with spicules of unequal length. Female worms are 25–30 mm long.

Final hosts: Rabbit, hare

Intermediate hosts: Several species of mosquito

Geographical distribution: North America and other regions

Pathogenesis and clinical signs: Generally non-pathogenic, although swelling and tenosynovitis can occur in the affected tissues.

Diagnosis: At necropsy, adult worms may be seen in the connective tissue surrounding the tendons of the hock and occasionally in the intermuscular fascia near the knee joint. Microfilariae may be seen in blood smears if the host has a patent infection.

Treatment and control: Not usually necessary

ECTOPARASITES

Mites

Psoroptes cuniculi

Synonyms: *Psoroptes ovis*, *Psoroptes cervinus*, *Psoroptes bovis*, *Psoroptes equi*

Common name: Ear canker mite

Predilection site: Ears

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Psoroptidae

Description: Mites of the genus *Psoroptes* are non-burrowing mites, up to 0.75 mm in length and oval in shape (see Fig. 3.92). All the legs project beyond the body margin. Its most important recognition features are the pointed mouthparts and the three-jointed pretarsi (pedicels) bearing funnel-shaped suckers (pulvilli). Adult females have jointed pretarsi and pulvilli on the first, second and fourth pairs of legs and long whip-like setae on the third pair. In contrast, the smaller adult males, which are recognisable by their copulatory suckers and paired posterior lobes, have pulvilli on the first three pairs of legs and setae on the fourth pair. The legs of adult

females are approximately the same length, whereas in males the fourth pair is extremely short.

The *Psoroptes* mite described as *P. cuniculi* is found primarily in rabbits, where it is usually localised in the ears, causing ear mange (psoroptic otocariosis). *Psoroptes cuniculi* may also be found in the ears of sheep and horses, causing irritation and head shaking, and also in sheep associated with haematomas.

In adult *P. cuniculi*, the outer opisthosomal setae are, on average, slightly shorter than those seen in *P. ovis*. Nevertheless, the usefulness of this character is questionable, since there is considerable variation and overlap in the lengths of the setae between the two groups, and the mean length of the setae of mites is known to decrease with the age of a body lesion. It appears very likely that *P. cuniculi* is simply a host-adapted population of the species *P. ovis*.

Hosts: Rabbit, goat, sheep and horse

Geographical distribution: Worldwide

Pathogenesis: *Psoroptes cuniculi* localises in the ears, where the mites may occur at relatively low intensities, but occasionally proliferate causing severe mange in which the auditory canal may be completely blocked with greyish debris. If untreated, the infection may extend over the rest of the body with scabs, loss of hair and excoriation from scratching. The initial preclinical stages may last for several months, during which the infestation is difficult to spot and causes little obvious problems to the infested rabbit. Mites are non-burrowing and therefore are found only in exudate, not in tissue.

Clinical signs: In the initial stages of the infection, small skin scales appear deep in the ear canal. These yellow–grey scales can be relatively thick; they contain large numbers of parasites, mite eggs, skin cells and blood. If untreated the scales begin to crust and may eventually grow to a thickness of 10 mm and fill the ear in severe cases. Scratching behaviour and shaking of the head may occur, and scabs and loss of hair may be observed in the ears. Eventually the mites may spread out of the ear and over the rest of the body.

Diagnosis: A sample of scab should be taken from the infected area. When placed in a glass jar or beaker the highly mobile mites will leave the scab and start to migrate up the sides of the jar. Mites can then be collected and examined under a microscope for key features: oval outline, all legs projecting beyond the body margin, three-jointed pretarsus.

Pathology: At low population densities, little pathology may be evident. In a rapidly expanding population, however, there may be chronic erosive and proliferative eosinophilic dermatitis.

Epidemiology: When in its preclinical phase deep in the ear, transmission is uncommon. However, once the infestation has spread transmission is more likely, primarily through physical contact but also may occur via the environment.

Treatment: Treatment is as for otodectic mange of cats and dogs. Insecticidal preparations, such as diazinon applied daily for 4 days and repeated in 10 days, have been found to be effective. Treatment with injected ivermectin is highly successful. The infected bedding should be burnt and the housing thoroughly disinfected. The crust will resolve itself, without the need to clean the ears, falling off approximately 10 days after the first treatment.

Control: All in-contact animals should be treated. The housing must be disinfected to prevent reinfection. Regular inspection

of the animal, paying particular attention to the ears, should help to control the parasite and reduce the effects of subsequent infestations.

Cheyletiella parasitivorax

Common name: Rabbit fur mite

Predilection site: Most commonly found on the dorsum, above the tail and on the neck, but may occur all over the body

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Cheyletidae

Description: Adults are about 400 µm in length and ovoid (Fig. 15.27; see also Fig. 3.101). They have blade-like chelicerae that are used for piercing their host, and short, strong, opposable palps with curved palpal claws. The palpal femur possesses a long serrated dorsal seta. The body tends to be slightly elongated with a 'waist'. The legs are short; tarsal claws are lacking and the empodium is a narrow pad with comb-like pulvilli at the ends of the legs. Adults are highly mobile and are able to move about rapidly. The solenidion, on the genu of the first pair of legs, is described as globose in *C. parasitivorax*.

Host: Rabbit

Geographical distribution: Worldwide, particularly North America, Europe, Asia, Australia and New Zealand

Pathogenesis: *Cheyletiella* is relatively common in rabbits, but the mite is not highly pathogenic at low densities and is often found in young animals in good physical condition. It is a characteristic of the dermatitis caused by *Cheyletiella* that many skin scales are shed

into the fur, giving it a powdery or mealy appearance, and the presence of moving mites among this debris has given it the common name of 'walking dandruff'. There is usually very little skin reaction or pruritus. In the rare severe case, involving much of the body surface, crusts are formed. *Cheyletiella parasitivorax* is capable of transmitting the myxomatosis virus among European rabbits.

Clinical signs: Infestation can result in eczema-like skin conditions and associated pruritus and hair loss. Severe cases may show serous exudate and extensive alopecia.

Diagnosis: In any case of excessive scurf or dandruff, *Cheyletiella* should be considered in the differential diagnosis. On parting the coat along the back, and especially over the sacrum, scurf will be seen, and if this is combed out on to dark paper the movement of mites will be detected among the debris. Skin scraping is not necessary as the mites are always on the skin surface or in the coat.

Pathology: The pathology of *Cheyletiella* infestation is poorly understood. In many cases there is very little skin reaction or pruritus. However, in severe cases rabbits may show alopecia with red scaly skin and dermatitis with hyperkeratosis.

Epidemiology: *Cheyletiella parasitivorax* is a common fur mite of rabbits. It is highly contagious and can spread rapidly through rabbit colonies. Transmission is usually by direct contact with infested animals, although the parasite can survive for over 10 days off the host and therefore bedding and housing can act as a source of infestation.

Treatment: Topical acaricides, such as pyrethrin and dichlorvos-containing sprays, are effective against *Cheyletiella*. Systemic treatment with ivermectin on three occasions, 7 days apart, is effective. Selamectin spot-on has also been used effectively. Fipronil should only be used with great caution because it has been associated with deaths in some cases.

Control: All in-contact animals should be treated, bedding replaced and housing disinfected.

Fig. 15.27 *Cheyletiella parasitivorax*.

Notes: Of all the mite infestations of domestic animals, this is one of the most readily transferable to humans. The mites can penetrate clothing and are easily transferred, even on short periods of contact. It is often found that when a positive diagnosis has been made on a pet, there is a history of persistent skin rash in the owner's family. In contrast to the condition in its natural hosts, the infestation in humans causes severe irritation and intense pruritus. The early sign is an erythema, which may progress to a vesicular and pustular eruption. Cases in humans invariably resolve spontaneously when the animal source has been treated.

Leporacarus gibbus

Synonyms: *Listrophorus gibbus*, *Listracarus gibbus*

Common name: Rabbit fur mite

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Listrophoridae

Description: *Leporacarus gibbus* is a small brown non-burrowing mite, occasionally present at low to moderate densities on domestic rabbits.

Host: Rabbit

Geographical distribution: Worldwide

Pathogenesis and clinical signs: *Leporacarus gibbus* may co-occur with *C. parasitivorax*. This mite is generally considered to be non-pathogenic and is found primarily on the back and abdomen.

Diagnosis: Hair plucks can be examined under a dissecting microscope or with a hand lens for the characteristic brown mite or its eggs.

Treatment and control: As for *C. parasitivorax*.

For occasional mite parasites of rabbits, see Table 15.2.

Fleas

Spilopsyllus cuniculi

Common names: Rabbit flea, European rabbit flea

Predilection site: Ears

Class: Insecta

Order: Siphonaptera

Family: Pulicidae

Table 15.2 Occasional mite parasites of rabbits.

| |
|--|
| <i>Notoedres cati</i> (see Chapter 12) |
| <i>Chorioptes bovis</i> (see Chapter 8) |
| <i>Sarcoptes scabiei</i> (see Chapter 11) |
| <i>Neotrombicula autumnalis</i> (see Chapter 17) |
| <i>Dermanyssus gallinae</i> (see Chapter 13) |

Fig. 15.28 *Spilopsylla cuniculi*.

Description: The rabbit flea, *S. cuniculi*, has both pronotal and genal combs, the latter being composed of four to six oblique spines. Adults are dark brown, and females are, on average, 1 mm in length; males are slightly smaller. Eyes are present and the frons at the front of the head is rounded with the frontal tubercle conspicuous. There are two stout spines beneath the eye (Fig. 15.28; see also Fig. 3.78).

Hosts: Rabbit, hare, dog, cat

Geographical distribution: Worldwide

Pathogenesis: When rabbits are not breeding, the distribution of *S. cuniculi* is related to skin temperature, with fleas usually congregating on the ears. Because they assemble here in large numbers, the intensity of bites may cause considerable irritation and tissue damage.

The rabbit flea may also be found on cats and dogs which hunt or frequent rabbit habitats. On these hosts they are commonly found on the face and attached to the margin of the pinna.

Spilopsyllus cuniculi is the main vector of myxomatosis and it also transmits the non-pathogenic *Trypanosoma nabiasi*.

Clinical signs: These fleas may cause a great deal of irritation and tissue damage at the congregation sites on the ears.

Diagnosis: The fleas may be seen on the skin of the host animal, particularly around the ears. They have a more sedentary habit than most fleas, and will remain on the ear even when it is handled.

Epidemiology: The fleas can survive for up to 9 months at low temperatures without feeding. The main method of transmission is from the mother to her young.

Treatment: Imidacloprid may be used in rabbits to kill adult fleas on contact. Fipronil should only be used with extreme care in rabbits due to its potential toxicity.

Control: Not usually necessary. In case of repeated infestation the source should be identified and contact prevented; all in-contact animals should be treated; bedding should be replaced and housing disinfected.

Table 15.3 Occasional flea parasites of rabbits.

| <i>Ctenocephalides felis</i> (see Chapter 12) |
| <i>Ctenocephalides canis</i> (see Chapter 12) |
| <i>Echidnophaga gallinacea</i> (see Chapter 13) |

Table 15.3 lists species of fleas which have also been found on rabbits. For more details see also Chapters 3 and 17.

Flies

Lucilia sericata

Synonym: *Phaenicia sericata*

Common names: Greenbottle, sheep blowfly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Family: Calliphoridae

Description, adults: *Lucilia sericata* blowflies measure up to 10 mm in length and are characterised by a metallic greenish to bronze sheen.

Description, larvae: Larvae are smooth, segmented and measure 10–14 mm in length. They possess a pair of oral hooks at the anterior extremity, and at the posterior extremity peritremes bearing spiracles.

Hosts: Mainly sheep, but a range of other domestic and wild animals may be affected including humans.

Geographical distribution: Worldwide

Pathogenesis: Blowfly strike of domestic rabbits and occasionally other domestic mammals and birds may be very common, particularly if dirty, debilitated by clinical disease or wounded. Strike is a very serious condition in rabbits and death may result within a few days.

Clinical signs: Infested animals show extensive skin ulceration, shock, weakness, depression, lethargy and anorexia.

Diagnosis: This is based on the clinical signs and recognition of maggots in the lesion.

Pathology: Struck animals have a rapid increase in body temperature and respiratory rate. The animals show extensive tissue damage, become anaemic and suffer severe toxemia.

Epidemiology: Predominantly a summer problem in temperate areas, but may occur all year round in more tropical regions.

Treatment: Once the problem is diagnosed, affected rabbits should be separated and the area surrounding the lesion clipped. Where possible, larvae should be removed. The use of a hair-drier, at a low heat setting, to direct dry air towards the maggots has been reported as an effective way to cause them to drop off the host. However, in advanced infestations the rabbit may require sedation, intravenous fluid therapy and analgesia. Ivermectin may be used to kill any remaining feeding larvae. Unless caught in its early stages the prognosis must be guarded, since myiasis can be extremely damaging to rabbits relatively quickly.

Control: To prevent fly strike, formulations of pour-on cyromazine are available specifically for rabbits. They offer prevention for up to 8–10 weeks. Longer-term steps should be taken to prevent diarrhoea and faecal contamination of the hair, either through worm control or diet as required.

Note: Several other species of blowfly or fleshfly may also strike rabbits in various parts of the world. The treatment is as described above for *L. sericata*.

Cuterebra

For details see section Rats and mice.

GUINEA PIGS

ENDOPARASITES

Parasites of the digestive system

Small intestine

Hymenolepis diminuta

For details see section Rats and mice.

Rodentolepis nana

For details see section Rats and mice.

Eimeria caviae

Predilection site: Large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal or ovoid, smooth, brown, 13–26 by 12–23 μm , without a micropyle or polar granule but with a residuum.

Life cycle: Following ingestion of oocysts, sporozoites enter the intestinal epithelium to become first-generation meronts. Following a further three merogony generations gamonts appear in epithelial cells of the large intestine leading to the excretion of oocysts in the faeces. The prepatent period is about 7 days and the patent period approximately 4–5 days.

Geographical distribution: Worldwide

Pathogenesis and clinical signs: *Eimeria caviae* is usually non-pathogenic but may occasionally cause diarrhoea and mortality. Clinical signs include unthriftiness and poor weight gain in young animals; droppings are slimy and contain blood.

Diagnosis: Diagnosis is based on identification of oocysts in the faeces in association with clinical and pathological findings.

Pathology: Lesions seen at postmortem occur in the mucosa of the colon and consist of small white, or pale yellow, plaques and petechial haemorrhages. In severe infections the whole mucosa may be destroyed. There have also been reports of hepatomegaly with focal necrosis containing oocysts.

Epidemiology: Crowding and lack of good sanitation promote spread of coccidiosis. Breeding establishments and rescue centres are potential sources of infection. Older guinea pigs are generally immune from disease but may seed the environment with oocysts leading to infection in young animals that have no previous exposure.

Treatment: Information on treatment in the guinea pig is scanty, although by analogy with other host species, the use of sulphonamides, such as sulphamezathine, should be tried.

Control: Good sanitation and isolation are effective measures in preventing coccidiosis. If possible, guinea pigs should be housed on wire floor cages to reduce the incidence of infection. Standard disinfectants are ineffective against coccidial oocysts but ammonia-based products are effective.

Cryptosporidium wrairi

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Description: Mature oocysts are ovoid, 4.8–5.6 by 4.0–5.0 μm (mean $5.40 \times 4.6 \mu\text{m}$), with a length/width ratio of 1.17. First-generation meronts are 3.4–4.4 μm when mature and contain eight merozoites; second-generation meronts contain four merozoites. Developing macrogametes are 4–7.0 μm in size.

Geographical distribution: Unknown

Pathogenesis and clinical signs: The infection has only been reported in small guinea pigs (weighing 200–300 g) and is not associated with diarrhoea or overt signs of disease. Clinical signs are usually inapparent.

Diagnosis: Oocysts may be demonstrated using Ziehl–Neelsen-stained faecal smears in which the sporozoites appear as bright-red granules. Speciation of *Cryptosporidium* is difficult, if not impossible, using conventional techniques. A range of molecular and immunological techniques has been developed that includes immunofluorescence and ELISA. More recently, DNA-based techniques have been used for the molecular characterisation of *Cryptosporidium* species.

Pathology: There may be chronic enteritis depending on the severity of infection. Lesions are usually focal when only limited areas of the intestine are affected. The organisms are more numerous in the posterior ileum and are distributed over the entire surface of the intestinal villi but are more numerous towards the tips and absent in the crypts.

Epidemiology: The primary route of infection is mainly direct animal-to-animal transmission via the faecal–oral route.

Treatment and control: Not required

Giardia intestinalis

For more details see Chapter 12.

Large intestine

Paraspidodera uncinata

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: Male worms are 16–17 mm and females 18–21 mm.

Description, microscopic: The egg is small, ellipsoidal and measures about 43 by 31 μm . The shell is thick with a smooth surface and the contents are unsegmented.

Hosts: Guinea pig, agouti

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Generally considered non-pathogenic, although heavy infections may cause weight loss, debility and diarrhoea.

Diagnosis: Diagnosis is based on identification of eggs in the faeces or adult worms in the large intestine.

Epidemiology: This caecal worm occurs naturally in the caecum and colon of the wild guinea pig in South America and in laboratory guinea pigs around the world. Infection is usually associated with guinea pigs housed in outdoor runs.

Treatment and control: Piperazine 3 g/L in the drinking water for 7 days is effective. Ivermectin 200–500 $\mu\text{g}/\text{kg}$ body weight given subcutaneously is also likely to be effective. Control is based on good hygiene and management.

A number of protozoa are found in the caecum of the guinea pig. All are considered non-pathogenic. *Entamoeba caviae* and *Tritrichomonas caviae* are common in the caeca of laboratory guinea pigs.

Entamoeba caviae

Predilection site: Caecum

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites are 10–20 μm in diameter. The nucleus, when stained, has a central or eccentric endosome with a ring of relatively coarse peripheral granules. The cysts, which are rare, are 11–17 μm in size and contain eight nuclei when mature.

Host: Guinea pig

Tritrichomonas caviae

Predilection site: Caecum

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is 10–22 μm long with a flat cylindrical nucleus, three anterior flagella and a prominent undulating membrane extending the length of the body (see Fig. 2.12). The axostyle is well defined with a prominent costa.

Host: Guinea pig

Monocercomonoides caviae

Predilection site: Caecum

Phylum: Preaxostyla

Class: Anaeromonadea

Family: Polymastigidae

Description: Trophozoites are ovoid, 4–8 μm long by 3–7 μm wide, and have three funises.

Host: Guinea pig

Monocercomonoides wenrichi

Predilection site: Caecum

Phylum: Preaxostyla

Class: Anaeromonadea

Family: Polymastigidae

Description: Trophozoites are 3–12 μm long by 3–8 μm wide and have a thick single sinuous funis.

Host: Guinea pig

Monocercomonoides quadrifunilis

Predilection site: Caecum

Phylum: Preaxostyla

Class: Anaeromonadea

Family: Polymastigidae

Description: Trophozoites are 3–13 μm long by 3–11 μm wide and have four funises.

Host: Guinea pig

Monocercomonoides exilis

Predilection site: Caecum

Phylum: Preaxostyla

Class: Anaeromonadea

Family: Polymastigidae

Description: Trophozoites are 4–9 μm long by 3–6 μm wide and have a single short funis.

Host: Guinea pig

Hexamastix caviae

Synonym: *Pentatrichomastix caviae*

Predilection site: Caecum

Phylum: Parabasalia

Class: Trichomonadea

Family: Hexamastigidae

Description: Trophozoites are 4–10 μm long by 3–5 μm wide.

Host: Guinea pig

Hexamastix robustus

Synonym: *Pentatrichomastix robustus*

Predilection site: Caecum

Phylum: Parabasalia

Class: Trichomonadea

Family: Hexamastigidae

Description: Trophozoites are 7–14 μm long by 3–8 μm wide.

Host: Guinea pig

Proteromonas brevifilia

Predilection site: Caecum

Phylum: Parabasalia

Class: Proteromonadida

Family: Proteromonadidae

Description: Trophozoites are 4–9 μm long by 2–4 μm wide.

Host: Guinea pig

Chilomitus caviae

Predilection site: Caecum

Phylum: Parabasalia

Class: Trichomonadea

Family: Monocercomonadidae

Description: Trophozoites are 6–14 μm long and 3–5 μm wide.

Host: Guinea pig

Chilomitus conexus

Predilection site: Caecum

Phylum: Parabasalia

Class: Trichomonadea

Family: Monocercomonadidae

Description: Trophozoites are 4–7 µm long by 1–2 µm wide.

Host: Guinea pig

Caviomonas mobilis

Predilection site: Caecum

Phylum: Fornicata

Class: Trepamonadea

Family: Hexamitidae

Description: Trophozoites have an ovoid to carrot-shaped body, 2–7 µm long by 2–3 µm wide, with a pointed posterior end. A single flagellum arises from the nucleus at the anterior end and extends posteriorly along the periphery of the body surface.

Hosts: Guinea pig, hamster

Enteromonas caviae

Predilection site: Caecum

Phylum: Fornicata

Class: Trepamonadea

Family: Enteromonadidae

Description: Trophozoites are 3–5 µm long and 2–4 µm wide.

Host: Guinea pig

Retortamonas caviae

Predilection site: Caecum

Phylum: Fornicata

Class: Retortamonadea

Family: Retortamonadorididae

Description: Trophozoites are 4–8 µm long by 4 µm wide, with cysts 4–6 by 3–4 µm wide.

Host: Guinea pig

Parasites of the respiratory system

No parasites of veterinary significance reported.

Parasites of the liver

No parasites of veterinary significance reported.

Parasites of the circulatory system

No parasites of veterinary significance reported.

Parasites of the nervous system

No parasites of veterinary significance reported.

Parasites of the reproductive/urogenital system

Klossiella cobayae

Predilection site: Kidney

Phylum: Apicomplexa

Class: Conoidasida

Family: Klossiellidae

Description: The mature zygote is 30–40 µm in diameter and produces 30 or more sporocysts each containing about 30 sporozoites.

Host: Guinea pig

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Although usually considered non-pathogenic, a chronic to subacute nephritis with degenerative lesions has been described.

Diagnosis: Sporocysts may be detected in urine sediments or trophozoite stages may be found on postmortem in the kidney. The site and location are pathognomonic.

Pathology: Only heavily parasitised kidneys have gross lesions, which appear as tiny grey foci on the cortical surface. Microscopically these foci are areas of necrosis, with perivascular infiltration of inflammatory cells, especially lymphocytes, with an increase in interstitial fibroblasts.

Epidemiology: Sporocysts are passed in the urine and infection takes place by the ingestion of the sporulated sporocysts.

Treatment and control: Not required

Parasites of the locomotory system

Toxoplasma gondii

For more details see section Rabbits (Parasites of the locomotory system).

Parasites of the integument

No parasites reported.

ECTOPARASITES

Lice

Gyropus ovalis

Common name: Guinea pig louse

Predilection site: Skin, especially the ears and neck

Class: Insecta

Order: Phthiraptera

Suborder: Amblycera

Family: Gyropidae

Description: *Gyropus ovalis* is a chewing louse with club-shaped antennae positioned within grooves in the head. It has a broad rounded head with four-segmented maxillary palps and stout mandibles. The body is pale yellow in colour, oval in shape and 1–1.5 mm in length and has eight abdominal segments (see Fig. 3.61).

Hosts: Guinea pig and rodents

Geographical distribution: Worldwide

Pathogenesis: This species tears pieces of skin until blood pools and then feeds from these pools. Underlying skin may be dry or oily and thickened or crusty. Severely infected animals may show secondary bacterial infection and stress, including weight loss. Infestation often accompanies manifestations of poor health, such as internal parasitism, infectious disease, malnutrition and poor sanitation.

Clinical signs: The signs of infestation are variable. Light infestation may have no obvious effects, but pruritis, dermatitis, scratching and hair loss are usually evident at heavier parasite loads.

Diagnosis: The lice and their eggs can be seen on the skin of the host animal when the hair is parted.

Epidemiology: Infection occurs after direct contact with an infested host animal. Cross-contamination between different host species is possible if the animals have physical contact.

Treatment: Since lice spend their entire life on the host animal, control is readily achieved through the use of topical insecticides. Treatment of *G. ovalis* involves dusting of the guinea pig and bedding with carbaryl 5% powder lightly once per week, dipping in 2.5% lime–sulphur solution once per weeks for 4–6 weeks, or treatment with ivermectin. However, since the eggs are quite resistant to most insecticides, repeat treatments 14 days apart are recommended to kill newly hatched nymphs. Imidacloprid is a very safe and effective treatment for guinea-pig lice and can be used on pregnant females and newly weaned young. One application lasts for 30 days.

Control: Prevention of infestation includes the use of clean bedding, which should be changed regularly. The cage and other areas where guinea pigs roam should be cleaned and rinsed thoroughly with a diluted bleach solution.

Notes: Closely related to the very similar *Gliricola porcelli*.

Gliricola porcelli

Common name: Guinea pig louse

Predilection site: Body fur

Class: Insecta

Order: Phthiraptera

Suborder: Amblycera

Family: Gyropidae

Description: A very similar species to *Gyropus ovalis*. However, *G. porcelli* is a slender yellow louse, typically measuring 1–2 mm in

length and 0.3–0.4 mm in width (see Fig. 3.62). The head is longer than it is wide and is rounded posteriorly. The maxillary palps have two segments. Antennae are four-segmented with pedicellate terminal segments and are almost concealed by the antennal fossae. The five pairs of abdominal spiracles are located ventrally within distinct sclerotised spiracular plates. The stout legs are modified for grasping hair but have no tarsal claws. A ventral furrow on the abdomen aids attachment to hair.

Host: Guinea pig

Pathogenesis: As for *Gyropus ovalis*.

Treatment and control: As for *Gyropus ovalis*.

Trimenopon hispidium

Common name: Guinea pig louse

Predilection site: Hair

Class: Insecta

Order: Phthiraptera

Suborder: Amblycera

Family: Trimenoponidae

Pathogenesis: Lice of this genus are very rare and light infestations are easily overlooked. Occasional heavy infestations may cause excessive scratching leading to alopecia and a roughened coat.

Host: Guinea pig

Treatment and control: As for *Gyropus ovalis*.

Mites

Chirodiscoides caviae

Synonym: *Campylochirus caviae*

Common name: Guinea pig fur mite

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Atopomelidae

Description: Females of *Chirodiscoides caviae* are about 500 µm and males about 400 µm in length (see Fig. 3.99). The gnathosoma is distinctly triangular. The propodosomal sternal shield is strongly striated and used to clasp hairs. The body is flattened dorsoventrally. All legs are slender and well developed, with legs I and II strongly modified for clasping to hair.

Host: Guinea pig

Geographical distribution: Worldwide

Pathogenesis: *Chirodiscoides caviae* is commonly found on guinea pigs. Light infestations probably have little effect and are easily overlooked. The mites may cause inflammation, scaling, crusting and pruritic dermatitis, leading to scratching and alopecia.

Clinical signs: Subclinical cases may be asymptomatic; clinical cases show pruritus and alopecia usually along the posterior trunk of the body.

Diagnosis: For confirmatory diagnosis, coat brushings must be examined; *C. caviae* is found only in the fur.

Epidemiology: New hosts are infected by contact with infected individuals.

Treatment: Systemic treatment with ivermectin on three occasions, 7 days apart, may be effective.

Control: All in-contact animals should be treated and the cage or housing should be cleaned.

Trixacarus caviae

Common name: Guinea pig mite

Predilection site: Skin, body

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Sarcoptidae

Description: *Trixacarus caviae* superficially resembles *Sarcoptes scabiei*. The dorsal striations of the idiosoma of *T. caviae* are similar to those of *S. scabiei* (Table 15.4). However, the dorsal scales, which break the striations, are more sharply pointed and the dorsal

Table 15.4 Differentiation between adult female *Trixacarus caviae*, *Sarcoptes scabiei* and *Notoedres cati*.

| | <i>Trixacarus caviae</i> | <i>Sarcoptes scabiei</i> | <i>Notoedres cati</i> |
|---------------|--|--------------------------|--|
| Length (µm) | 230–240 | 400–430 | 225–250 |
| Anus position | Dorsal | Terminal | Dorsal |
| Dorsal setae | All dorsal setae simple (not spine-like) | Some stout dorsal spines | All dorsal setae simple (not spine-like) |
| Dorsal scales | Many, pointed | Many, pointed | Few, rounded |

setae are simple and not spine-like. Like *Notoedres cati*, the anus is located on the dorsal surface. *Trixacarus caviae* is also smaller than *S. scabiei* and similar in size to *N. cati*; females are about 240 µm in length and 230 µm in breadth (Fig. 15.29; see also Fig. 3.91).

Host: Guinea pig

Geographical distribution: Originated in South America but has now spread worldwide.

Pathogenesis: These are burrowing mites, and the burrowing activity results in irritation, inflammation and pruritus, causing biting, scratching and rubbing of the infested areas and leading to alopecia. The infestation spreads quickly from the initial lesions to cause more generalised mange. Death may occur within 3–4 months of infestation. Transmission is by close physical contact and from mother to offspring.

Clinical signs: Infestation causes irritation, biting, scratching, rubbing and general restlessness.

Diagnosis: Confirmatory diagnosis is by examination of skin scrapings for the presence of mites. However, since these are sometimes

Fig. 15.29 *Trixacarus caviae*.

difficult to demonstrate, a negative finding should not preclude a tentative diagnosis of mange and initiation of treatment.

Pathology: Affected areas display marked acanthosis and hyperkeratosis and may become secondarily infected with bacteria.

Treatment: Ivermectin may be administered twice at intervals of 7–10 days.

Control: All bedding must be replaced, and housing and the guinea pig's local environment thoroughly cleaned.

For further details about *Sarcoptes* mites, see Chapter 11.

Demodex caviae

Predilection site: Hair follicles and sebaceous glands

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Demodicidae

Description: Small mites with an elongated cigar-shaped body, up to 0.1–0.4 mm in length, with four pairs of stumpy legs that end in small blunt claws in the adult. Setae are absent from the legs and body. The legs are located at the front of the body, and as such the striated opisthosoma forms at least half the body length.

Host: Guinea pig

Psoroptes cuniculi

Synonyms: *Psoroptes ovis*, *Psoroptes cervinus*, *Psoroptes bovis*, *Psoroptes equi*, *Psoroptes aucheniae*

Common name: Ear canker mite

Predilection site: Ears

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Psoroptidae

For detail see section Rabbits.

Guinea pigs may also be affected by the cat flea, *Ctenocephalides felis*. For details see Chapter 17.

RATS AND MICE

ENDOPARASITES

Parasites of the digestive system

Small intestine

Nippostrongylus brasiliensis

Synonyms: *Nippostrongylus muris*, *Heligmosomum muris*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: Adults are filiform and reddish in colour; males measure about 2.1–4.5 mm and females 2.5–6 mm in length. They usually appear as a tight coil.

Description, microscopic: The medium-sized eggs are ellipsoidal, thin-shelled with a smooth surface and measure about 52–63 by 28–35 µm. They contain a morula.

Hosts: Rat, mouse, hamster, gerbil, rabbit, chinchilla

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Initial light infections cause inflammation of the skin, lungs and intestines. Severe infections cause verminous pneumonia and death.

Diagnosis: Diagnosis depends on the identification of the eggs in faeces or adult worms in the intestine on postmortem.

Epidemiology: This parasite is common in wild rats but can become problematical in animal colonies where management and sanitation are poor.

Treatment: Piperazine 5 g/L in the drinking water and ivermectin by injection are effective.

Control: In laboratory colonies of rodents, eradication depends on strict hygiene and good management.

Nematospiroides dubius

Synonym: *Heligmosomoides polygyrus*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: Adults are long red worms around 0.6–1.3 cm long, with a coiled tail.

Description, microscopic: Worms possess a cephalic vesicle. The medium-sized eggs are ovoid with a thin smooth shell, measure around 68 by 43 µm and contain a morula.

Hosts: Rat, mouse

Geographical distribution: North America, Europe

Pathogenesis: Infections are usually asymptomatic but may produce small cysts in the intestinal wall.

Diagnosis: Identification of the eggs in faeces or the adult worms in the small intestine.

Epidemiology: Internal autoinfection occurs in humans, but infection in rodents usually involves an intermediate host.

Treatment and control: As for *N. brasiliensis*.

Notes: *Nematospiroides dubius* is widely used as a laboratory model for nematode infection studies.

Rodentolepis nana

Synonyms: *Hymenolepis nana*, *Hymenolepis fraterna*, *Vampirolepis nana*

Common name: Dwarf tapeworm

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Hymenolepididae

Description, gross: The tapeworm is small, 2.5–4 cm in length, and has a characteristically slender strobila with about 200 segments.

Description, microscopic: The scolex has four suckers and is armed with a retractable rostellum bearing a single row of 20–30 hooks. The genitalia are single and the segments are wider than they are long. Eggs are small, round or oval in shape and measure 44–62 by 30–55 μm . They are colourless with a smooth shell and contain a lemon-shaped embryophore with protruding polar plugs that bear long fine undulated filaments. The embryo has three pairs of small hooks.

Final hosts: Rat, mouse, birds, human, primates

Intermediate hosts: Flour beetles (*Tenebrio*) or fleas

Geographical distribution: Worldwide; common in Asia, Africa, South America and parts of southern Europe

Pathogenesis and clinical signs: Infections in laboratory rodents are relatively uncommon and usually asymptomatic, although heavy infestations can cause weight loss, vomiting and occasionally obstruction of the intestine. Heavy infections in humans may cause enteritis, anorexia and anal pruritis.

Diagnosis: Identification of the eggs in faeces or the adult worms in the small intestine.

Epidemiology: Internal autoinfection occurs in humans, but infection in rodents usually involves an intermediate host. Under conditions of poor hygiene infected rodents will contaminate food with their faeces, leading to human infection. In addition, such an environment will support the intermediate hosts. Human prevalence is highest in children.

Treatment: Not usually indicated. Niclosamide mixed in powdered feed at 10 mg per 100 mg body weight for two 7-day periods, 1 week apart, has been reported to be effective; alternatively, praziquantel 5–10 mg/kg repeated in 10 days may be used.

Control: In laboratory colonies of rodents, eradication depends on strict hygiene and elimination of potential intermediate hosts.

Notes: *Rodentolepis nana* is of peripheral veterinary importance in that it is a common tapeworm of humans and of laboratory and wild rodents. This is the only species of tapeworm for which an intermediate host is not required.

Rodentolepis diminuta

Synonym: *Hymenolepis diminuta*

Common name: Rat tapeworm

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Hymenolepididae

Description, gross: A small tapeworm, about 20–60 mm in length.

Description, microscopic: The rostellum does not possess hooks. The eggs are larger than those of *R. nana*, measuring about 60 μm , and the outer membrane is darker and may be striated.

Final hosts: Rat, mouse, occasionally dog and human

Intermediate hosts: Larvae, nymphs and adults of various species of moths, cockroaches, fleas, flour beetles and millipedes

All other details as for *R. nana*, except that *R. diminuta* requires an intermediate host whereas *R. nana* can complete its full life cycle within the intestinal tract of the definitive host. Because *R. diminuta* infection is dependent on ingestion of an infected insect, infection of humans is less likely to occur.

Coccidia***Eimeria nieschulzi***

Synonym: *Eimeria halli*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal or ovoid, smooth, colourless or yellowish, 16–26 by 13–21 μm , without a micropyle or oocyst residuum but with a polar granule. Sporocysts are elongate, ovoid and have a small Stieda body and residuum. Sporozoites contain a central nucleus with an eosinophilic globule at each end (Fig. 15.30).

Fig. 15.30 Oocyst of *Eimeria nieschulzi*. (Adapted from Pérard, 1926.)

Host: Rats (*Rattus norvegicus*, *Rattus rattus*)

Life cycle: Infection is by ingestion of sporulated oocysts. First-generation meronts occur after 36 hours followed by three further merogony generations and gametogony within the epithelial cells of the small intestine. The prepatent period is 7 days and patency 4–5 days. Sporulation time is approximately 72 hours.

Geographical distribution: Worldwide

Pathogenesis and clinical signs: *Eimeria nieschulzi* primarily affects young animals causing weakness, diarrhoea and emaciation. Animals that recover are immune but disease may occur in adults under periods of stress.

Diagnosis: Diagnosis is based on identification of oocysts in the faeces in association with clinical and pathological findings.

Epidemiology: Crowding and lack of good sanitation promote spread of coccidiosis.

Treatment: None of the available anticoccidials have been reported as effective in the rat.

Control: Infection is usually self-limiting in the individual and colony. Good sanitation and isolation are effective measures in preventing coccidiosis. Wherever possible, rats should be housed on wire floor cages to reduce the incidence of infection. Standard disinfectants are ineffective against coccidial oocysts but ammonia-based products are effective.

Eimeria falciformis

Predilection site: Small and large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are broadly ellipsoidal, smooth, colourless, 14–26 by 13–24 µm, without a micropyle or oocyst residuum. Sporocysts are elongate and have a Stieda body and residuum. Sporozoites lie longitudinally within the sporocyst (Fig. 15.31).

Host: Mouse (*Mus musculus*)

Life cycle: Infection is by ingestion of sporulated oocysts. The number of merogony stages has not been determined. The prepatent period is 4 days.

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Mild infections have little effect, but severe ones cause anorexia, diarrhoea and sometimes death.

Diagnosis: Diagnosis is based on identification of oocysts in the faeces in association with clinical and pathological findings.

Pathology: Catarrhal enteritis, haemorrhage and epithelial sloughing have been reported.

Epidemiology: Crowding and lack of good sanitation promote spread of coccidiosis. Breeding establishments and laboratory mice are potential sources of infection. In one study, eight out of ten conventional laboratory mouse colonies were found to be infected.

Treatment: None of the available anticoccidials have been reported as effective in the mouse.

Fig. 15.31 Oocyst of *Eimeria falciformis*. (Adapted from Schneider, 1875.)

Control: Control depends on good hygiene and isolation as effective measures in preventing coccidiosis. Wherever possible, laboratory mice should be housed on wire floor cages to reduce the incidence of infection. Standard disinfectants are ineffective against coccidial oocysts but ammonia-based products are effective. Deriving a new colony by Caesarean section can eliminate infection.

Several other species of coccidia are found in rats and mice worldwide but are generally considered non-pathogenic and control measures are not usually required.

Eimeria hasei

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, ellipsoidal or spherical, 16–20 by 12–17 µm, without a micropyle or oocyst residuum but with a polar granule. Sporocysts are 9 by 5 µm.

Host: Rat (*Rattus rattus*)

Geographical distribution: Russia

Eimeria nochtii

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, 15–24 by 12–22 μm , without a micropyle, oocyst residuum or polar granule.

Hosts: Rats (*Rattus rattus*, *Rattus norvegicus*)

Geographical distribution: Russia

Eimeria ratti

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are cylindrical to ovoid, 16–28 by 15–16 μm , without a micropyle or oocyst residuum but with a polar granule.

Host: Rat (*Rattus rattus*)

Geographical distribution: Russia

Eimeria musculi

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are spherical, smooth, greenish, 21–26 μm in diameter, without a micropyle or oocyst residuum. Sporocysts are broadly ovoid.

Host: Mouse (*Mus musculus*)

Geographical distribution: Russia, Kazakhstan

Eimeria scheuffneri

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal, smooth, colourless or yellowish, 18–23 by 13–16 μm , without a micropyle or oocyst residuum. Sporocysts are ovoid.

Host: Mouse (*Mus musculus*)

Geographical distribution: Russia

Eimeria krijgsmani

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are cylindrical, smooth, colourless, 18–26 by 15–16 μm , without a micropyle or oocyst residuum. Sporocysts are ovoid.

Host: Mouse (*Mus musculus*)

Geographical distribution: Russia, Kazakhstan

Eimeria keilini

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal, smooth, yellowish, 24–32 by 18–21 μm , without a micropyle or oocyst residuum.

Host: Mouse (*Mus musculus*)

Geographical distribution: Russia

Eimeria hindlei

Predilection site: Unknown

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ovoid, smooth, greenish, 22–27 by 18–21 μm , without a micropyle or oocyst residuum.

Host: Mouse (*Mus musculus*)

Geographical distribution: Russia

Cryptosporidium muris

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Description: Oocysts are small, ovoid, 7.4 by 5.6 μm , and contain four free sporozoites (Fig. 15.32). Trophozoites attached to the surface of a gland cell consist of a small amount of cytoplasm with a nucleus, and often appear to be surrounded by a cyst wall (peritrophic membrane). The maturing first-generation meronts reach a maximum size of 7 by 6 μm and contain eight merozoites. Microgametocytes are 5 by 4 μm and contain 16 microgametes; macrogametocytes are 7 by 5 μm .

Hosts: Rat, mouse, hamster, squirrel, Siberian chipmunk, wood mouse (*Apodemus sylvaticus*), bank vole (*Clethrionomys glareolus*), Patagonian mara (*Dolichotis patagonum*), rock hyrax, Bactrian camel, mountain goat, human and cynomolgus monkey

Geographical distribution: Worldwide

Fig. 15.32 Oocysts of *Cryptosporidium muris*.

Pathogenesis and clinical signs: Infections in rodents appear to cause few pathogenic effects and infections are usually asymptomatic.

Diagnosis: Oocysts may be demonstrated using Ziehl-Neelsen-stained faecal smears in which the sporozoites appear as bright-red granules. Speciation of *Cryptosporidium* is difficult, if not impossible, using conventional techniques. A range of molecular and immunological techniques has been developed that includes ELISA. More recently, DNA-based techniques have been used for the molecular characterisation of *Cryptosporidium* species.

Pathology: In heavy infections there may be large numbers of parasites within the gastric glands of the stomach (pars glandularis) with meronts and gamonts extending from the isthmus down to the base of each gland (Fig. 15.33). Infection results in thickening of the glandular mucosa with some glands becoming dilated and hypertrophied, and parasitised glands lined with undifferentiated cells.

Epidemiology: Transmission appears to be mainly via the faecal-oral route.

Treatment and control: Not required

Giardia muris

Predilection site: Small intestine

Phylum: Fornicata

Class: Trepomonadea

Family: Giardiidae

Description: The trophozoite has a pyriform to ellipsoidal, bilaterally symmetrical body, 7–13 µm long by 5–10 µm wide. The dorsal side is convex and there is a large sucking disc on the ventral side. There are two anterior nuclei, two slender axostyles, eight flagellae in four pairs and a pair of small and rounded median bodies.

Hosts: Rodents (mouse, rat, hamster)

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Infections are generally asymptomatic but have been reported to cause chronic enteritis in young mice.

Diagnosis: *Giardia* cysts can be detected in faeces by a number of methods. Traditional methods of identification involve direct examination of faecal smears, or faecal concentration by formalin-ethyl acetate or zinc sulphate methods and subsequent microscopic examination. It is generally recommended that three consecutive samples be examined as cysts are excreted intermittently.

Pathology: The pathology has not been described. There may be villous atrophy, crypt hypertrophy and an increased number of intraepithelial lymphocytes. Trophozoites may be seen between villi, attached by their concave surface to the brush border of epithelial cells.

Epidemiology: Limited epidemiological studies suggest that direct animal-to-animal contact and faecal contamination are the most

Fig. 15.33 *Cryptosporidium muris* in gastric mucosa of mouse (phase contrast).

likely methods of transmission, although water contamination can also be considered as a possible route.

Treatment and control: Metronidazole 0.5% in the drinking water for 10 days is reported to be effective. As infection is transmitted by the faecal–oral route, good hygiene and prevention of faecal contamination of feed and water are essential.

Spironucleus muris

Synonyms: *Hexamita muris*, *Octomitus muris*, *Syndyomita muris*

Predilection site: Small intestine, caecum

Phylum: Fornicata

Class: Trepanondea

Family: Hexamitidae

Description: The body is pyriform, 7–9 by 2–3 μm , with two nuclei near the anterior end, and six anterior and two posterior flagella. There is no cytostome.

Hosts: Mouse, rat, hamster

Pathogenesis and clinical signs: Infection causes enteritis and diarrhoea in laboratory rodents. With chronic infections there is weight loss and listlessness and diarrhoea is uncommon.

Diagnosis: Identification of characteristic trophozoites in mucosal smears or on histopathology. Cysts may be seen in fresh faecal smears or in smears stained with Giemsa.

Pathology: Lesions are generally confined to the anterior small intestine with inflammation of the duodenum, and the duodenal crypts are cystic and filled with trophozoites of *S. muris*.

Epidemiology: Infection is common in some rodent colonies. Transmission presumably occurs by ingestion of trophozoites or cysts from faeces or by faecal contamination.

Treatment and control: Control relies mainly on good hygiene and management in rodent colonies and culling of animals with symptoms of diarrhoea unresponsive to treatment or those showing chronic weight loss.

Large intestine

Pinworms

Pathogenesis and clinical signs: Pinworms are relatively common but non-pathogenic parasites in the large intestine of laboratory rodents.

Diagnosis: Diagnosis is based on identification of oocysts in the faeces.

Epidemiology: Crowding and lack of good sanitation promote spread of infection.

Treatment: Piperazine 4–7 g/mL given as three separate 7-day courses in drinking water; or ivermectin 0.4 mg/kg by injection or orally twice 5 days apart; or fenbendazole 0.1% in feed for 3–4 weeks.

Control: Eradication is extremely difficult and repeat anthelmintic treatment may be required.

Notes: Human infections have been reported with *Syphacia* spp. in laboratory workers.

Syphacia obvelata

Common name: Mouse pinworm

Predilection site: Caecum, colon

Phylum: Nematoda

Class: Secernentea

Superfamily: Oxyuroidea

Description, gross: Small white pointed worms, up to about 6 mm in size; males are around 1.0–1.6 mm and females 3.4–5 mm.

Description, microscopic: The mouth has three distinct lips without a buccal capsule. The oesophagus is typically oxyurid and has a pre-bulbular swelling and a posterior globular bulb. Small cervical alae are present. The male has a long slender spicule. Eggs are asymmetrical, one side being flattened or occasionally slightly concave. They have a thin shell, contain a morula and are larger than those of *Syphacia muris*, measuring 118–153 by 33–55 μm (see Fig. 4.9).

Hosts: Mouse, rat.

Geographical distribution: Worldwide

Aspicularis tetraptera

Common name: Mouse pinworm

Predilection site: Caecum, colon

Phylum: Nematoda

Class: Secernentea

Superfamily: Oxyuroidea

Description, gross: Small worms, males measuring around 2–4 mm and females 3–4 mm in length.

Description, microscopic: Three lips surround the mouth but a vestibule is absent. The oesophageal bulb is oval and the oesophagus club-shaped. Broad cervical alae are present. The male has a conical tail and lacks a spicule and a gubernaculum. The medium-sized eggs are a symmetrical ellipsoid with pointed poles. The thin shell has a smooth surface and contains a morula and occasionally a thick stubby embryo. Eggs measure 75–98 by 36–48 μm (see Fig. 4.9).

Hosts: Mouse, rat

Geographical distribution: Worldwide

Life cycle: The life cycle differs from that of *Syphacia* in that the eggs are passed in the faeces and are not found on the perineum. Infection is by ingestion of infected eggs.

Syphacia muris

Common name: Rat pinworm

Predilection site: Caecum, colon

Phylum: Nematoda

Class: Secernentea

Superfamily: Oxyuroidea

Description, gross: Small white pointed worms, up to 4 mm in size; males are about 1.2–1.3 mm and females 2.8–3.5 mm.

Description, microscopic: Morphology of the worms is similar to *Syphacia obvelata*. Eggs are ovoid and asymmetrical, one side being flattened or occasionally slightly concave. They have a smooth shell and contain a larva and measure 72–82 by 25–36 μm (see Fig. 4.9).

Hosts: Rat, mouse

Trichuris muris

Common name: Whipworms

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, microscopic: Eggs are lemon-shaped and measure about 67–70 by 31–34 μm and contain a morula. They have a thick shell with a smooth surface and two very visible protruding transparent polar plugs.

Hosts: Rat, mouse

Eimeria separata

Predilection site: Large intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are ellipsoidal or ovoid, smooth, colourless or yellowish, 10–19 by 10–17 μm , without a micropyle or oocyst residuum, but with one to three polar granules. Sporocysts are ellipsoidal and have a small Stieda body and residuum (Fig. 15.34).

Host: Rat (*Rattus norvegicus*)

Geographical distribution: North America, Europe, Asia, Africa

Entamoeba muris

Predilection site: Large intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites are 8–30 μm long. The nucleus, when stained, has a central or eccentric endosome with a ring of relatively

Fig. 15.34 Oocyst of *Eimeria separata*.

coarse peripheral granules. The cysts are 9–20 μm in size and contain eight nuclei when mature.

Hosts: Rat, house mouse, golden hamster, wild rodents

Endolimax nana

Synonyms: *Amoeba limax*, *Entamoeba nana*, *Endolimax intestinalis*, *Endolimax suis*, *Endolimax ratti*

Predilection site: Large intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites are 6–15 μm with granular vacuolated cytoplasm and a nucleus which contains an irregular endosome composed of chromatin granules. Mature cysts are oval, 8 by 1 μm long, and contain four nuclei.

Hosts: Human, apes, monkeys, pig, rat

Geographical distribution: Worldwide

Pathogenesis: Non-pathogenic

Notes: *Endolimax nana* is common in humans, primates and pigs.

Tritrichomonas muris

Synonym: *Trichomonas criceti*

Predilection site: Large intestine

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is pyriform, 12–20 μm long, and there are three anterior flagella which arise from a conspicuous blepharoplast. The undulating membrane is prominent and extends the length of the body in ribbon-like folds bounded by a thick marginal filament, which extends beyond the body as a free trailing flagellum. The costa is well developed and the axostyle is present as a thick tubular structure and has a short posterior extension.

Hosts: Mouse, rat, vole

Tritrichomonas minuta

Predilection site: Large intestine

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is 4–9 μm long and there are three anterior flagella. The undulating membrane extends almost the length of the body and there is a trailing posterior flagellum.

Hosts: Rat, mouse, hamster

Tritrichomonas wenyoni

Synonym: *Trichomitus wenyoni*

Predilection site: Large intestine

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is 4–16 μm long and there are three anterior flagella. The undulating membrane extends the length of the body and has a long trailing posterior flagellum. The axostyle is broad and hyaline.

Hosts: Rat, mouse, hamster, monkey

Tetratrichomonas microti

Synonym: *Trichomonas microti*

Predilection site: Large intestine

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is 4–9 μm long and there are four anterior flagella. The undulating membrane extends almost the length of the body and there is a trailing posterior flagellum (see Fig. 2.15). The axostyle is slender.

Hosts: Rat, house mouse, golden hamster, vole (*Microtus pennsylvanicus*), wild rodents

Enteromonas hominis

Synonyms: *Octomitus hominis*, *Tricercomonas intestinalis*, *Enteromonas bengalensis*

Predilection site: Caecum

Phylum: Fornicata

Class: Trepanomdea

Family: Enteromonadidae

Description: Trophozoites are 4–10 µm long and 3–6 µm wide and contain numerous food vacuoles.

Hosts: Rat, hamster, human, primates (chimpanzee, macaques)

Parasites of the respiratory system

Angiostrongylus cantonensis

Synonym: *Parastrongylus cantonensis*

Common name: Rat lungworm

Predilection site: Pulmonary veins

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description, gross: The body is filariform and tapered at both ends. Males measure about 18 mm and females 23 mm in length. Fresh female worms have a 'barber's pole' appearance as the white uterine tubules spiral round the blood-filled intestine.

Description, microscopic: The slender spicules are of equal length and are striated. A gubernaculum is present. The ovoid eggs laid in the pulmonary arteries are thin-shelled, transparent and unembryonated.

Final hosts: Rat, human

Intermediate hosts: Molluscs: land snails of the genera *Agrolimax*, *Limax* and *Deroceras*. Crustaceans, such as prawns and crabs, and amphibians can act as paratenic hosts.

Geographical distribution: Asia and Pacific Islands, Australia, India, Africa, Caribbean, parts of USA

Pathogenesis and clinical signs: Light infections are usually asymptomatic. Heavy infestations can lead to uncoordinated movement and weakness. There may be blood-stained fluid from the eyes and a bloody nasal discharge. The presence of parasites in the lung can cause coughing and sneezing. In humans, signs may include a stiff neck, headache, paraesthesiae, nausea, vomiting and fever.

Diagnosis: The presence of larvae in faeces. An ELISA has been developed for detection of infection in humans.

Pathology: The migration of larvae is accompanied by an eosinophilic reaction. In the lung there may be intra-alveolar haemorrhages and in the brain granulomatous reactions, haemorrhage and abscesses. The lung parenchyma may become consolidated.

Epidemiology: Rate of infection in rats and in the intermediate hosts is usually highest during the rainy seasons.

Treatment and control: Mebendazole and albendazole have been used. Anthelmintic treatment is not usually recommended for treatment of infection in humans. Control in humans is through education and cooking of the snail hosts and thorough washing of raw vegetables and salad greens.

Notes: Humans can be a paratenic host following the ingestion of infective intermediate hosts. *Angiostrongylus cantonensis* can cause meningitis and meningoencephalitis with mild to moderate symptoms, often of sudden onset, with intense headaches, vomiting, moderate intermittent fever and, in about 50% of cases, coughing, anorexia, malaise, constipation and somnolence, and in severe cases coma and death.

Parasites of the liver

Capillaria hepatica

Synonyms: *Callodium hepatica*, *Hepaticola hepatica*

Predilection site: Liver

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: These very fine filamentous worms generally measure between 1 and 5 cm in length.

Description, microscopic: The males have a long thin single spicule and often possess a primitive bursa-like structure.

Hosts: Rat, mouse, squirrel, rabbit and farmed mustelids; occasionally dog, cat, human, primates

Pathogenesis: Adult worms are found in the parenchyma of the liver where they provoke traumatic hepatitis. Eggs are laid in groups in the liver parenchyma from which there is no natural access to the exterior. Granulomas develop around the eggs, accompanied by fibrosis. Heavy infections can cause hepatitis and/or cirrhosis and ascites. The liver may be enlarged and severe infections can be fatal.

Clinical signs: Mild infections are usually asymptomatic. At necropsy, the liver may have yellowish white streaks on the surface.

Diagnosis: Most infections are discovered at routine necropsy. Granulomatous tissue in the liver parenchyma can be examined for the presence of eggs or worm fragments after squashing between microscope slides.

Pathology: The eggs, which are deposited in clusters, provoke the development of localised granulomas, which are visible through the capsule as yellowish streaks or patches.

Epidemiology: Although the prevalence of *C. hepatica* is high in the liver of rodents, it lacks host specificity and occurs in a variety of mammals.

Taenia taeniaeformis

Synonyms: *Hydatigera taeniaeformis*, *Taenia crassicollis*, *Cysticercus fasciolaris*, *Strobilocercus fasciolaris*

Predilection site: Small intestine (definitive host); liver (intermediate host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, microscopic: The metacestode stage is a small vesicle in which the scolex is not invaginated but is connected to the vesicle by a semented strobila so that the whole larva looks like a small tapeworm (a strobilocercus, i.e. *Cysticercus fasciolaris*).

Definitive hosts: Cat, lynx, stoat, fox

Intermediate hosts: Mouse, rat, rabbit, squirrel

Geographical distribution: Cosmopolitan

Pathology: Each strobilocercus is found within a pea-sized nodule partially embedded in the liver parenchyma.

Epidemiology: Rodents are infected by grazing pasture and forages contaminated with cat faeces harbouring eggs of *T. taeniaeformis*. Two cycles can occur: an urban cycle that involves the domestic cat and house and field rodents, and a sylvatic cycle that occurs in North America and which involves bobcats and wild rodents.

Notes: The correct nomenclature for the intermediate host stage is 'metacestode stage of *Taenia taeniaeformis*' rather than '*Cysticercus fasciolaris*'.

Hepatozoon muris

Synonyms: *Hepatozoon perniciosum*, *Leucocytozoon muris*, *Leucocytozoon ratti*

Predilection site: Liver, blood (lymphocytes)

Phylum: Apicomplexa

Class: Conoidasida

Family: Hepatozoidae

Description: Meronts in the liver are 10–30 µm in diameter. Gamonts in the lymphocytes appear in stained blood smears as elongated oval bodies, and are 8–12 by 3–6 µm in size.

Host: Rat

Geographical distribution: France, Israel, India, South Africa

Pathogenesis and clinical signs: Non-pathogenic

Diagnosis: Diagnosis is based on the detection of the gamonts in blood smears.

Pathology: Anaemia, emaciation, splenomegaly and hepatic degeneration have been reported in rats with severe infections but these changes may have been caused by a concurrent heavy infection with the mite vector.

Epidemiology: The vector is the spiny rat mite, *Echinolaelaps echidninus*.

Treatment and control: No effective treatment has been reported. Control of the mites will prevent transmission of the parasite.

Parasites of the circulatory system

Angiostrongylus costaricensis

Predilection site: Mesenteric arteries and arterioles

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description, gross: The worms are tapered at both ends and are filiform in shape. Males measure about 20 mm and females 30–40 mm in length. The spicules are equal in length, slender and striated.

Description, microscopic: The cephalic ends of the spicules are blunt and the caudal tips are pointed. A gubernaculum is present. The ovoid eggs laid in the mesenteric arterioles are thin-shelled, transparent and unembryonated. The embryonated eggs shed in faeces measure around 90 µm.

Definitive hosts: Rodents, common in the cotton rat; can also infect human

Intermediate hosts: Terrestrial molluscs such as slugs and snails. The slug *Vaginulus plebeius* is the main intermediate host for infection in the cotton rat and human.

Geographical distribution: Mainly Central and South America, in particular Costa Rica. Infection has occasionally been reported in other parts of the world.

Pathogenesis and clinical signs: Heavy infections with adult worms in rats can cause obstruction and necrosis of the gut wall and the mesentery and may sometimes be fatal. In humans, infection causes anorexia, vomiting, diarrhoea and fever.

Diagnosis: The L₁ larvae may be detected in faeces. At necropsy, adult worms can often be seen in the mesenteric vessels.

Pathology: Large infections can induce local haemorrhages in the arterioles. In cases where large numbers of eggs have been shed into the mesenteric capillaries, the serosal surface can have a yellowish coloration. In humans, the adult parasites are frequently present in the ileocaecocolic arteries where they induce a thickening of the intestinal wall and a granulomatous eosinophilic inflammatory response. The syndrome is termed abdominal angiostrongylosis.

Epidemiology: The cotton rat (*Sigmodon hispidus*) is the most common definitive host in the Americas. Infection of humans in endemic areas is probably through accidental ingestion of infected slugs on vegetables or salads or via infected mucous trails on green vegetation.

Treatment: Anthelmintic treatment is not advised in humans.

Control: This is not practical in rodents. Control of slugs and rodents and greater public awareness of the zoonotic disease should reduce infection in humans. Thorough washing of vegetables and salad greens is important.

Notes: Other *Angiostrongylus* species are found in wild rodents, such as *A. mackerrasae* (rats in Australia) and *A. schmidtii* (rice rat in the USA).

Parasites of the nervous system

No parasites of veterinary significance reported.

Parasites of the reproductive/urogenital system

Trichosomoides crassicauda

Common name: Bladder threadworm

Predilection site: Bladder

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description: The female is 10–19 mm long; the male measures 1.5–3.5 mm and is a permanent hyperparasite living within the reproductive tract of the female. The medium-sized egg is lemon-shaped with protruding transparent polar plugs and measures about 60–70 by 30–36 μm . The shell is thick and brown in colour, and contains either a morula or an L₁ larva. Eggs are only found in the urine.

Host: Rat

Pathogenesis and clinical signs: The parasite is generally considered non-pathogenic, although there have been reports of urinary calculi and bladder tumours associated with infection.

Pathology: The female worms occur either free in the urinary bladder or are embedded in the bladder wall. The presence of the worms can cause granulomatous lesions in the lungs, and white nodules in the bladder wall.

Epidemiology: Transmission in laboratory animals occurs from parents to offspring.

Treatment and control: Laboratory rats have been treated successfully with either orally or subcutaneously administered ivermectin.

Klossiella muris

Predilection site: Kidney

Phylum: Apicomplexa

Class: Conoidasida

Family: Klossiellidae

Description: Sporocysts measure 16 by 13 μm and contain 25–34 sporozoites.

Host: Mouse

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Infections in mice appear to cause few pathogenic effects and are usually asymptomatic.

Diagnosis: Sporocysts may be detected in urine sediments or trophozoite stages may be found on postmortem in the kidney. The site and location are pathognomonic.

Pathology: Only heavily parasitised kidneys have gross lesions, which appear as tiny grey foci on the cortical surface. Microscopically these foci are areas of necrosis, with perivascular infiltration of inflammatory cells, especially lymphocytes, with an increase in interstitial fibroblasts.

Epidemiology: Sporocysts are passed in the urine and infection takes place by the ingestion of the sporulated sporocysts.

Treatment and control: Not required

Parasites of the locomotory system

Toxoplasma gondii

For more details see section Rabbits (Parasites of the locomotory system).

ECTOPARASITES

Lice

Polyplax spinulosa

Predilection site: Fur

Class: Insecta

Order: Phthiraptera

Suborder: Anoplura

Family: Polyplacidae

Description: These lice are slender, 0.6–1.5 mm in length and yellow–brown in colour (see Fig. 3.57). The head bears prominent five-segmented antennae but has no eyes and no ocular points. There is a distinct sternal plate on the ventral surface of the thorax. The forelegs are small and the hindlegs are large with large claws and tibial spurs. The abdomen has 7–13 dorsal plates and approximately seven lateral plates on each side. The ventral thoracic plate is triangular in shape. The egg is elongated, with a cone-like operculum.

Hosts: Mouse, rat

Geographical distribution: Worldwide

Pathogenesis: These blood-sucking lice are commonly encountered in wild rats and mice, but rarely seen in laboratory rodents. They cause irritation, restlessness and constant scratching, particularly behind the ears. Anaemia, unthrifty appearance and debilitation occur in heavy infestations.

Clinical signs: Pruritus, restlessness, debilitation and anaemia

Diagnosis: Adult lice, nymphs or eggs may be found on the fur.

Treatment and control: Lice may be killed by most organophosphates (e.g. diazinon, malathion methoxychlor) and pyrethroids (e.g. permethrin). Topical application of fipronil or imidacloprid or systemic ivermectin may also be highly effective, but care must be taken because adverse effects to ivermectin have been reported in some strains of mice.

Polyplax serrata**Common name:** Spined rat louse**Predilection site:** Fur**Class:** Insecta**Order:** Phthiraptera**Suborder:** Anoplura**Family:** Polyplacidae**Description:** Similar to *P. spinulosa*. The species are differentiated on the shape of the ventral thoracic plate. In this species, the ventral thoracic plate is pentagonal.**Host:** Mouse**Pathogenicity:** *Polyplax serrata* may be a vector for murine eperythrozoonosis.**Treatment and control:** As for *P. spinulosa*.**Mites*****Ornithonyssus bacoti*****Synonyms:** *Liponyssus bacoti*, *Macronyssus bacoti***Common name:** Tropical rat mite**Predilection site:** Skin**Class:** Arachnida**Order:** Mesostigmata**Family:** Macronyssidae**Description:** This rapidly moving, long-legged mite has an oval body of about 1.0 mm in length. Both sexes feed on blood. The colour varies from white to reddish-black depending on the amount of blood it has ingested. It is similar in appearance and life cycle to the fowl mite, *Ornithonyssus sylviarum*. The body carries many long setae and is much more hairy than the red mite of poultry, *Demodex gallinae*. The adult female survives for around 70 days, during which it feeds every 2 or 3 days and lays about 100 eggs.**Hosts:** Rat, mouse, hamster and a wide variety of mammals and birds**Geographical distribution:** Worldwide**Pathogenesis:** Bites are painful and in heavy infections hosts are restless and lose weight from irritation and there may be severe anaemia.**Clinical signs:** Skin irritation and dermatitis**Diagnosis:** White or off-white eggs can be seen in the hair. Mites should be collected and identified under a dissecting microscope.**Pathology:** Feeding results in severely pruritic papular dermatitis, thickened crusty skin and soiled fur.**Epidemiology:** A common parasite worldwide, despite its name. It is particularly common in laboratory rodent colonies. Being an almost permanent parasite, infection is by contact or contamination from accommodation recently vacated by infected stock.**Treatment and control:** Treatment includes the application of topical acaricides such as pyrethrin or systemic ivermectin given orally or topically. Repeat treatments will be required to kill newly hatched nymphs.***Myocoptes musculus*****Predilection site:** Fur**Class:** Arachnida**Order:** Astigmata (Sarcoptiformes)**Family:** Myocoptidae**Description:** These mites are soft-bodied, strongly striated with a distinct dorsal shield, and have mouthparts and legs modified for grasping hairs (see Fig. 3.96). Adult female *Myocoptes musculus* are elongated ventrally, about 300 µm in length, and the propodosomal body striations have spine-like projections. The genital opening is a transverse slit. The anal opening is posterior and ventral. Legs I and II are normal, possessing short-stalked, flap-like pretarsi. Legs III and IV are highly modified for clasping hair. Males are smaller than females, about 190 µm in length, with less pronounced striations and a greatly enlarged fourth pair of legs for grasping the female during copulation. The posterior of the male is bilobed.**Hosts:** Mouse, but will also infest guinea pigs**Geographical distribution:** Worldwide**Pathogenesis:** This mite causes myocoptic mange in wild and laboratory mice. It is extremely widespread but is usually of little pathogenic significance. Problems may occur, however, in crowded laboratory colonies or in animals in poor condition. Lesions are often found along the head and neck and between the shoulder blades. With heavy infestation, mice may scratch constantly, leading to self-induced skin trauma and alopecia.**Clinical signs:** Infestation may be asymptomatic, or the mite may cause inflammation, scaling, crusting and pruritic dermatitis, leading to scratching and alopecia.**Diagnosis:** For confirmatory diagnosis, skin scrapings or coat brushings must be examined for eggs and mites.**Pathology:** Infestations may be asymptomatic, but the mite may cause erythema, inflammation, scaling, crusting and pruritic dermatitis with secondary alopecia. Chronic cases may develop secondary bacterial infection.**Epidemiology:** New hosts are infected by contact with infected individuals.**Treatment:** Application of pyrethrin dusts, or oral or systemic ivermectin on three occasions 7 days apart, may be effective. Adverse reactions to ivermectin have been reported in some strains of mice.**Control:** All in-contact animals should be treated and the cage or housing should be cleaned.***Leptotrombidium deliense*****Common names:** Scrub typhus mite, chigger**Predilection site:** Fur

Class: Arachnida

Order: Prostigmata (Trombidiformes)

Family: Trombiculidae

Hosts: Ground-dwelling rodents

Geographical distribution: Southeast Asia and Japan

Pathogenesis: Only the larvae blood feed. Infestation causes pruritus, erythema and scratching, though there may be considerable individual variation in response. The larvae of this species are vectors of scrub typhus caused by *Rickettsia tsutsugamushi*.

Notes: There are several closely related species in the genus *Leprotrombidium*. For further details see Chapter 17.

Myobia musculi

Common name: Mouse fur mite

Predilection site: Fur

Class: Arachnida

Order: Astigmata (Sarcoptiformes)

Family: Myobiidae

Description: The fur mite of mice is a small translucent mite, typically around 300 µm in length and 190 µm wide (see Fig. 3.104). The body is broadly rounded at the rear with transverse striations on the integument. The gnathosoma is small and simple with stylet-like chelicerae. Between the second, third and fourth pairs of legs there are lateral bulges and each tarsus bears an empodial claw. The anus is dorsal and flanked by a long pair of setae.

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Light infestations are asymptomatic and hence often go unnoticed. Larger mite populations result in alopecia, dermatitis, pruritus and a harsh coat. The preferred site of infestation is the head and the underside of the neck. *Myobia musculi* has a worldwide distribution.

Treatment and control: As for *Myocoptes musculinus*.

Notes: *Radfordia ensifera* and *R. affinis* are closely related species of Myobiidae, normally found on rats and mice, respectively. They are morphologically similar to *M. musculi*, but can be distinguished by the presence of two tarsal claws as opposed to just one (see Fig. 3.105). *Radfordia ensifera* produces intense itching, leading to scabs most frequently seen on the shoulders, neck and face.

A large number of other closely related species of mites may also occasionally be found on rats and mice (Table 15.5); treatment and control are as for *Myocoptes musculinus*. Distinguishing between individual genera and species is beyond the scope of this text.

Fleas

Nosopsyllus fasciatus

Common name: Northern rat flea

Predilection site: Fur and skin

Class: Insecta

Order: Siphonaptera

Family: Ceratophyllidae

Description: The northern rat flea has a pronotal comb with 18–20 spines (see Fig. 3.72). A genal ctenidium is absent. Eyes are present, and the head carries a row of three setae below the eye. The frontal tubercle on the head of both sexes is conspicuous. There are three or four bristles on the inner surface of the hind femur. The body is elongated and about 3–4 mm in length.

Hosts: Rat, mouse, human

Geographical distribution: Although originally European in distribution, the northern rat flea, *Nosopsyllus fasciatus*, has now been transported to temperate habitats worldwide.

Pathogenesis: Its main hosts are rodents, particularly the Norway rat, *Rattus norvegicus*. However, it has also been found on house mice, gophers and many other hosts. The northern rat flea will attack and feed on humans, although it is not thought to be an important vector of plague. It is known to be a vector of *Hymenolepis diminuta* in parts of Europe, Australia and South America.

Table 15.5 Species of mites found on rats and mice.

| Species | Family | Details |
|--|---------------|---|
| <i>Psorobia simplex</i> (syn. <i>Psorergates simplex</i>) | Psorergatidae | A follicular mite that causes small white intradermal nodules. Closely related to the more pathogenically important <i>Psorobia ovis</i> (see Chapter 9) |
| <i>Demodex musculi</i> , <i>Demodex ratticola</i> | Demodicidae | Largely non-pathogenic but may occasionally cause follicular dermatitis (see <i>Demodex</i> , Chapter 12) |
| <i>Notoedres muris</i> | Sarcoptidae | An ear mite of rats. It is relatively rare. It burrows into skin, and may result in yellowish crusty-looking warts on edges of ears and nose (see <i>Notoedres cati</i> , Chapter 12) |
| <i>Ornithonyssus sylviarum</i> | Macronyssidae | See Chapter 13 |
| <i>Dermanyssus gallinae</i> | Dermanyssidae | See Chapter 13 |
| <i>Liponyssoides sanguineus</i> | Dermanyssidae | House mouse mite. A blood-feeding mite of mice and rats found worldwide. It readily bites humans and may act as a vector of rickettsial pox caused by infection with <i>Rickettsia akari</i> . Distinguished from <i>D. gallinae</i> by more pointed posterior of dermal shield |
| <i>Laelaps nuttalli</i> <i>Hirstionyssus isabellinus</i> <i>Haemogamasus pontiger</i> <i>Eulaelaps stabularis</i> | Laelapidae | Adults have a single dorsal shield and the sternal plates are wider than long. Though capable of biting, they more commonly feed on skin debris and serous exudate, infesting already abraded areas of skin |
| <i>Laelaps echidninus</i> | | The spiny rat mite. A known vector of a number of disease agents such as <i>Francisella tularensis</i> and <i>Hepatozoon muris</i> |
| <i>Androlaelaps casalis</i> | | Common on a wide variety of rodents; there are several species within this genus (e.g. <i>A. rotundus</i> , <i>A. frontalis</i> and <i>A. sinuosa</i>). <i>Androlaelaps casalis</i> may also cause dermatitis of humans |

Clinical signs: Symptoms include restlessness and scratching of affected areas. The bites may be visible on the skin. Allergic dermatitis may be seen, but should be differentiated from other similar conditions such as sarcoptic mange.

Diagnosis: Diagnosis is not easy as adults may leave the host and eggs and larvae are difficult to find. The bites of these fleas are similar to those of mosquitoes, lice and mites, with inflammation and itchiness.

Epidemiology: *Nosopsyllus fasciatus* fleas are not host-specific and may attack any available mammal or bird for a blood meal. As they are able to survive off the host, transmission can occur from the bedding and housing. This flea is highly mobile on the host and can be especially common in host nesting material.

Treatment: Several organophosphate, carbamate and pyrethrin-based insecticides are effective. Imidacloprid and fipronil may be highly effective and kill adult fleas on contact.

Control: Should this species become established in pet rats or mice the animal should be treated, all litter and bedding should be removed and burnt, and the cage sprayed with an insecticide. If there is invasion of other domestic hosts or humans from wild animals, the source must be eradicated.

Xenopsylla cheopis

Common name: Oriental or black rat flea

Predilection site: Skin

Class: Insecta

Order: Siphonaptera

Family: Pulicidae

Description: *Xenopsylla cheopis* resembles *Pulex irritans* in that both genal and pronotal combs are absent (see Fig. 3.81). The head is smoothly rounded anteriorly. The flea has a light amber coloration. The maxillary laciniae reach nearly to the end of the forecoxae. Eyes are present, yet it can only see very bright light. Immediately behind the eyes are two short antennae. The segments of the thorax appear relatively large and the pleural ridge is present in the mesopleuron of the thorax. There is a conspicuous row of bristles along the rear margin of the head and a stout ocular bristle in front of the eye.

Hosts: Rat, human; this species may also infest mice, cottontail rabbits and ground squirrels

Geographical distribution: Worldwide. The distribution of the Oriental rat flea, *X. cheopis*, largely follows that of its primary host the black rat, *Rattus rattus*. It has a worldwide distribution and is one of the most abundant fleas in the southern states of the USA. It is particularly common in urban areas.

Pathogenesis: The bites of the flea may prove irritating to the host animal causing it to scratch and rub itself. *Xenopsylla cheopis* is also an intermediate host of helminths, such as *Rodentolepis diminuta* and *R. nana*. *Xenopsylla cheopis* is the main vector of *Yersinia pestis*, the cause of bubonic plague in humans. *Xenopsylla cheopis* acquires *Y. pestis* when feeding on its usual hosts. When the bacilli multiply in its gut the proventriculus becomes blocked so that blood cannot be ingested; the hungry flea moves from host to host in attempts to feed, and in its wanderings the infection may be transferred from its endemic base in rodents to the human population. Bacteria

secreted in faeces may also enter a host through abrasions. Though now rare in humans, plague still exists in wild rodents ('sylvatic plague') in parts of Africa, Asia, South America and the western states of the USA. *Xenopsylla cheopis* is also a vector of murine typhus (*Rickettsia typhi*). In the case of typhus, the disease is only transmitted by rickettsia in faeces. However, the pathogen can invade the ovary, leading to its transovarial transmission via eggs.

Clinical signs: The adult fleas may be seen on the skin and coat of the host animal. Other signs are the host scratching affected areas.

Diagnosis: Diagnosis can be achieved by identifying the flea species on the host.

Epidemiology: The fleas are able to survive off the host for long periods, making infection possible from the environment. They are uncommon in laboratory or pet rats and mice so their presence may indicate that there is contamination by wild rodents.

Pathology: Flea feeding does not appear to produce histopathology at flea feeding sites nor does the elevated blood basophilic response of infested rats affect subsequent feeding or longevity of the fleas.

Treatment: A wide range of products is available to treat infested hosts. Imidacloprid and fipronil may be used in rats to kill adult fleas on contact. Growth regulators such as methoprene or pyriproxyfen are another effective longer-term alternative.

Control: For optimal control nesting material must be removed and replaced, the housing treated and reinfestation from the environment or introduced animals prevented.

Leptopsylla segnis

Common name: Mouse flea

Predilection site: Fur

Class: Insecta

Order: Siphonaptera

Family: Leptopsyllidae

Description: In the adult there are both genal and pronotal combs and the genal comb contains only four spines.

Hosts: Mouse, rat

Geographic distribution: Europe and the east and west coasts of the USA

Pathogenesis: Bites cause irritation causing the host to scratch and rub and may provoke allergic responses. This species of flea has been infected experimentally with plague and murine typhus, but generally it is considered a poor disease vector.

Epidemiology: Found largely in temperate areas and it does not survive hot dry conditions.

Treatment and control: As for *Xenopsylla cheopis*.

Flies

Cuterebra

Common name: New World skin bot flies

Predilection site: Skin

Class: Insecta

Family: Oestridae

Subfamily: Cuterebrinae

Description, adults: The adults are large flies (up to 30 mm in length) covered by dense short hairs, and have a blue-black abdomen. They have small non-functional mouthparts and do not feed as adults.

Description, larvae: Larvae have strongly curved mouth hooks and numerous strong body spines.

Hosts: Rodents and rabbits, but may occasionally infest dogs and cats

Geographical distribution: New World

Pathogenesis: Species of the genus *Cuterebra* are largely dermal parasites of rodents and rabbits, but may occasionally infest dogs and cats. The larvae cause subdermal nodules. They are not commonly seen in laboratory colonies, but may be found in animals maintained outdoors.

Clinical signs: Symptoms include the swellings and lesions made by larvae.

Diagnosis: The presence of one or more superficially situated swellings with central openings indicates myiasis. Specific diagnosis can only be made after extraction and identification of the larvae.

Pathology: In the warble formed around each larva, a thin layer of necrotic tissue develops and the larva feeds off the tissue debris and exudate. In general, the cuterebrid species are of little economic veterinary importance. However, occasional fatal cases of infestation have been recorded in cats and dogs.

Epidemiology: Twenty-six species are known to occur in the USA and Canada. They are also found in Mexico and the neotropical regions; however, the taxonomy of this genus is not yet clearly defined. In most regions there is only a single generation per year; adults are active in spring and summer and they overwinter as pupae in the ground.

Treatment: Surgical removal of larvae can be performed relatively easily if required for infected captive animals. The cyst opening should be enlarged by incision and the parasite excised. The wound should then be rinsed with an antiseptic solution and a topical antibiotic administered.

Control: Area-wide control is impractical; for long-term management, areas of known fly activity should be avoided.

PRIMATES

Numerous parasites have been described from all the major non-human primate groups. Some of these are considered to be non-pathogenic, or at least their detrimental effects on the host have yet to be elucidated. However, a large number are pathogenic and can create opportunities for secondary infections that may be fatal, especially following immunosuppression and stress. Because of their close relationship with humans, a number of human diseases have been reported in species of monkeys used for experimental purposes.

Non-human primates are classified according to the currently most widely accepted taxonomy. **Prosimians** include the lemurs and lorises; **New World monkeys** include species in the families

Cebidae, Pitheciidae and Atelidae; **Old World monkeys** are classified within the superfamily Cercopithecoidea, which has two subfamilies, Cercopithecinae and Colobinae; and the **apes** include species in the families Hylobatidae (lower apes) and Pongidae (great apes). While extensive checklists of parasites exist for specific species of non-human primates, it is outside the scope of this section to cover all primate parasites in detail, and reference will be made mainly to the more common parasites encountered in laboratory primates and those more commonly seen in zoological collections.

ENDOPARASITES

Parasites of the digestive system

Mouth

Gongylonema macrogubernaculum

Predilection site: Oesophagus, tongue, buccal cavity

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description: Long slender whitish worms, with males up to 5.0 cm and females up to about 14.0 cm in length. Worms are characterised by the presence of longitudinal rows of cuticular bosses in the anterior region of the body.

Hosts: Old World and New World monkeys

Intermediate hosts: Coprophagous beetles, cockroaches

Clinical signs: Usually asymptomatic

Diagnosis: Scrapings of the tongue or oral mucosa and identification of the eggs.

Pathology: Adult worms bury in tunnels in the squamous epithelium of the oesophagus, lips and buccal cavity.

Epidemiology: Infection is very much dependent on the presence and abundance of the intermediate hosts, dung beetles and cockroaches.

Treatment: Ivermectin, benzimidazole anthelmintics (mebendazole, thiabendazole) and levamisole all have reported activity.

Control: Control is not practical nor necessary.

Trichomonas tenax

Synonyms: *Tetratrachomonas buccalis*, *Trichomonas buccalis*

Predilection site: Mouth

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is ovoid, ellipsoisal or pyriform, 4–16 by 2–15 mm, with four anterior flagella and a short undulating membrane with no free anterior flagella. The costa is slender and

an accessory filament is present. The capitulum of the axostyle is enlarged and spatulate and the axostyle itself is slender and extends some way beyond the body.

Hosts: Macaques (rhesus, crab-eating), baboon, chimpanzee, human

Geographic distribution: Worldwide

Notes: A number of flagellate protozoa are found throughout the gastrointestinal tract of primates and, with the exception of one or two species, are generally considered to be non-pathogenic. Some of the enteric trichomonads that infect non-human primates are also known to infect humans but are probably non-pathogenic to humans.

Entamoeba gingivalis

Synonyms: *Amoeba gingivalis*, *Amoeba buccalis*, *Amoeba dentalis*, *Entamoeba buccalis*, *Entamoeba maxillaris*, *Entamoeba canibuccalis*

Predilection site: Mouth

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites vary in size (10–20 µm long) and have no cysts. The nucleus has a small central endosome and a ring of small peripheral granules.

Hosts: Human, chimpanzee, macaques, baboons

Geographic distribution: Worldwide

Notes: This species occurs commonly in the human mouth as a harmless commensal feeding on epithelial cells and bacteria.

Stomach

Several species of nematodes have been reported from the stomach and upper gastrointestinal tract of monkeys and apes (Table 15.6).

Entamoeba histolytica

For details see section Large intestine.

Small intestine

Helminths

A large number of helminth parasites have been reported from the intestine of non-human primates, but only some are peculiar to these hosts. Primates can, under certain circumstances, become infected with common helminths affecting humans and may be used as experimental models for some major helminth diseases affecting humans.

Ancylostoma duodenale

Common name: Old World hookworm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ancylostomatoidea

Description: *Ancylostoma duodenale* is a small cylindrical worm, greyish-white in colour. There are two ventral plates on the anterior margin of the buccal capsule, each with two large teeth that are fused at their bases. A pair of small teeth is present in the depths of the buccal capsule. Males are 8–11 mm long with a copulatory bursa at the posterior end. Females are 10–13 mm long, with the vulva located at the posterior end. Eggs are typically 'strongylate' with slightly dissimilar bluntly rounded poles, barrel-shaped side walls and a thin smooth shell (Fig. 15.35).

Hosts: Human, primates (mandrills, baboons, gibbons, chimpanzees, gorillas and other species of monkeys)

Table 15.6 Species of stomach/oesophageal worms in primates.

| Species | Hosts | Site | Distribution |
|--|--|--------------------------------------|---|
| Superfamily Trichostrongyloidea | | | |
| <i>Nochtia nochtii</i> | Old World monkeys | Stomach | Africa, Asia |
| Superfamily: Spiruroidea | | | |
| <i>Gongylonema pulchrum</i> | Sheep, goat, cattle, pig, zebu, buffalo, horse, donkey, deer, camel, human, primates | Oesophagus, stomach | Worldwide |
| <i>Gongylonema macrogubernaculum</i> | Old World and New World monkeys | Oesophagus, stomach | Unknown |
| <i>Streptopharagus armatus</i> | Rhesus, cynomologus monkeys, Japanese macaque, guenon, baboon, gibbon | Stomach | Africa, Asia |
| <i>Streptopharagus pigmentatus</i> | Rhesus, cynomologus monkeys, Japanese macaques, guenon, baboon, gibbon | Stomach | Africa, Asia |
| <i>Protospirura muricola</i> | New World and Old World monkeys | Stomach | Africa, Asia, Central and South America |
| <i>Physaloptera tumefasciens</i> | Macaques | Stomach | Asia |
| <i>Physaloptera dilatata</i> | New World monkeys, marmosets | Stomach | Central and South America |
| <i>Physaloptera caucasica</i> (syn. <i>Abbreviata caucasica</i>) | Rhesus macaque, baboon, orangutan | Oesophagus, stomach, small intestine | Africa, Asia |
| <i>Physaloptera poicilometra</i> (syn. <i>Abbreviata poicilometra</i>) | Mangabey, guenon | Stomach | Africa |
| Superfamily Subuluroidea | | | |
| <i>Subulura distans</i> | Old World monkeys (baboons, mangabeys, macaques) | Stomach | Africa, Asia |

Fig. 15.35 Hookworm egg.

Geographic distribution: Southern Europe, northern Africa, India, China, Southeast Asia, parts of USA, Caribbean islands

Pathogenesis: Light infections cause abdominal pain and loss of appetite. Heavy infections cause iron-deficiency anaemia, oedema and 'pot-belly', dyspnoea on exercise and debilitation.

Diagnosis: Diagnosis is based on finding eggs in the faeces or adult worms in the intestine on postmortem.

Treatment and control: Ivermectin and mebendazole are reportedly effective. Strict sanitation is required, and routine screening and treatment should be maintained in primate colonies to ensure adequate control.

Necator americanus

Common name: New World hookworm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ancylostomatoidea

Description: Males are 7–9 mm and females about 9–11 mm long. There are two dorsal and two ventral cutting plates around the anterior margin of the buccal capsule, and a pair of subdorsal and a pair of subventral teeth posteriorly.

Hosts: Human, primates, pig, dog

Geographic distribution: USA, Brazil, Africa, China, India, South-east Asia, Pacific Islands

Strongyloides stercoralis

Synonyms: *Strongyloides canis*, *Strongyloides intestinalis*, *Anguillula stercoralis*

Common name: Threadworm

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Rhabditoidea

Description, gross: Slender hair-like worms around 2 mm long. Only females are parasitic.

Description, microscopic: The long oesophagus may occupy up to one-third of the body length and the uterus is intertwined with the intestine, giving the appearance of twisted thread. Unlike other intestinal parasites of similar size, the tail has a blunt point. *Strongyloides* eggs are oval, thin-shelled and small, 50–58 by 30–34 µm. The hatched L₁ is passed out in the faeces.

Hosts: Dog, fox, cat, human, apes, monkeys

Geographical distribution: Worldwide in warmer climates, Europe (Portugal, France, Poland, Ukraine, Romania, and Hungary)

Pathogenesis: Severe infections have been reported in chimpanzees, gibbons, orangutans, patas monkeys and woolly monkeys. Histologically, there is a multifocal erosive and ulcerative enteritis. The mucosa contains numerous parasites within epithelial tunnels or lumina of the intestinal crypts. The intestinal villi are shortened, blunted and fused. In cases of autoinfection, there may be a severe and acute granulomatous or necrotising enterocolitis associated with varying degrees of lymphatic obstruction with submucosal and serosal oedema.

Clinical signs: Bloody diarrhoea, dehydration, sometimes death. Other clinical signs include dermatitis, urticaria, anorexia, depression, listlessness, debilitation, vomiting and emaciation.

Diagnosis: The clinical signs, particularly in young animals, together with the finding of large numbers of the characteristic eggs or larvae in the faeces are suggestive of strongyloidosis.

Pathology: Lesions consist of catarrhal to haemorrhagic or necrotising enterocolitis, and multifocal and diffuse haemorrhage in the lungs with granulomas on the pleural surface. Filariform larvae are also seen in many tissues throughout the body, most commonly in the liver and lymph nodes.

Epidemiology: Transmission is via the faecal–oral route or via skin penetration by the infective larvae. A strain of *Strongyloides stercoralis* has become adapted to humans and usually occurs in warm climates. Infection in primates should be considered a potential zoonotic risk.

Treatment: Ivermectin 200 µg/kg and moxidectin 0.5 mg/kg are effective in primates. Benzimidazoles such as thiabendazole, albendazole and mebendazole are also reported to be effective.

Control: Strict hygiene, daily removal of faeces and keeping water and food free of contamination are important control measures. It is important to keep enclosures and bedding dry to reduce levels of infective larvae. Newly acquired primates should be checked on arrival and, if infected, treated.

Notes: *Strongyloides stercoralis* can cause several forms of disease in humans.

- 1 Penetration and subcutaneous migration of filariform larvae (larva migrans) can cause an itching dermatitis that often resolves spontaneously.
- 2 Migration in the mucosa of the intestinal tract can cause a chronic intestinal syndrome. Symptoms include sporadic diarrhoea, epigastric abdominal pain, heartburn, bloating and weight loss.
- 3 A mild transient pulmonary form can occasionally occur that induces mild coughing.
- 4 Occasionally, disseminated infection can induce neurological manifestations, such as Gram-negative polymicrobial meningitis. Less frequently, *S. stercoralis* has been associated with cerebral and cerebellar abscesses.

Table 15.7 Other *Strongyloides* species reported in non-human primates.

| Species | Hosts | Site |
|---------------------------------|---|-----------------|
| <i>Strongyloides fulleborni</i> | Old World monkeys (rhesus, cynomolgus monkeys, baboons, etc.), apes (chimpanzees) | Small intestine |
| <i>Strongyloides cebus</i> | New World monkeys (cebus, woolly, spider, squirrel monkeys, marmosets) | Small intestine |

Several other species of *Strongyloides* have been reported from primates and are summarised in Table 15.7. Some of these species may be synonymous.

Ascaris lumbricoides

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description: Male worms are 15–31 cm long and the posterior end is curved ventrally and has a bluntly pointed tail. Female worms are 20–49 cm long with the vulva located in the anterior end, which accounts for about one-third of its body length. The egg is ovoid and yellowish-brown, with a thick shell, the outer layer of which is irregularly mamillated (Fig. 15.36).

Hosts: Human, some primates

Pathogenesis: Generally of little clinical significance, although fatal cases have been reported in monkeys and apes due to intestinal blockage when large numbers of worms are present.

Diagnosis: The typical ascarid eggs can be detected in faeces.

Treatment and control: Strict hygiene and treatment with anthelmintics. Piperazine, mebendazole and pyrantel are reported to be effective.

Notes: *Ascaris lumbricoides* is the ascarid species found in humans. Ascarid worms isolated from primates are morphologically identical to *Ascaris lumbricoides* and therefore pose a potential zoonotic threat.

Other small intestinal nematode species of primates are listed in Table 15.8.

Intestinal trematodes

Intestinal flukes are found in both the small and large intestines of primates but natural transmission is unlikely to occur in laboratory or captive primates due to the absence of intermediate hosts. Fluke species that may be encountered in wild-caught individuals are listed in Table 15.9.

Cestodes

A range of tapeworm species has been described in primates. Tapeworm genera and species are shown in Table 15.10. Similar to the situation with intestinal flukes, most reported species of tapeworms are mainly seen in wild-caught primate species as they require an intermediate host to complete the life cycle.

Fig. 15.36 *Ascaris* egg.

Rodentolepis nana

Synonyms: *Hymenolepis nana*, *Hymenolepis fraterna*, *Vampirolepis nana*

Common name: Dwarf tapeworm

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Hymenolepididae

Table 15.8 Other small intestinal nematode species of primates.

| Species | Superfamily | Hosts |
|--------------------------------------|---------------------|-------------------------------------|
| <i>Globocephalus simiae</i> | Ancylostomatoidea | Old World monkeys |
| <i>Angiostrongylus costaricensis</i> | Metastrongyloidea | Rats, human, marmosets |
| <i>Pterygodermatitidis alphi</i> | Spiruroidea | Loris, tamarins, marmosets, gibbons |

| <i>Molineus vexillarius</i> | Trichostrongyloidea | Marmosets |
| <i>Nematodirus weinbergi</i> | Trichostrongyloidea | Apes |
| <i>Tupaiostrongylus liei</i> | Trichostrongyloidea | Prosimians (tree shrews) |
| <i>Tupaiostrongylus major</i> | Trichostrongyloidea | Prosimians (tree shrews) |
| <i>Tupaiostrongylus minor</i> | Trichostrongyloidea | Prosimians (tree shrews) |

Description, gross: The tapeworm is small, 2.5–4 cm in length, and has a characteristically slender strobila with about 200 segments.

Description, microscopic: The scolex has four suckers and is armed with a retractable rostellum bearing a single row of 20–30 hooks. The genitalia are single and the segments are wider than they are long. Eggs are small, round or oval in shape and measure 44–62 by 30–55 μm . They are colourless with a smooth shell and contain a lemon-shaped embryophore with protruding polar plugs that bear long fine undulated filaments. The embryo has three pairs of small hooks.

Final hosts: Rat, mouse, birds, human, primates

Intermediate hosts: Flour beetles (*Tenebrio*) or fleas

Geographical distribution: Worldwide; common in Asia, Africa, South America and parts of southern Europe

Pathogenesis and clinical signs: Infections in laboratory primates are usually asymptomatic, although heavy infestations can cause catarrhal enteritis and abscessation of the mesenteric lymph nodes.

Diagnosis: Identification of the eggs in faeces or the adult worms in the small intestine.

Control: Control is difficult because infection can be transmitted in a number of ways. Eradication depends on strict hygiene, elimination of potential intermediate hosts, screening of newly arrived individuals and treatment. Effective drugs include niclosamide and praziquantel.

Notes: *Rodentolepis nana* is of some veterinary importance in that it is a common tapeworm of humans and laboratory animals. This is the only species of tapeworm for which an intermediate host is not required.

Acanthocephalans

Acanthocephalan species reported in primates belong to the genera *Moniliformis* or *Prosthenorchis*. *Prosthenorchis* spp. are distributed throughout Central and South America and have been reported in a variety of New World Monkeys. *Prosthenorchis elegans* occurs in the caecum and colon and *Prosthenorchis spirula* in the terminal ileum. The life cycle is indirect, with beetles and cockroaches acting as intermediate hosts. Clinical signs vary in severity and can result in diarrhoea, anorexia, debilitation, dehydration and death.

Protozoa

Coccidian infections are generally considered to be of little importance in monkeys with few reports of associated diseases. Several species of *Eimeria* and *Isospora* (*Cystisospora*) have been reported in species of monkeys but their significance is not

known (Table 15.11). Reported species of *Eimeria* may be synonymous and host specificity between species is unknown due to lack of cross-transmission studies.

Cryptosporidium parvum

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Description: Mature oocysts are ovoidal or spheroidal, 5.0 by 4.5 µm in size (range 4.6–5.4 × 3.8–4.7 µm), with a length/width ratio of 1.19.

Hosts: Cattle, sheep, goat, horse, deer, human, primates (macaques, monkeys)

Geographical distribution: Worldwide

Pathogenesis: *Cryptosporidium* has been reported in several species of macaques, monkeys and lemurs. In rhesus monkeys it has been associated with acquired immune deficiency syndrome. In these animals, the organisms may be identified in multiple sites including the intestine, stomach, bile and pancreatic ducts.

Clinical signs: Clinical disease was associated with depression, dehydration, weight loss and intractable diarrhoea.

Diagnosis: Oocysts may be demonstrated using Ziehl–Neelsen-stained faecal smears in which the sporozoites appear as bright-red granules (see Fig. 2.25) or by fluorescence staining with auramine O. Speciation of *Cryptosporidium* is difficult, if not impossible, using conventional techniques. A range of molecular and immunological techniques has been developed that includes immunofluorescence and ELISA. More recently, DNA-based techniques have been used for the molecular characterisation of *Cryptosporidium* species.

Pathology: Lesions in the small intestine consist of stunting and fusion of the villi, hyperplasia of the surface epithelium, with focal areas of necrosis and crypt regeneration and adherent trophozoites on the enterocysts of the villi and within the crypts.

Epidemiology: A variety of mammals act as hosts to *C. parvum* but little is known of the importance of their involvement in transmitting or maintaining infection. In many instances where *Cryptosporidium* is diagnosed in animals, it appears that infections usually originate from the same host species. The primary route of infection is mainly direct animal to animal via the faecal–oral route and infected monkeys should be considered to have a high potential for zoonotic transmission.

Treatment: There is no known treatment, although spiramycin may be of some value, and the infection is difficult to control since the oocysts are highly resistant to most disinfectants except formol-saline and ammonia. Symptomatic treatment may be given in the form of antidiarrhoeals and fluid and electrolyte replacement therapy.

Control: Good hygiene and management are important in preventing disease from cryptosporidiosis. Care should be taken in handling neonatal monkeys; in addition to wearing protective clothing, handlers should follow strict personal hygiene practices.

Tritrichomonas mobilensis

Predilection site: Large intestine

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The trophozoites are 7–10 by 1.3–3 µm and lanceolate in shape. There are three anterior flagella and a well-developed undulating membrane that continues as a trailing posterior flagellum as long as the body. The nucleus is ovoid and situated in the anterior portion of the body.

Hosts: New World Monkeys (common in squirrel monkeys)

Pathogenesis: The clinical significance is unknown. The organisms invade the mucosal epithelium causing mucosal ulceration, multifocal cryptitis and focal epithelial necrosis.

Giardia intestinalis

Synonyms: *Giardia duodenalis*, *Giardia lamblia*, *Lambliablamblia*

Predilection site: Small intestine

Phylum: Fornicata

Class: Trepomonadea

Family: Giardiidae

Description: The trophozoite has a pyriform to ellipsoidal, bilaterally symmetrical body, 12–15 µm long by 5–9 µm wide. The dorsal side is convex and there is a large sucking disc on the ventral side. There are two anterior nuclei, two slender axostyles, eight flagellae in four pairs and a pair of darkly staining median bodies (see Fig. 2.21). The median bodies are curved bars resembling the claws of a hammer. Cysts are ovoid, 8–12 by 7–10 µm and contain four nuclei.

Hosts: Human, primates, cattle, sheep, goat, pig, horse, alpaca, dog, cat, guinea pig, chinchilla

Geographical distribution: Worldwide

Pathogenesis: *Giardia* is commonly seen in rhesus and cynomolgus monkeys, chimpanzees and other non-human primates.

Clinical signs: When disease does occur, the signs often include chronic pasty diarrhoea, weight loss, lethargy and failure to thrive. The diarrhoea may be continuous or intermittent.

Diagnosis: *Giardia* cysts can be detected in faeces by a number of methods. Traditional methods of identification involve direct examination of faecal smears, or faecal concentration by formalin-ethyl acetate or zinc sulphate methods and subsequent microscopic examination. It is generally recommended that three consecutive samples be examined as cysts are excreted intermittently.

Pathology: There may be villous atrophy, crypt hypertrophy and an increased number of intraepithelial lymphocytes. Trophozoites may be seen between villi, attached by their concave surface to the brush border of epithelial cells.

Epidemiology: Molecular studies have revealed a substantial level of genetic diversity in *G. intestinalis* isolates. Human isolates fall into two major groups (assemblage A and B) with a wide host range in other mammals and some separate species names may be applicable. Other assemblages may also represent distinct species. Limited epidemiological studies suggest that in animal isolates,

direct animal-to-animal contact and faecal soiling is the most likely method of transmission, although water contamination can also be considered as a possible route.

Treatment: Treatment with quinacrine and metronidazole has been reported to be effective. Quinacrine is not well tolerated in some species such as squirrel monkeys.

Control: As infection is transmitted by the faecal–oral route, good hygiene and prevention of faecal contamination of feed and water is essential.

Cyclospora cayetenensis

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are small. 8–10 µm in diameter and when sporulated contain two sporocysts, each with two sporozoites.

Hosts: Human, monkeys, reptiles

Geographic distribution: Unknown

Pathogenesis: The clinical significance in monkeys is unknown. The organism has been reported from chimpanzees and baboons but may well occur in other species of monkeys. Infection in humans can cause severe watery diarrhoea.

Treatment: Trimethoprim–sulphamethoxazole results in rapid improvement in humans and should be equally effective in primates.

Large intestine

Enterobius vermicularis

Common name: Pinworms

Predilection site: Caecum, colon

Phylum: Nematoda

Class: Secernentea

Superfamily: Oxyuroidea

Description: Adults are slender cream-coloured worms, with males around 2–5 mm and females 8–13 mm with long tails.

Hosts: Human, apes (chimpanzees)

Geographic distribution: Worldwide

Pathogenesis: Infections are usually innocuous, although fatal cases in chimpanzees characterised by ulcerative colitis and peritonitis have been reported.

Clinical signs: Anal pruritis and irritation, which may lead to self-mutilation and restlessness.

Diagnosis: Pinworm infection can be diagnosed by either observing adult worms emerging from the anus or by use of sticky tape on the anus and microscopic identification of the characteristic ellipsoidal asymmetric eggs.

Treatment and control: Control is based on strict hygiene procedures and treatment of infected animals. Pyrantel pamoate and benzimidazole anthelmintics are effective.

Other species of pinworms found in primates are listed in Table 15.12.

Oesophagostomum spp.

Common name: Nodular worms

Predilection site: Caecum, colon

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description: Adult worms are stout and whitish with a narrow cylindrical buccal capsule and measure up to 2 cm in length.

Hosts: Primates (baboons, macaques, mangabeys, guenons, chimpanzees, gorillas)

Geographic distribution: Widespread in Asia and Africa

Table 15.12 Other species of pinworms.

| | Prosimians | New World monkeys | Old World monkeys | Apes |
|-------------------------------|--------------------------------|-----------------------------------|--------------------------------|------------------------------------|
| Superfamily Oxyuroidea | <i>Enterobius lemoris</i> | <i>Trypanoxyuris trypanuris</i> | <i>Enterobius brevicauda</i> | <i>Enterobius anthropopithecii</i> |
| | <i>Primasubulura otolicini</i> | <i>Trypanoxyuris atelis</i> | <i>Enterobius bipapillata</i> | <i>Enterobius buckleyi</i> |
| | | <i>Trypanoxyuris duplicideus</i> | <i>Enterobius pitheci</i> | <i>Enterobius lerouxi</i> |
| | | <i>Trypanoxyuris lagothricis</i> | <i>Enterobius parallela</i> | <i>Probstmayria gombensis</i> |
| | | <i>Trypanoxyuris clementinae</i> | <i>Enterobius zakari</i> | <i>Probstmayria gorillae</i> |

| | | <i>Trypanoxyuris satanus</i> | <i>Enterobius inglisi</i> | |
| | | <i>Trypanoxyuris scleratus</i> | <i>Enterobius pesteri</i> | |
| | | <i>Trypanoxyuris brachylelesi</i> | <i>Enterobius macaci</i> | |
| | | <i>Trypanoxyuris callithricis</i> | <i>Enterobius presbytis</i> | |
| | | <i>Trypanoxyuris callicebi</i> | <i>Probstmayria natalensis</i> | |
| | | <i>Trypanoxyuris oedepi</i> | | |
| | | <i>Trypanoxyuris goedeli</i> | | |
| | | <i>Oxyuronema atelophorum</i> | | |
| | | <i>Primasubulura jacchi</i> | | |

Pathogenesis: The presence of larvae causes the formation of smooth elevated nodules, 2–4 mm in diameter, in the mucosa of the large intestine, and these may be blackish in colour if associated with haemorrhages. Older nodules become caseous and contain mineralised deposits. Histopathologically, the nodules are surrounded by a fibrous capsule and contain inflammatory cells, mainly neutrophils, macrophages, with eosinophils, lymphocytes, plasma cells, and with foreign-body giant cells also present.

Clinical signs: Infections are usually asymptomatic, but severely infected animals may show general unthriftiness and debilitation, characterised by weight loss and diarrhoea.

Diagnosis: Eggs present in the faeces have to be differentiated from other strongyle eggs and faecal culture may be required to identify the larvae. Postmortem diagnosis is based on the presence of typical nodular lesions.

Treatment and control: Good hygiene practices and treatment of infected animals are required to control nodular worm infections. Benzimidazole anthelmintics and levamisole are reportedly effective.

Notes: At least 11 species have been described, the main species being *O. apiostomum*, *O. bifurcatum*, *O. aculeatum* and *O. stephanostomum*.

Trichuris trichiura

Common name: Whipworms

Predilection site: Large intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description: Females are approximately 3.5–5.0 cm long and are slightly larger than males (3.0–4.5 cm). The females have a bluntly round posterior while males have a coiled posterior end.

Hosts: Human, primates

Pathogenesis: Light infections do not usually cause any significant problems. Heavy infections have been reported to result in anorexia, grey mucoid diarrhoea and sometimes death in primates.

Diagnosis: Identification of eggs, with characteristics polar plugs, in the faeces (Fig. 15.37).

Treatment and control: Strict personal hygiene is required for all animal care personnel because of the risk of zoonotic transmission. Mebendazole, flubendazole and levamisole are reportedly effective.

Ternidens deminutus

Predilection site: Caecum, colon

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Fig. 15.37 *Trichuris* egg.

Description: Adult worms are 8–16 mm long and have a large globose buccal capsule with three forked teeth at the base.

Hosts: Old World monkeys (macaques, guenons, baboons), apes (chimpanzees, gorillas), human

Geographical distribution: Africa, Asia

Entamoeba histolytica

Synonyms: *Entamoeba dysenteriae*, *Endamoeba histolytica*, *Amoeba coli*, *Entamoeba pitheci*

Predilection site: Large intestine, liver, lungs, rarely brain, spleen and stomach

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Two forms of the parasite exist: trophozoites of the large form are 20–30 µm in diameter, those of the small form are 12–15 µm. The nucleus, when stained, has a small central endosome with a ring of small peripheral granules. The cysts of both forms are 10–12 µm in size and contain four nuclei when mature and often contain rod-like chromatin bodies with rounded ends.

Hosts: Human, apes, monkeys, dog, cat, pig, rat

Geographic distribution: Worldwide

Pathogenesis: Non-pathogenic forms of the organism normally live in the lumen of the large intestine. Pathogenic forms invade the mucosa causing ulceration and dysentery. From there they may be carried via the portal system to the liver and other organs where large abscesses may form. The amoeba-like trophozoites secrete proteolytic enzymes and produce characteristic flask-shaped ulcers in the mucosa of the large intestine. Their erosion may allow the parasites to enter the bloodstream, when the most common sequela is the formation of amoebic abscesses in the liver. Infections with *E. histolytica* can cause considerable problems in colonies of chimpanzees. Infection has also been found in many species of monkeys throughout the world. Spider monkeys are particularly susceptible, often developing liver infections. Gastric amoebiasis has been reported in proboscis monkeys, colobus monkeys, silver leaf monkeys and langurs.

Clinical signs: Infections may be asymptomatic or produce mild to severe clinical signs, with invasion of the mucosa causing diarrhoea or dysentery. Clinically affected animals may show apathy, lethargy, weakness, dehydration, weight loss, anorexia, vomiting and severe haemorrhagic, or catarrhal, diarrhoea.

Diagnosis: Diagnosis is based on the identification of the causative agent in faeces or associated with typical lesions. These organisms are common non-pathogenic commensals in the digestive tract of non-human primates and their presence in the faeces of animals is not necessarily a definitive diagnosis. Motile organisms and cysts of *E. histolytica* may be detected in smears from faeces. Trophozoites and cysts can be stained with iodine, trichrome or iron haematoxylin. The organisms can also be cultured in a number of media, including Boeck and Drbohlav's, Dobell and Laidlaw's, TYI-S-33 and

Robinson's. Isoenzyme markers can be used to differentiate the two forms seen, but there is some debate as to whether the two types represent different species or if they can change from one type to another under certain circumstances.

A number of serological tests have been evaluated for the diagnosis of *E. histolytica* infections, including ELISA, latex agglutination, complement fixation and indirect haemagglutination. A number of polymerase chain reaction (PCR) methods have also been used to detect *E. histolytica* in clinical samples. These are based on the amplification of specific DNA sequences that correlate to the pathogenic/non-pathogenic isoenzyme categorisation and appear to be very sensitive and specific.

Pathology: Pathogenic strains of amoebae penetrate the mucosa of the large intestine and multiply to form small colonies that extend into the submucosa and muscularis. In the absence of bacterial infection there is little reaction, but in complicated infections there is hyperaemia and inflammation with predominantly neutrophils. Amoebae may pass into the lymphatic system and mediastinal lymph nodes and from there migrate in the portal system to the liver where they may cause abscessation. Abscesses may also form in other organs including the lungs and brain.

Epidemiology: *Entamoeba histolytica* is primarily a parasite of primates; humans are the reservoir for animals.

Treatment: Treatment, if required, relies on the combined use of metronidazole and diiodohydroxyquin.

Control: Strict sanitation is important in the prevention of amoebiasis. Trophozoites are killed by common disinfectants, but cysts are more resistant and steam cleaning may be required. Infected humans are a potential source of infection for monkeys, so routine screening of handlers or laboratory technicians is required. Insects, such as flies and cockroaches, act as mechanical vectors and should be controlled.

Entamoeba hartmanni

Predilection site: Large intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: *Entamoeba hartmanni* resembles the small form of *E. histolytica*, being slightly smaller with rounded trophozoites measuring 3–10.5 µm and a nucleus 1.5–2.5 µm in size. The peripheral chromatin is usually more variable, and consists of widely separated discrete granules. Cysts are also smaller, measuring 3.8–8.0 µm in size.

Hosts: Human, apes, monkeys

Geographic distribution: Worldwide

Notes: True incidence is not known as this species has often been considered to be synonymous with *E. histolytica*.

A number of other species of amoebae are found in monkeys and apes but are generally considered to be non-pathogenic commensals.

Entamoeba coli

Synonyms: *Amoeba coli*, *Endamoeba hominis*, *Entamoeba cynocephalusae*

Predilection site: Large intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites are 15–50 µm in diameter. The nucleus is large and eccentric and has a ring of coarse peripheral granules with scattered chromatin granules. The cysts are 10–33 µm and have eight nuclei and contain splinter-like chromatin granules.

Hosts: Human, apes, monkeys, pig, white-tailed deer

Geographic distribution: Worldwide

Pathogenesis: Non pathogenic

Notes: This is the commonest species of amoeba in humans.

Entamoeba chattoni

Synonym: *Entamoeba polecki*

Predilection site: Large intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: *Entamoeba chattoni* trophozoites are 9–25 µm long. The nucleus has a small central endosome with a row of fine peripheral granules. Cysts are 6–18 µm in size and usually uninucleate.

Hosts: Macaques and other species of monkeys; rarely human

Geographic distribution: Unknown

Iodamoeba buetschlii

Synonyms: *Iodamoeba wenyonii*, *Iodamoeba suis*, *Entamoeba williamsi*, *Endolimax williamsi*

Predilection site: Large intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites are 4–20 µm with blunt pseudopods that form slowly. The nucleus is large and contains a large nuclear endosome rich in chromatin surrounded by a layer of globules. The cysts are irregular in form, ranging from 5 to 14 µm and contain a single nucleus and a large glycogen body.

Hosts: Pig, human, apes (chimpanzee, gorilla), monkeys

Geographical distribution: Worldwide

Pathogenesis: Non-pathogenic

Endolimax nana

Synonyms: *Amoeba limax*, *Entamoeba nana*, *Endolimax intestinalis*, *Endolimax suis*, *Endolimax ratti*

Predilection site: Large intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Description: Trophozoites are 6–15 µm with granular vacuolated cytoplasm and a nucleus which contains an irregular endosome composed of chromatin granules. Mature cysts are oval, 8–10 µm long, and contain four nuclei.

Hosts: Human, apes, monkeys, pig, rat

Geographical distribution: Worldwide

Pathogenesis: Non-pathogenic

Notes: *Endolimax nana* is common in humans, primates and pigs.

Pentatrachomonas hominis

Synonyms: *Pentatrachomonas felis*, *Cercomonas hominis*, *Monocercomonas hominis*, *Trichomonas felis*, *Trichomonas intestinalis*

Predilection site: Large intestine

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is pyriform, 8–20 µm long, and there are usually five anterior flagella. Four of the anterior flagella are grouped together, and the fifth is separate and directed posteriorly. A sixth flagellum runs along the undulating membrane and extends beyond the body as a free trailing flagellum. The undulating membrane extends the length of the body. The axostyle is thick and hyaline with a sharply pointed tip. The pelta is crescent-shaped.

Hosts: Human, monkey, dog, cat, rat, mouse, hamster, guinea pig

Geographical distribution: Worldwide

Pathogenesis: *Pentatrachomonas hominis* is considered non-pathogenic.

Diagnosis: Morphological identification of the organisms from fresh and stained faecal preparations. The organism can also be cultured in trichomonad culture medium.

Treatment and control: Not required

Dientamoeba fragilis

Predilection site: Caecum, colon

Phylum: Parabasalia

Class: Trichomonadea

Family: Monocercomonadidae

Description: Only trophozoites have been described, which are 3–22 µm in diameter and contain one or two vesicular nuclei connected by a filament or desmose.

Hosts: Human, monkeys

Geographical distribution: Worldwide

Pathogenesis: Generally considered to be non-pathogenic but can cause diarrhoea in humans, with mild to moderate abdominal pain.

Enteromonas hominis

Synonyms: *Octomitus hominis*, *Tricercomonas intestinalis*, *Enteromonas bengalensis*

Predilection site: Caecum

Phylum: Fornicata

Class: Trepanonadea

Family: Enteromonadidae

Description: Trophozoites are 4–10 µm long and 3–6 µm wide and contain numerous food vacuoles.

Hosts: Rat, hamster, human, primates (chimpanzee, macaques)

Retortamonas intestinalis

Synonyms: *Embadomonas intestinalis*, *Waskia intestinalis*

Predilection site: Large intestine

Phylum: Fornicata

Class: Retortamonadea

Family: Retortamonadorididae

Description: The trophozoite is small, measuring 4–9 µm long by 4–7 µm wide, with two anterior flagella and a prominent cytostome. It has a relatively large nucleus at the anterior end with a small compact karyosome.

Hosts: Human, chimpanzee, monkeys

Tritrichomonas wenyoni

Synonym: *Trichomitus wenyoni*

Predilection site: Large intestine

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is 4–16 µm long and there are three anterior flagella. The undulating membrane extends the length of the body and has a long trailing posterior flagellum. The axostyle is broad and hyaline.

Hosts: Rat, mouse, hamster, monkey

Tritrichomonas mobilensis

Predilection site: Large intestine

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: Trophozoites are lanceolate-shaped, 7–10.5 µm long, and there are three anterior flagella with a well-developed undulating membrane that extends the length of the body and has a long trailing posterior flagellum. The nucleus is ovoid and situated anteriorly.

Host: Squirrel monkey

Pathogenesis: The clinical significance of this species is uncertain. Invasive infection has been reported in squirrel monkeys leading to focal epithelial necrosis and associated inflammatory response.

Treatment: Metronidazole has been reported to be effective.

Chilomastix mesnili

Synonyms: *Chilomastix suis*, *Chilomastix hominis*, *Macrostoma mesnili*

Predilection site: Caecum, colon

Phylum: Fornicata

Class: Retortamonadea

Family: Retortamonadorididae

Description: Trophozoites are pear-shaped, 6–24 by 3–10 µm, with a spiral groove crossing the middle half of the body and three anterior flagella. A slit-like cytostome, enclosing a fourth flagellum, is located in the anterior portion of the body. The lemon-shaped cysts are 6–10 µm in diameter and contain a single nucleus and cytostome.

Hosts: Human, apes (chimpanzee, orangutan) monkeys (macaques), pig

Geographical distribution: Worldwide

Pathogenesis: Non-pathogenic

Diagnosis: Identification of trophozoites or cysts in large intestinal contents or faeces.

Treatment and control: Not required

Spiroucleus pitheci

Synonyms: *Hexamita pitheci*, *Octomitus muris*

Predilection site: Caecum, colon

Phylum: Fornicata

Class: Trepanonadea

Family: Hexamitidae

Description: The body is pyriform, 2.5–6 by 1.5–4 µm, with two nuclei near the anterior end, and six anterior and two posterior flagella. There is no cytostome.

Hosts: Chimpanzees, monkeys (rhesus)

Balantidium coli

Predilection site: Large intestine

Phylum: Ciliophora

Class: Litostomatea

Family: Balantidiidae

Description: An actively motile organism, up to 300 μm , whose pellicle possesses rows of longitudinally arranged cilia (Fig. 15.38). At the anterior end there is a funnel-shaped depression, the peristome, which leads to the cytostome or mouth; from this, food particles are passed to vacuoles in the cytoplasm and digested. Internally there are two nuclei – a reniform macronucleus and adjacent micronucleus – and two contractile vacuoles which regulate osmotic pressure. Cysts are spherical to ovoid, 40–60 μm in diameter.

Hosts: Pig, human, camel, apes, monkeys, dog (rarely), rat

Geographical distribution: Worldwide

Pathogenesis: Generally non-pathogenic, and is a common inhabitant of the caecum of non-human primates. However, infection can cause severe ulcerative enterocolitis in great apes.

Clinical signs: Signs in clinically affected apes include weight loss, anorexia, muscle weakness, lethargy, watery diarrhoea, tenesmus and rectal prolapse.

Diagnosis: *Balantidium* is easily recognised by microscopic examination of intestinal contents or by histological examination of intestinal lesions.

Pathology: The organisms are found in enormous numbers in the lumen of the large intestine with normal caecal mucosa. However, the organism may be found within mucosal ulcers initiated by other infections. It produces hyaluronidase, which might help to enlarge the lesions by attacking the intercellular ground substance.

Fig. 15.38 *Balantidium coli* trophozoite.

Table 15.13 Filarial worms of the peritoneal cavity.

| Prosimians | New World monkeys | Old World monkeys | Apes |
|-----------------------------|-----------------------------------|-----------------------------|----------------------------|
| Family Onchocercidae | <i>Mansonella barbascalensis</i> | <i>Mansonella digitatum</i> | <i>Mansonella vanhoofi</i> |
| | <i>Mansonella zakii</i> | | |
| | <i>Mansonella nicollei</i> | | |
| | <i>Dipetalonema gracile</i> | | |
| | <i>Dipetalonema caudispina</i> | | |
| | <i>Dipetalonema graciliformis</i> | | |
| | <i>Dipetalonema robini</i> | | |
| | <i>Dipetalonema tenue</i> | | |

Epidemiology: *Balantidium coli* exists as a common commensal in the large intestine of most monkeys. Humans and apes may occasionally become clinically affected through faecal contamination of foodstuffs or hands. Transmission occurs by ingestion of cysts or trophozoites. The cysts are resistant to environmental conditions and can survive for weeks in faeces.

Treatment: Tetracyclines, metronidazole and diiodohydroxyquin are effective.

Control: Strict sanitation to prevent ingestion of cysts or faeces should prevent infection in non-human primate colonies.

Peritoneum

A variety of filarial worms (Filarioidea) commonly parasitise primates, being found in the subcutaneous tissues and the abdominal and thoracic cavities (Table 15.13). Worms in the abdominal cavity may cause fibrinopurulent peritonitis with associated fibrinous adhesions. Transmission of these parasites within primate colonies is unlikely and no special control measures are required other than control of possible arthropod vectors.

The larval form of several species of pentastomids are also found in the peritoneum and peritoneal cavity of primates, which act as intermediate hosts to the adult stages which are found in either dogs or snakes depending on the genus.

Linguatula sericata is a parasite of dogs and nymph stages have been reported in the viscera of Old World and New World monkeys. Species of *Armillifer* and *Porocephalus* are parasites of snakes with nymph stages reported in prosimians, Old World and New World monkeys and apes throughout Africa, Asia and South America.

Parasites of the respiratory system

Anatrichosoma cynomolgi

Synonyms: *Anatrichosoma cutaneum*, *Anatrichosoma rhina*, *Anatrichosoma nacepobi*

Predilection site: Nasal mucosa, nares, skin

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description: Adult worms are small and slender.

Hosts: Old World primates (macaques, mangabeys, langurs, baboons), New World primates (marmoset), apes (orangutan, gibbon), human

Geographical distribution: Africa, Asia

Pathogenesis: Female worms migrate through the stratified layers of the squamous epithelium forming tunnels and pustules around the nares.

Diagnosis: Nasal or skin scrapings reveal the characteristic eggs.

Nasal mites (genus *Rhinophaga*) are found in the nasal cavity and upper respiratory tract of Old World monkeys and apes (Table 15.14). Their presence can cause inflammation and nasal polyp formation.

Filaroides spp.

Predilection site: Lungs

Phylum: Nematoda

Class: Secernentea

Superfamily: Metastrongyloidea

Description: Adult worms are very slender and fragile.

Hosts: New World monkeys (marmosets, squirrel, cebus and howler)

Pathogenesis: Infection produces varying numbers of small subpleural nodules.

Clinical signs: Infections are usually asymptomatic.

Notes: Reported species include *F. barretoi*, *F. gordius* and *F. cebus*. A related species, *Filariopsis arator*, also occurs in New World primates.

Table 15.14 Nasal mites of primates.

| Species | Hosts | Site |
|---------------------------------|---------------|------------------------|
| <i>Rhinophaga papinois</i> | Baboon | Maxillary sinuses |
| <i>Rhinophaga elongata</i> | Baboon | Nasal cavities |
| <i>Rhinophaga dinolti</i> | Rhesus monkey | Nasal cavities, lung |
| <i>Rhinophaga cercopithecii</i> | Guenons | Frontal sinuses, lungs |
| <i>Rhinophaga pongicola</i> | Orangutan | Maxillary sinuses |

Paragonimus westermani

Common name: Oriental lung fluke

Predilection site: Lung

Phylum: Platyhelminthes

Class: Trematoda

Family: Paragonimidae

Description, gross: The parasite is rounded and thick, reddish-brown in colour, 7.5–16 by 4–8 mm, and covered in scale-like spines. The ventral sucker is situated slightly anterior to the middle of the fluke.

Description, microscopic: Species differentiation is based on the shape of the spines. Those in *P. westermani* are large and have bifid points. Eggs are yellowish-brown in colour, operculate, 75–118 by 42–67 μm , and the shell is thickened at the opposite end to the operculum (Fig. 15.39).

Hosts: Dog, cat, pig, goat, cattle, fox, other carnivores, human, primates (cynomolgus monkey)

Geographical distribution: Asia, North America

Pathogenesis: Parasites in the lungs are not usually of great importance, but some may lodge in the brain or other organs causing

more severe damage. Pulmonary signs are comparatively rare in cats or dogs and the veterinary interest is in the potential reservoir of infection for humans. Extrapulmonary infections may produce cutaneous larva migrans and abscess formation in the skin and viscera. Brain and spinal cord involvement may lead to seizures, paraplegia and occasional deaths.

Clinical signs: In lung infections there may be a cough and eggs may be found in the sputum in large numbers.

Diagnosis: Diagnosis is by identifying the presence of eggs in the sputum or faeces.

Pathogenesis: Infection causes focal emphysema and the formation of cysts (2–3 cm in size) that may cause pleural adhesions.

Epidemiology: Infections in cynomolgus monkeys are associated with the ingestion of crabs or crayfish.

Pneumocystis carinii

Predilection site: Lungs

Phylum: Ascomycota

Class: Pneumocystidomycetes

Family: Pneumocystidaceae

Fig. 15.39 *Paragonimus westermani* egg.

Description: Trophozoites are usually pleomorphic and found in clusters. These multiply asexually resulting in the formation of a pre-cyst initially, and then an early cyst and a mature cyst eventually.

Notes: *Pneumocystis carinii* was originally considered to be a protozoan, but is now recognised as a fungus and is therefore not described in detail.

Pneumonyssus simicola

Common name: Lung mite

Predilection site: Lungs

Class: Arachnida

Subclass: Acari

Family: Halarachnidae

Description: The mites are oval and yellowish-white, with adults measuring approximately 0.5 mm. The legs are large, with leg segments wider than long and with well-developed claws.

Hosts: Old World monkeys (rhesus, cynomolgus, patas, colobus, proboscis, Celebes ape, mangabey, baboons, langurs) and apes (chimpanzee, gorilla, orangutan).

Geographical distribution: Africa, Asia

Pathogenesis: Infections result in pale spots throughout the lung parenchyma and pleural adhesions may be present. The lesions are soft and pale and contain 1–20 mites, and are surrounded by a brown to black pigment are characterised by a localised bronchiolitis, focal pneumonitis, alveolar consolidation and occasional bronchiolectasis. The inflammatory cell exudate comprises neutrophils, eosinophils and macrophages containing pigment and refractile crystals.

Clinical signs: Infections are usually asymptomatic and clinical signs are uncommon. Death has been reported in rhesus monkeys with massive infestations.

Diagnosis: Diagnosis in the live animal is difficult. Tracheobronchial washings may demonstrate lung mite larvae, but negative washings are not conclusive that infections do not exist. Gross lesions are characteristic but need to be differentiated from tuberculosis.

Epidemiology: *Pneumonyssus simicola* is very common in imported rhesus monkeys.

Treatment and control: There is no reported effective treatment and control can only be achieved through the establishment of mite-free colonies.

Other *Pneumonyssus* species in the respiratory tract of primates are listed in Table 15.15.

Parasites of the liver

Capillaria hepatica

Synonyms: *Callodium hepatica*, *Hepaticola hepatica*

Predilection site: Liver

Phylum: Nematoda

Table 15.15 *Pneumonyssus* species in the respiratory tract of primates.

| Species | Hosts | Site |
|------------------------------------|-------------------------|---------------------------------------|
| <i>Pneumonyssus duttoni</i> | Old World monkeys | Lungs |
| <i>Pneumonyssus longus</i> | Old World monkeys, apes | Lungs, bronchi, trachea |
| <i>Pneumonyssus oudemansi</i> | Old World monkeys, apes | Lungs, bronchi, trachea |
| <i>Pneumonyssus africanus</i> | Old World monkeys | Bronchi |
| <i>Pneumonyssus mossambicensis</i> | Old World monkeys | Lungs |
| <i>Pneumonyssus congoensis</i> | Old World monkeys | Trachea, lungs |
| <i>Pneumonyssus rodhaini</i> | Old World monkeys | Lungs, nasal fossae |
| <i>Pneumonyssus vitzthumi</i> | Old World monkeys | Lung, maxillary sinuses, nasal fossae |
| <i>Pneumonyssus vocalis</i> | Old World monkeys | Larynx, vocal pouches |

Class: Secernentea

Superfamily: Trichuroidea

Description: These are very fine filamentous worms measuring 10–50 mm in length. The anterior portion of these parasites is more slender than the posterior.

Hosts: Rat, mouse, squirrel, rabbit and farmed mustelids; occasionally dog, cat, human and primates including New World monkeys (*Cebus*, squirrel, spider), Old World monkeys (rhesus) and apes (chimpanzee).

Pathogenesis: Adult worms are found in the parenchyma of the liver where they provoke traumatic hepatitis. Eggs are laid in groups in the liver parenchyma from which there is no natural access to the exterior. Granulomas develop around the eggs, accompanied by fibrosis. Fatal hepatitis has been reported in primates.

Clinical signs: Mild infections are usually asymptomatic. At necropsy, the liver may have yellowy white streaks on the surface.

Diagnosis: Most infections are discovered at routine postmortem. Granulomatous tissue in the liver parenchyma can be examined for the presence of eggs or worm fragments after squashing between microscope slides.

Pathology: The eggs, which are deposited in clusters, provoke the development of localised granulomas, which are visible through the capsule as yellowish streaks or patches.

Notes: Although the parasite can infect humans, the zoonotic risk is low.

Echinococcus granulosus

Common names: Dwarf dog tapeworm, hydatidosis

Predilection site: Mainly liver and lungs (intermediate hosts); small intestine (definitive host)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: ‘Hydatid’ cysts are large fluid-filled vesicles 5–10 cm in diameter, with a thick concentrically laminated cuticle and an internal germinal layer.

Description, microscopic: The germinal layer produces numerous small vesicles or brood capsules each containing up to 40 scolices, invaginated into their neck portions and attached to the wall by stalks. Brood capsules may become detached from the wall of the vesicle and float freely in the vesicular fluid and form ‘hydatid sand’.

Final hosts: Dog and many wild canids

Intermediate hosts: Domestic and wild ruminants, human and primates, pig and lagomorphs; horses and donkeys are resistant

Geographical distribution: Worldwide

Pathogenesis: Hydatid cysts have been described from a number of Old World monkeys (guenons, colobus, mangabeys, mandrill, macaques, Celebes ape, baboons), New World monkeys (marmosets), apes (chimpanzee, gorilla, orangutan) and prosimians (lemurs). Cysts may be located in the abdomen, thoracic cavity, liver, lungs or subcutis.

Clinical signs: Infections are usually asymptomatic but may cause abdominal distension or localised swellings depending on the size and location of the cysts.

Diagnosis: The diagnosis of hydatidosis is not usually made until the cysts reach a large size and symptoms may be mistaken for a tumour. Ultrasound and radiography have been used in diagnosis in apes. Serological tests developed for use in humans have also proven useful.

Notes: Considerable phenotypic and genetic variability has been observed within the species *E. granulosus* and several strains have been identified based on molecular genotyping. New data demonstrate that ‘*E. granulosus*’ is an assembly of several rather diverse strains and genotypes (designated G1–G10) that show fundamental differences not only in their epidemiology but also in their pathogenicity to humans.

Two other species, *E. multilocularis* in lemurs, macaques, gorillas, gibbons and orangutan, and *E. vogeli* in great apes (gorillas, orangutans and chimpanzees) have also been reported.

Flukes

A number of species of flukes have been reported in primates (Table 15.16). Reported fluke species are invariably seen in wild-caught primates as they require an intermediate host to complete their life cycles.

Table 15.16 Fluke species from primates.

| Prosimians | New World monkeys | Old World monkeys | Apes |
|-----------------------------|----------------------------------|-------------------------------------|---------------------------------|
| Family Dicrocoelidae | <i>Athesmia heterolecithodes</i> | <i>Brodedia lacinata</i> | <i>Eurytrema brumpti</i> |
| | <i>Controrchis biliophilus</i> | <i>Dicrocoelium colobusciola</i> | <i>Dicrocoelium lanceolatum</i> |
| | | <i>Dicrocoelium lanceolatum</i> | <i>Dicrocoelium macaci</i> |
| | | <i>Dicrocoelium macaci</i> | <i>Eurytrema satoi</i> |
| | | <i>Euparadistomum cercopithecii</i> | |
| | | <i>Eurytrema satoi</i> | |

Entamoeba histolytica

For more details see section Large intestine.

Parasites of the pancreas

Eurytrema pancreaticum

Synonyms: *Distoma pancreaticum*, *Eurytrema ovis*

Common name: Pancreatic fluke

Predilection site: Pancreatic ducts, rarely the bile ducts

Phylum: Platyhelminthes

Class: Trematoda

Family: Dicrocoeliidae

Description, gross: Oval, leaf-shaped, reddish-brown flukes measuring around 8–16 by 5–8.5 mm.

Description, microscopic: The body is thick and the juvenile flukes are armed with spines which are often absent by the adult stage. The oral sucker is larger than the ventral sucker and the pharynx and oesophagus are short. The testes are positioned horizontally just behind the ventral sucker. A tubular cirrus sac is present. The uterus completely occupies the posterior body. Eggs measure around 40–50 by 25–35 µm and are similar to those of *Dicrocoelium*.

Final hosts: Cattle, buffalo, sheep, goat, pig, camel, human, primates

Intermediate hosts: Two are required. Host 1: land snails, particularly of the genus *Bradybaena*. Host 2: grasshoppers of the genus *Conocephalus* or tree crickets (*Oecanthus*).

Geographical distribution: South America, Asia and Europe

Parasites of the circulatory system

Schistosomes

Schistosomes are flukes found in the circulatory system. The sexes are separate, the small adult female lying permanently in a longitudinal groove, the gynaecophoric canal, in the body of the male. The genus has been divided into four groups – *haematobium*, *indicum*, *mansoni* and *japonicum* – but the genus as currently defined is paraphyletic so revisions are likely.

Several species of *Schistosoma* have been reported to infect non-human primates but are generally of little consequence in captive

animals and are usually only observed as incidental findings on post-mortem. Infected primates are not of direct public health significance because of the need for an obligate intermediate molluscan host.

Haematobium group

Schistosoma haematobium

Predilection site: Bladder veins, urethra

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: Adult males are around 10 mm and females 15 mm in length.

Description, microscopic: Both sexes have a strong oral sucker and a smaller posterior ventral sucker. Males have a gynaecophoric canal where females are usually located. Males have five to nine testes and no cirrus pouch, cirrus or prostate cells. The genital pore is located directly behind the ventral sucker. Females have only one ovary near the centre of the body and a uterus that can contain 20–100 eggs.

Final hosts: Human, primates (mangabeys, patas monkeys, guenons, baboons)

Intermediate hosts: Snails (*Bulinus*)

Geographical distribution: Africa, Middle East

Schistosoma mattheei

Predilection site: Portal, mesenteric and bladder veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The sexes are separate; the males are 9–22 mm long and 1–2 mm wide, and the females 12–28 mm long. The suckers and the body of the male behind the suckers are armed with minute spines, while the dorsal surface of the male bears small cuticular tubercles.

Description, microscopic: The eggs passed in faeces are usually spindle-shaped, but smaller ones may be oval. They measure 170–280 by 72–84 µm. There is no operculum.

Final hosts: Cattle, sheep, goat, camel, rodents, human, primates (baboons)

Intermediate hosts: Snails (*Bulinus*)

Geographical distribution: South and Central Africa, Middle East

Mansoni group

Schistosoma mansoni

Predilection site: Mesenteric veins

Phylum: Platyhelminthes

Class: Trematoda

Family: Schistosomatidae

Description, gross: The adult male is up to 10 mm in length and possesses a longitudinal groove, the gynaecophoric canal, that enfolds the female, which is longer (12–16 mm) and more slender. The tegument of the male has tubercles on the dorsal surface, whereas the tegument of the female is smooth. The male has six to nine testes, and the male genital pore opens ventrally, immediately posterior to the ventral sucker. The female possesses a single ovary located in the anterior portion of the body.

Geographical distribution: South America, Caribbean, Africa, Middle East

Brugia spp.

The lymphatic filarial worms (*Brugia* spp.) are carried by many species of mosquito and occur in Southeast Asia, notably Malaysia, causing elephantiasis in humans (Table 15.17). The most important human species, *B. malayi*, is also infective for monkeys and domestic and wild carnivores. Adult parasites inhabit lymph nodes and afferent lymphatic vessels.

Trypanosoma cruzi cruzi

Synonyms: *Schizotrypanum cruzi*, *Trypanosoma lesourdi*, *Trypanosoma rhesii*, *Trypanosoma prowazeki*, *Trypanosoma vickersae*

Common name: Chagas' disease

Predilection site: Blood, heart, muscle

Phylum: Euglenozoa

Class: Kinetoplastea

Family: Trypanosomatidae

Subgenus: *Schizotrypanum*

Description: Trypanosomes are monomorphic, 16–20 µm long, with a pointed posterior end and a curved stumpy body and a narrow undulating membrane with a trailing flagellum. The kinetoplast is large and subterminal, causing the body to bulge around it. Amastigotes are 1.5–4 µm in diameter and occur in groups.

Hosts: Human, dog, cat, New World primates, wild animals

Table 15.17 Lymphatic filarial worms in primates.

| | Prosimians | New World monkeys | Old World monkeys | Apes |
|----------------------|-----------------------|-------------------|-----------------------|------|
| Family Onchocercidae | <i>Brugia tupaiae</i> | | <i>Brugia malayi</i> | |
| | | | <i>Brugia pahangi</i> | |

Intermediate hosts: Reduviid bugs (assassin or kissing bugs)

Geographical distribution: South America

Pathogenesis: Tryptomastigote forms are found in blood, and amastigote forms are found in pseudocysts in skeletal and cardiac muscle, the reticuloendothelial system and other tissues. Infection causes generalised oedema, anaemia, hepatosplenomegaly and lymphadenitis.

Clinical signs: Depression, anorexia and weight loss can occur.

Diagnosis: In acute stages of the disease, trypomastigotes can be found in thick blood smears stained with Giemsa. The size and morphology make it relatively easy to distinguish from other trypomastigotes found in primates. Complement fixation or ELISA serological tests are available for humans and may be helpful in screening monkeys.

Pathology: Myocarditis is commonly seen in non-human primates, leading to destruction of myocardial fibres caused by the parasite pseudocysts.

Epidemiology: Reduviid bugs commonly defecate after feeding, and animals become infected when they lick the insect bites or eat the infected bugs. Transmission also occurs by ingesting infected animals, via infected maternal milk, by fly contamination, or contamination by urine or saliva of heavily infected animals.

Treatment and control: There is no effective treatment. Control is based on eliminating the insect vector. Because the disease is zoonotic, handlers should take precautions to avoid exposure or contamination of mucous membranes or skin to infective secretions.

Plasmodium

Plasmodium spp. cause malaria in both humans and animals. Malaria is one of the most common haemoprotozoal parasitic diseases of primates in tropical and semi-tropical regions. Malaria parasites that infect the apes are different to those affecting monkeys, and are homologous to human malaria parasites and morphologically indistinguishable. The parasites are classified on the basis of the host infected, the parasite morphology and on the type of cyclic fever produced (quotidian, 24 hours; tertian, 48 hours; quartan, 72 hours). Reported species are summarised in Table 2.23.

Pathogenesis: Malaria infections in most primates are generally not fatal. However, they may cause debilitation and disease which can be precipitated by stress, concurrent disease or immunosuppression. Infection causes hepatosplenomegaly and lymphoid hyperplasia in the spleen, liver and bone marrow. Myeloid hyperplasia of the bone marrow leads to erythropoiesis and malarial pigmentation (hemozoin) in the Kupffer cells of the liver, in bone marrow macrophages and in red pulp of the spleen. Splenic rupture, nephron necrosis in the kidney and haemorrhages in the brain have been reported in infected animals.

Diagnosis: Diagnosis depends on the morphological identification of the organisms in the erythrocytes in blood smears stained with Giemsa. Fluorescent antibody tests have been developed for non-human primates to determine current, or previous, malaria infections.

Treatment: Malaria in primates can be treated with chloroquine given intramuscularly, followed by primaquine given orally. Both

drugs should be given separately because of increased risk of toxicity when given together.

Control: Effective mosquito control is essential to prevent malaria transmission in primate colonies. Infected primates are also a source of infection to humans, if the mosquito vectors are present, and appropriate steps should be taken to minimise risk of zoonotic transmission.

Malaria parasites of prosimians

Plasmodium hylobati, Plasmodium eylesi, Plasmodium jefferyi, Plasmodium youngi

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Hosts: Gibbons

Geographical distribution: Southeast Asia

Pathogenesis: *Plasmodium hylobati*, *P. eylesi* and *P. youngi* produce a quartan malaria in gibbons and are reported to be pathogenic, producing a fever associated with the parasitaemia.

Malaria parasites of Old World monkeys

Plasmodium knowlesi

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Hosts: *Cynomolgus* monkey, leaf monkey, pig-tailed macaque, rhesus monkey, human

Geographical distribution: Southeast Asia

Pathogenesis: This quotidian malaria parasite produces a virulent infection in the rhesus monkey that is almost always fatal and resembles acute *P. falciparum* infection in humans.

Plasmodium cynomolgi

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Hosts: Toque monkey, pig-tailed macaque, bonnet macaque, leaf monkeys, rhesus monkey, human

Geographical distribution: Southeast Asia, East Indies, Philippines

Pathogenesis: A tertian malaria parasite of low pathogenicity that causes a low-grade parasitaemia resembling *P. ovale* infection in humans.

Plasmodium gonderi

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Hosts: Mangabeys, drills

Geographical distribution: West and Central Africa

Pathogenesis: A tertian malaria parasite that produces a high, chronic parasitaemia in rhesus monkeys, and which can also infect baboons, guenons and humans.

Plasmodium fieldi

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Hosts: Cynomolgus monkey, pig-tailed macaque

Geographical distribution: Malay Peninsula

Pathogenesis: A tertian malaria parasite that can cause severe disease in rhesus monkeys that is often fatal.

Plasmodium fragile

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Hosts: Toque monkey, bonnet macaque

Geographical distribution: Southern India, Sri Lanka

Pathogenesis: A tertian malaria parasite that causes severe disease and death in rhesus monkeys.

Plasmodium siminovale

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Host: Toque monkey

Geographical distribution: Sri Lanka

Pathogenesis: A tertian malaria parasite of low pathogenicity but which can cause severe anaemia and is similar to *P. ovale* infection in humans.

Plasmodium coatneyi

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Host: Cynomolgus monkey

Geographical distribution: Malay Peninsula, Philippines

Pathogenesis: A tertian malaria parasite similar to *P. knowlsei* that causes severe anaemia in rhesus monkeys.

Plasmodium inui

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Hosts: Cynomolgus monkey, pig-tailed macaque, Celebes black ape, human

Geographical distribution: Southeast Asia extending from India to the Philippines

Pathogenesis: A quartan malaria parasite of low pathogenicity that causes a mild to moderate non-fatal illness resembling *P. malariae* infection in humans.

Plasmodium shorti

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Hosts: Toque monkey, bonnet macaque

Geographical distribution: Sri Lanka

Pathogenesis: A quartan malaria parasite which has been transmitted experimentally to humans.

Malaria parasites of New World monkeys

Plasmodium simium

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Hosts: Howler monkeys, spider monkeys, capuchin, woolly monkeys, squirrel monkeys, human

Geographical distribution: Southern Brazil

Pathogenesis: A tertian malaria parasite resembling *P. vivax* infection in humans.

Plasmodium brazilianum

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Hosts: Howler monkeys, spider monkeys, capuchin, woolly monkeys, squirrel monkeys, human

Geographical distribution: Mexico, Central America and into South America

Pathogenesis: A quartan malaria parasite that causes severe symptoms and is considered to be the same as *P. malariae* infection in humans.

Notes: The most common malarial parasite of New World monkeys.

Plasmodium rodhaini

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Hosts: Chimpanzees, gorillas, human

Geographical distribution: West to Central Africa

Pathogenesis: A quartan malaria parasite that is considered synonymous with *P. malariae* infection in humans.

Malaria parasites of apes

Plasmodium pitheci

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Host: Orangutan

Geographical distribution: Borneo

Pathogenesis: Little is known about this parasite in terms of pathogenicity and disease produced.

Plasmodium silvaticum

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Host: Orangutan

Geographical distribution: Borneo

Pathogenesis: Little is known about this parasite in terms of pathogenicity and disease produced.

Plasmodium reichenowi

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Hosts: Chimpanzees, gorillas, human

Geographical distribution: West, Central and East Africa

Pathogenesis: A mildly pathogenic quartan malaria parasite similar to *P. falciparum* infection in humans.

Plasmodium schwetzi

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Hosts: Chimpanzees, gorillas, human

Geographical distribution: West Africa

Pathogenesis: A mildly pathogenic tertian malaria parasite similar to *P. vivax* infection in humans. The disease caused is often subclinical.

Hepatocystis kochi

Predilection site: Blood

Phylum: Apicomplexa

Class: Conoidasida

Family: Hepatozoidae

Hosts: Old World monkeys, apes (gibbons, orangutan)

Description: The intraerythrocytic parasite has an unusual nucleus which, when stained with Giemsa, has a large, oval, pink nucleoplasm that occupies one-third or more of the parasite. Within the nucleus are numerous red chromatin granules.

Geographical distribution: Indian subcontinent, Africa (south of Sahara)

Table 15.18 Other *Hepatocystis* species.

| Species | Hosts | Vectors |
|-----------------------------------|---------|------------------------------|
| <i>Hepatocystis semnopithecii</i> | Monkeys | Midges (<i>Culicoides</i>) |
| <i>Hepatocystis taiwanensis</i> | Monkeys | Midges (<i>Culicoides</i>) |
| <i>Hepatocystis bouillezi</i> | Monkeys | Midges (<i>Culicoides</i>) |
| <i>Hepatocystis cercopithecii</i> | Monkeys | Midges (<i>Culicoides</i>) |
| <i>Hepatocystis foleyii</i> | Monkeys | Midges (<i>Culicoides</i>) |

Pathogenesis and clinical signs: Infected primates have numerous scattered greyish-white foci on the surface of the liver due to the presence of mature merocysts. Histologically, the cysts are surrounded by neutrophils. Following rupture of the cyst, a granulomatous inflammatory reaction occurs with infiltration of lymphocytes and macrophages. Because of this location, clinical disease, cyclical fever and blood parasitaemia do not usually occur in infected animals.

Diagnosis: Diagnosis is based on demonstration and identification of the parasite in blood smears or finding the typical hepatic lesions on postmortem.

Epidemiology: Incidence is high in primates within endemic areas.

Treatment and control: Treatment is not usually required. An effective vector control programme prevents spread within primate colonies.

Other *Hepatocystis* species in monkeys are listed in Table 15.18.

Babesia pitheci

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Babesiidae

Description: The piroplasms are pyriform in shape and measure 2–6 µm long. Round, oval and lanceolate shapes have also been reported.

Hosts: Old World monkeys (mangabeys, guenons, macaques, baboons), New World monkeys (marmosets)

Geographical distribution: Unknown

Pathogenesis and clinical signs: *Babesia pitheci* is considered to be only slightly pathogenic.

Parasites of the nervous system

Taenia multiceps

Synonyms: *Multiceps multiceps*, *Coenurus cerebralis*

Common names: Gid, coenurosis

Predilection site: CNS, subcutaneous tissues, liver and other organs (intermediate hosts); small intestine (final hosts)

Phylum: Platyhelminthes

Class: Cestoda

Family: Taeniidae

Description, gross: When mature the *Coenurus cerebralis* cyst is readily recognised as a large fluid-filled transparent bladder up to 5 cm or more in diameter.

Description, microscopic: The coenurus bears clusters of several hundred protoscolices on its internal wall.

Final hosts: Dog, fox, coyote, jackal

Intermediate hosts: Sheep, cattle, deer, pig, horse, camel, human, primates (macaques, vervets, baboons)

Geographical distribution: Worldwide

Pathogenesis: The coenurus takes about 8 months to mature in the CNS and, as it develops, it causes damage to the brain tissue resulting in neurological disturbances. These cysts can cause pressure atrophy, which may lead to perforation of the skull. When cysts locate in the spinal cord the resulting pressure can lead to paresis of the hindlimbs. Although an acute form of coenurosis can occur, chronic disease is more frequently identified. The migration of large numbers of larval stages through the brain can rapidly lead to neurological dysfunction and death.

Clinical signs: Clinical signs depend on the number of cysts present and their location. When the CNS is involved, neurological symptoms may occur.

Diagnosis: Diagnosis can be made by radiography or the finding of masses in the subcutaneous tissues. Identification is based on the morphology of the scolices.

Pathology: The cyst or cysts are mainly located in one cerebral hemisphere and occur less frequently in the cerebellum and spinal cord (see Fig. 9.58). The growth of the cysts within the brain or skull causes pressure atrophy of adjacent cerebral tissue. The migration of large numbers of immature stages in the brain of lambs can lead to acute meningoencephalitis. In acute cases of coenurosis, pale yellow tracts are frequently present on the surface of the brain. They comprise necrotic tissue with marked cellular infiltration. In chronic coenurosis there may be compression of brain tissue by the developing cyst and the increased intracranial pressure can result in local softening of the bones of the skull, either above the cyst or in other areas.

Thelazia callipaeda

Common name: Eye worm

Predilection site: Eye, conjunctival sac and lacrimal duct

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Small thin white worms 1.0–1.7 cm long; males are 7–11.5 mm and females 7–17 mm.

Description, microscopic: In the male the left spicule is much longer than the right. In the female the vulva is in the oesophageal region. When laid the eggs contain a fully developed larva.

Final hosts: Dog, cat, human, primates and occasionally sheep and deer

Intermediate hosts: Muscid flies, particularly *Fannia* spp., and drosophilid fruit flies of the genera *Amiota* and *Phortica*

Geographical distribution: Far East

Pathogenesis: Invasion of the lacrimal gland and ducts may cause inflammation leading to occlusion and reduced tear production. Mechanical irritation of the conjunctiva produces inflammation, while damage to the cornea leads to opacity, keratitis and corneal ulceration.

Clinical signs: Conjunctivitis, excessive lacrimation

Diagnosis: This is based on observation of the parasites in the conjunctival sac or on the conjunctiva following local anaesthesia, or finding larvae in the lacrimal secretion.

Epidemiology: *Thelazia* infections occur seasonally and are linked to periods of maximum fly activity.

Treatment: Surgical removal with forceps following the application of an ocular local anaesthetic. In cases of secondary bacterial infection the use of antibiotic eye preparations may be indicated. Ivermectin 0.2 mg/kg subcutaneously has been reported to be effective as has direct instillation of 1% moxidectin.

Several opportunistic pathogens known to infect humans and other mammals have been reported in the brains of primates. Their significance is as a cause of meningoencephalitis in humans, particularly in immunosuppressed or immunocompromised individuals. Infections with several of these pathogens have been established in macaques under experimental conditions.

***Acanthamoeba* spp.**

Predilection site: Brain, lung

Phylum: Amoebozoa

Class: Archamoeba

Family: Acanthamoebidae

Description: Relatively small amoebae with a vesicular nucleus and a large endosome but without well-developed cytoplasm. Cysts have a single nucleus.

Hosts: Old World monkeys, human

Geographical distribution: Presumed worldwide

Pathogenesis and clinical signs: *Acanthamoeba* are opportunistic pathogens that have reportedly caused meningoencephalitis and keratitis in humans.

Naegleria fowleri

Predilection site: CNS, nasal mucosa

Phylum: Percolozoa

Class: Heterolobosea

Family: Vahlkampfiidae

Description: The trophozoites are characterised by a nucleus and a surrounding halo. They travel by pseudopodia, temporary round processes which fill with granular cytoplasm. The pseudopodia form at different points along the cell, thus allowing the trophozoite to change direction.

Hosts: Old World monkeys, human

Geographical distribution: Presumed worldwide

Pathogenesis and clinical signs: *Naegleria* are opportunistic pathogens found in water, faeces and sewage, and cause amoebic meningoencephalitis in humans.

Treatment: There is no effective treatment.

Encephalitozoon cuniculi

Synonym: *Nosema cuniculi*

Predilection site: Brain, kidney, heart, lungs

Kingdom: Fungii

Phylum: Microsporidia

Order: Microsporida

Family: Enterocytozoonidae

Description: Microsporidia are obligate, intracellular, spore-forming protozoa. Trophozoites are 2–2.5 by 0.8–1.2 µm in tissue sections or 4 by 2.5 µm in smears. Spores are about 2 µm long and contain a spirally coiled polar filament with four to five coils.

Hosts: Rabbit, dog, red fox (*Vulpes vulpes*), blue fox (*Alopex lagopus*), silver fox, cat, mouse, rat, human, monkeys

Geographical distribution: Worldwide

Parasites of the reproductive/urogenital system

Schistosoma haematobium

For more details see Parasites of the circulatory system.

***Klossiella* spp.**

An unknown species of *Klossiella* has been reported from the kidneys of marmosets. In other hosts, where these parasites are more commonly found, infections are not considered significant.

Parasites of the locomotory system

Infections with *Sarcocystis* have been described in the skeletal muscle, and occasionally in the heart and smooth muscle, of a number of primate species. The two main species reports in rhesus monkeys involve *Sarcocystis kortei* and *Sarcocystis nesbitti*. Other unnamed species have been reported from both Old World and New World monkeys. Their life cycles and definitive hosts are also unknown.

Table 15.19 Filarial worms of the subcutis in primates.

| | Prosimians | New World monkeys | Old World monkeys | Apes |
|-----------------------|-----------------------------|--------------------------------|-------------------------------------|-------------------------------------|
| Family: Onchocercidae | <i>Dipetalonema petteri</i> | <i>Mansonella atelenis</i> | <i>Dirofilaria corynoides</i> | <i>Dirofilaria immitis</i> (pongoi) |
| | | <i>Mansonella parvum</i> | <i>Dirofilaria immitis</i> | <i>Mansonella rohmani</i> |
| | | <i>Mansonella panamensis</i> | <i>Dirofilaria repens</i> | <i>Mansonella streptocerca</i> |
| | | <i>Mansonella saimiri</i> | <i>Dirofilaria magnilarvatum</i> | <i>Mansonella leopoldi</i> |
| | | <i>Mansonella columbiensis</i> | <i>Cercopithifilaria papionis</i> | <i>Mansonella gorillae</i> |
| | | <i>Dipetalonema tenue</i> | <i>Cercopithifilaria degraffi</i> | <i>Mansonella lopeensis</i> |
| | | | <i>Cercopithifilaria verveti</i> | <i>Loa loa</i> |
| | | | <i>Cercopithifilaria narokensis</i> | |
| | | | <i>Cercopithifilaria eberhardi</i> | |
| | | | <i>Loa papionis</i> | |

Sarcocystis spp.

Predilection site: Muscle

Phylum: Apicomplexa

Class: Conoidasida

Family: Sarcocystiidae

Description: Sarcocysts present in the muscle are cylindrical, spindle-shaped or irregular in structure and variable in size, depending on host and species, and lie lengthwise in the muscle cells.

Diagnosis: Sarcocystiosis is usually an incidental finding, and diagnosis is based on the identification of the characteristic intramuscular cysts.

Pathology: Lesions associated with naturally occurring infections are rare. Infection causes inflammation characterised by infiltrates of lymphocytes, plasma cells and eosinophils associated with degeneration of cysts within the muscle fibres.

Notes: Reported species include *S. kortei* and *S. nesbitti* from Old World monkeys.

Toxoplasma gondii

For details see section Rabbits (Parasites of the locomotory system).

Trypanosoma cruzi

For details see Parasites of the circulatory system.

Parasites of the integument

Subcutaneous filarial worms

A variety of filarial worms (Filarioidea) commonly parasitise primates, being found in the subcutaneous tissues and the abdominal and thoracic cavities (Table 15.19). Subcutaneous worms cause little if any inflammatory response, whereas those in the serous cavities may cause a fibrinopurulent peritonitis or pleuritis with associated fibrinous adhesions. Transmission of these parasites within primate colonies is unlikely and no special control measures are required other than control of possible arthropod vectors.

ECTOPARASITES

Lice

Chewing (biting) lice (Suborder Amblyocera, Ischnocera = Mallophaga) are rare on primates and of little significance (Table 15.20). In contrast, numerous species of sucking lice (Suborder Anoplura) have been reported from a wide variety of primates (Table 15.21). Many species of sucking lice are considered interchangeable between apes, humans and New World monkeys and thus some of the species names used may be synonymous or no longer valid. For further details of the lice genera see Chapter 3 (Order Phthiraptera).

Mites

Sarcoptes scabiei

Common name: Scabies

Predilection site: Skin

| Family Pthiridae | | | | <i>Pthirus pubis</i> |

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Sarcoptidae

Description, adults: The adult of this species has a round, ventrally flattened, dorsally convex body. Adult females are 0.3–0.6 mm long and 0.25–0.4 mm wide, while males are smaller, typically up to 0.3 mm long and 0.1–0.2 mm wide. The posterior two pairs of limbs do not extend beyond the body margin (see Fig. 3.89). In both sexes, the pretarsi of the first two pairs of legs bear empodial claws and a sucker-like pulvillus, borne on a long stalk-like pretarsus. The sucker-like pulvilli help the mite grip the substrate as it moves. The third and fourth pairs of legs in the female and the third pair of legs in the male end in long setae and lack stalked pulvilli. The mouthparts have a rounded appearance. These mites have no eyes or stigmata. The dorsal surface of the body of *S. scabiei* is covered with transverse ridges, but also bears a central patch of triangular scales. The dorsal setae are strong and spine-like. The anus is terminal and only slightly dorsal. There are several host-adapted varieties of *S. scabiei* that differ subtly in their morphology.

Description, larvae and nymphs: The hexapod larvae and the octopod nymphs resemble the adults in general form.

Hosts: All domestic mammals, human, primates (cynomolgus monkey, drills, chimpanzees, gorillas, orangutans, gibbons)

Geographical distribution: Worldwide

Pathogenesis: Host reactions occur primarily in response to the feeding and burrowing activity of the mites and their faecal deposits.

Clinical signs: Signs include intense pruritis, anorexia, emaciation and self-mutilation with bleeding and secondary bacterial dermatitis. There may be thickening of the skin and hair loss.

Diagnosis: Confirmatory diagnosis is by examination of skin scrapings for the presence of mites. However, since these are sometimes difficult to demonstrate, a negative finding should not preclude a tentative diagnosis of mange and initiation of treatment.

Epidemiology: Infestations on primates are transmissible to humans by direct contact and infected animals should be handled with caution.

Treatment and control: Infected animals should be treated with an acaricide and successful treatment has been reported with ivermectin.

Other mite species found on primates are listed in Table 15.22.

Fleas

There is little information on flea infestations in primates. Most recorded species are opportunistic species that are natural parasites of other animals. Flea species are covered in more detail in Chapter 17.

Flies

The larval bots of several species of flies in the families Cuterebrinae and Calliphoridae are reported to infect primates. Further details are provided in the checklist at the end of this chapter and in Chapter 17.

Ticks

A number of species of ixodid ticks have been reported from numerous species of primates throughout the areas of the world where wild primates are found. Ticks are important as vectors of disease, many of which are zoonotic, and their importance in primates is very much dependent on tick abundance and species distribution. In captive primates, ticks are less of a problem because when engorged they drop off, and under conditions of captivity the hosts are unlikely to become reinfested.

Where they do occur, tick infestations are generally asymptomatic, but with heavy parasite loads irritation and anaemia may manifest. Because ticks can be vectors of zoonotic diseases, newly acquired primates should be quarantined, examined and treated if infested.

Species of ticks reported from primates are provided in the checklists at the end of this chapter and in Chapter 17.

HOST–PARASITE CHECKLISTS

In the following checklists, the codes listed below apply:

Helminths

N, nematode; T, trematode; C, cestode; A, acanthocephalan.

Arthropods

F, fly; L, louse; S, flea; M, mite; Mx, maxillopod; Ti, tick; Pn, pentastomid.

Protozoa

Co, coccidia; Bs, blood sporozoa; Am, amoeba; Fl, flagellate; Ci, ciliate.

Miscellaneous ‘protozoal organisms’

B, blastocyst; Mi, microsporidian; My, *Mycoplasma*; P, Pneumocystidomycete; R, *Rickettsia*.

ENDOPARASITES

Parasites of the digestive system

Dispharynx nasuta

For details see section Crop and proventriculus.

Crop and proventriculus

Trichomonas gallinae

Synonyms: *Cercomonas gallinae*, *Trichomonas columbae*

Common names: Canker, frounce, roup

Predilection site: Pharynx, oesophagus, crop, proventriculus

Phylum: Parabasalia

Class: Trichomonadea

Family: Trichomonadidae

Description: The body is elongate, ellipsoidal or pyriform, 5–19 by 2–9 μm , with four anterior flagella that arise from the blepharoplast. The undulating membrane does not reach the posterior end of the body and a free posterior flagellum is absent (see Fig. 2.13). An accessory filament is present. The axostyle is narrow, protrudes 2–8 μm from the body and its anterior portion is flattened into a spatulate capitulum. There is a crescent-shaped pelta anterior to the axostyle and there is no chromatic ring at its point of emergence. The parabasal body is hook-shaped and has a parabasal filament and the costa is a very fine rod running three-quarters the length of the body.

Hosts: Pigeon, turkey, chicken, raptors (hawks, falcons, eagles)

Geographical distribution: Worldwide

Pathogenesis: The domestic pigeon is the primary host, but the parasite has been found in birds of prey that feed on pigeons, and it has been experimentally established in a wide range of other birds. *Trichomonas gallinae* is extremely common in domestic pigeons and often causes serious losses. Previous infection leads to a varying degree of immunity, and adult pigeons that have survived infection as squabs are symptomless carriers. Infection with a relatively harmless strain produces immunity against virulent strains. Injection of plasma from infected pigeons also confers immunity.

In pigeons, trichomonosis is essentially a disease of young birds; 80–90% of adults are infected but show no signs of disease. Trichomonosis varies from a mild condition to a rapidly fatal one with death 4–18 days after infection (there are strain differences in virulence).

Clinical signs: Severely affected birds lose weight, stand huddled with ruffled feathers and may fall over when forced to move. Yellow necrotic lesions are present in the mouth, oesophagus and crop of pigeon squabs and a greenish fluid containing large numbers of trichomonads may be found in the mouth. The condition is often fatal.

Diagnosis: The clinical signs are pathognomonic and can be confirmed by identifying the characteristic motile trichomonads from samples taken from lesions in the mouth or from fluid.

Pathology: The early lesions in the pharynx, oesophagus and crop are small, whitish to yellowish caseous nodules. These grow in size and may remain circumscribed and separate, or may coalesce to form thick, caseous, necrotic masses that may occlude the lumen. The circumscribed disc-shaped lesions are often described as 'yellow buttons'. The lesions in the liver, lungs and other organs are solid, yellowish, caseous nodules up to 1 cm or more in diameter.

Epidemiology: In pigeons and doves, trichomonosis is transmitted from the adults to the squabs in the 'pigeon milk' which is produced in the crop. The squabs become infected within minutes of hatching. Hawks and wild raptors become infected by eating infected birds.

Treatment: Carnidazole is used for the treatment and prophylaxis of trichomonosis in pigeons at a dose rate of 10 mg for adult birds and 5 mg for squabs. Other nitroimidazole compounds, such as dimetridazole and metronidazole, are also effective, but their availability has declined in many countries through legislative changes and toxicity concerns.

Control: Control of trichomonosis in pigeons depends on elimination of the infection from the adult birds by drug therapy.

Notes: *Trichomonas gallinae* parasitises the mouth, sinuses, orbital region, pharynx, oesophagus, crop and even proventriculus, but is not found beyond the proventriculus. It often occurs in the liver and, to a lesser extent, in other organs including the lungs, air sacs, heart, pancreas and, more rarely spleen, kidneys, trachea and bone marrow.

Ornithostrongylus quadriradiatus

Predilection site: Crop, proventriculus, small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: The adult worms, which measure up to around 2.5 cm, are blood-suckers, have a reddish colour and can be seen by the naked eye.

Description, microscopic: The anterior of the worm has a long, slightly inflated vesicle, which is present from the cephalic area to the cervical region. The tail of the female worm is blunt with a small spine. In the male bursa, the ventral rays are close together and the dorsal ray is short. The telamon is shaped like a small bar with two arms and covers the tips of the spicules. Spicules end in three pointed processes. Eggs are ovoid and measure 70–75 by 38–40 µm.

Hosts: Pigeon, doves

Geographical distribution: North America, South Africa, Australia, Europe

Pathogenesis: The worms are voracious blood-feeders and burrow into the mucosa and in severe infections cause a catarrhal enteritis.

Clinical signs: Causes an enteritis and anaemia, which in heavy infections may result in severe mortality in domestic pigeons.

Diagnosis: Identification of the worms on postmortem or eggs in the faeces.

Pathology: Haemorrhagic enteritis with ulceration and necrosis may occur in severe infections.

Epidemiology: The parasite may be responsible for heavy losses in breeding establishments.

Treatment: Oral benzimidazoles used for other nematode species should be effective.

Control: Where pigeons or doves are kept should be cleaned regularly to avoid build-up of eggs and infective larvae.

Spiruroid nematodes

Several species of spiruroid worms belonging to the genera *Tetrameres* and *Dyspharynx* are found in the proventriculus of pigeons. These species have been described in detail in Chapter 13.

Tetrameres americana

Synonym: *Tropisurus americana*

Predilection site: Proventriculus

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: The adults show sexual dimorphism. The males are pale white, slender and only about 5–6 mm long. The females are bright red and almost spherical, with a diameter of about 3.5–5.0 mm (see Fig. 13.1).

Description, microscopic: Males have spiny cuticles and no cordons; females have four deep longitudinal furrows on the surface. Eggs are oval, thick-shelled, 42–60 by 24–45 µm, and embryonated when passed. They are transparent in appearance and have thickened poles.

Final hosts: Chicken, turkey, duck, goose, grouse, quail, pigeon

Intermediate hosts: Cockroaches, grasshoppers and beetles

Geographical distribution: Africa and North America

Tetrameres fissispina

Synonym: *Tropisurus fissispina*

Predilection site: Proventriculus

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Final hosts: Duck, goose, chicken, turkey, pigeon and wild aquatic birds

Intermediate hosts: Aquatic crustaceans such as *Daphnia* and *Gammarus*; grasshoppers, earthworms

Geographical distribution: Most parts of the world

Dispharynx nasuta

Common name: Spiral stomach worm

Synonyms: *Dispharynx spiralis*, *Acuaria spiralis*, *Acuaria nasuta*

Predilection site: Oesophagus, proventriculus

Phylum: Nematoda

Class: Secernentea

Superfamily: Acuarioidea

Description, gross: The body is slender and coiled, particularly the posterior of the male. Males measure up to around 8 mm and the females 11 mm long.

Description, microscopic: The cuticle is ornamented with four wavy cordons that re-curve anteriorly and do not fuse. The left spicule is slender and the right spicule shorter and oval-shaped. The eggs are thick-shelled, 33–40 by 18–25 µm and embryonated when passed.

Final hosts: Chicken, turkey, pigeon, guinea fowl, grouse, pheasant and other birds

Intermediate hosts: Various isopods such as sowbugs (*Porcellio scaber*) and pillbugs (*Armadillidium vulgare*)

Geographical distribution: Asia, Africa and the Americas

Small intestine

Ascaridia columbae

Synonym: *Ascaridia maculosa*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: The worms are stout and densely white; males measure 16–17 mm and females 20–95 mm in length.

Description, microscopic: The egg is distinctly oval, with a smooth shell, and measures 80–90 by 40–50 μm .

Host: Pigeon

Geographical distribution: Presumed worldwide

Pathogenesis: Non-pathogenic

Clinical signs: Large numbers of worms produce no clinical signs.

Diagnosis: Adult worms may be found in the intestine on postmortem or the characteristic ascarid eggs may be seen in faeces.

Pathology: No associated pathology

Epidemiology: Adult birds are symptomless carriers, and the reservoir of infection is on the ground, either as free eggs or in earthworm transport hosts. Infection is heaviest in young squabs.

Treatment: Not usually required although treatment with piperazine salts, levamisole or a benzimidazole such as fenbendazole is effective. Capsules containing fenbendazole or cambendazole are effective and can be given by mouth to pigeons.

Control: Strict hygiene and feeding and watering systems, which will limit the contamination of food and water by faeces, should be used.

The following helminths have been reported in the intestines of pigeons and have been described in detail in Chapter 13.

Capillaria caudinflata

Synonym: *Aonchotheca caudinflata*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: These are very fine filamentous worms, the narrow stichosome oesophagus occupying about one-third to half the body length. Males measure around 6–12 mm and females up to 25 mm. Females have a characteristic vulval appendage.

Description, microscopic: The males have a long thin single spicule, with a spiny spicule sheath, and often possess a primitive bursa-like structure.

Final hosts: Chicken, turkey, goose, pigeon and wild birds

Intermediate hosts: Earthworms

Geographical distribution: Worldwide

Treatment and control: Oral capsules containing fenbendazole or cambendazole are effective.

Capillaria obsignata

Synonyms: *Baruscapillaria obsignata*, *Capillaria columbae*

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: Males measure around 10–12 mm and females up to 15 mm.

Description, microscopic: The tail of the female worm tapers posteriorly. The medium-sized eggs are barrel-shaped with slightly striated bipolar plugs and possess a shell with a reticulate pattern (see Fig. 4.7).

Hosts: Pigeon, chicken, turkey, wild birds

Geographical distribution: Worldwide

Davainea proglottina

Predilection site: Small intestine, particularly the duodenum

Phylum: Platyhelminthes

Class: Cestoda

Family: Davaineidae

Description, gross: *Davainea proglottina* is a very small cestode, up to 1–4 mm long, and usually possesses only four to nine segments (see Fig. 13.2).

Description, microscopic: The rostellum bears 80–94 hooks, arranged in a double row, and the suckers bear a few rows of small hooks. Each segment contains a single set of reproductive organs. The genital pores alternate regularly.

Final hosts: Chicken, turkey, pigeon and other gallinaceous birds

Intermediate hosts: Gastropod molluscs such as *Agriolimax*, *Arion*, *Cepaea* and *Limax* and land snails

Geographical distribution: Most parts of the world

Railletina tetragona

Predilection site: Posterior half of small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Davaineidae

Description, gross: A large tapeworm reaching around 20–25 cm in length.

Description, microscopic: The scolex is small and the 'neck' is quite prominent. The oval suckers are lightly armed with several rows of fine hooklets and the rostellum bears one or sometimes two rows of around 100 hooks.

Final hosts: Chicken, guinea fowl and pigeon

Intermediate hosts: Ants of the genera *Pheidole* and *Tetramorium* and house flies

Geographical distribution: Worldwide

Echinoparyphium recurvatum

Predilection site: Small intestine, particularly the duodenum

Phylum: Platyhelminthes

Class: Trematoda

Family: Echinostomatidae

Description, gross: The fluke is about 4 by 0.7 mm and curved ventrally.

Description, microscopic: Spines are present anterior to the ventral sucker and the head-crown is armed with spines.

Final hosts: Duck, goose, chicken, pigeon and human

Intermediate hosts: Host 1: snails such as *Lymnaea* spp. and *Planorbis* spp. Host 2: frogs, tadpoles and snails, such as *Valvata piscinalis* and *Planorbis albus*, and shellfish

Geographical distribution: Worldwide, particularly Asia and North Africa

Hypoderaeum conoideum

Predilection site: Posterior small intestine

Phylum: Platyhelminthes

Class: Trematoda

Family: Echinostomatidae

Description, gross: Adult fluke have an elongate body, 5–12 mm long and tapering posteriorly.

Description, microscopic: The anterior body is armed with about 50 small spines and bears a large ventral sucker.

Final hosts: Chicken, turkey, duck, goose, swan, pigeon and other aquatic birds

Intermediate hosts: As for *E. recurvatum*.

Geographical distribution: Worldwide

Eimeria labbeana

Synonyms: *Eimeria peifferi*, *Eimeria columbarum*

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are subspherical to spherical, smooth, colourless or slightly yellowish-brown, 13–24 by 12–23 μm , without a micropyle or a residuum but with a polar granule. Sporocysts are elongate ovoid, with a Stieda body and residuum. The sporozoites are slightly crescent-shaped with one end wider than the other, lie lengthwise head to tail in the sporocysts, and have a clear globule at each end.

Hosts: Pigeon (*Columba domestica*), rock dove (*Columba livia*), collared dove (*Streptopelia decaoto*)

Life cycle: After the sporulated oocysts are ingested, the sporozoites are released and invade the epithelial cells of the intestine. First-generation meronts are present 20–48 hours after infection in the epithelial cells of the anterior ileum. Mature second-generation meronts are present 96 hours and mature third-generation meronts 144 hours after infection. The macrogametes are in the epithelial cells of the ileum. The prepatent period is about 5 days. The sporulation time is 4 days or less.

Geographical distribution: Worldwide

Pathogenesis: *Eimeria labbeana* is slightly to markedly pathogenic, depending on the strain of parasite and age of the birds. Adults are fairly resistant, although fatal infections have been seen. The birds become weak and emaciated, eat little but drink a great deal, and have a greenish diarrhoea. The heaviest losses occur among squabs in the nest. A high percentage of the squabs may die, and those that recover are often somewhat stunted.

Clinical signs: Light infections are usually asymptomatic. In heavier infections, birds are listless, have a puffed-up appearance, and show weakness, emaciation and diarrhoea.

Diagnosis: Diagnosis is based on identification of oocysts in the faeces in association with any clinical and pathological findings.

Pathology: In severe infections there is inflammation of the intestinal mucosa with the lumen filled with a haemorrhagic exudate.

Epidemiology: Transmission is via the faecal–oral route and is more common in young birds. Sources of infection include dirty contaminated baskets, eating or drinking contaminated food or water, or drinking from contaminated water in roosts such as roof guttering.

Treatment: Sulphonamides administered in the drinking water (e.g. sulphamethoxine 120 g per 2000 mL) are effective in treating infection. Clazuril 2.5 mg given as an oral tablet per pigeon, regardless of weight, is also effective. All birds in the same loft are usually treated simultaneously to prevent reinfection of untreated birds.

Control: Prevention is based on good management, avoidance of overcrowding and stress, and attention to hygiene.

Wenyonella columbae

Predilection site: Small intestine

Phylum: Apicomplexa

Class: Conoidasida

Family: Eimeriidae

Description: Oocysts are spherical or slightly ovoid, 21–27 by 21–26 μm , without a micropyle, polar granule or oocyst residuum.

Host: Pigeon

Geographical distribution: India

One other species of coccidia has been described in the small intestine of pigeons in India, although details of the life cycle and pathogenicity are lacking. In *Eimeria columbae*, the oocysts are subspherical, 16 by 14 μm , without a micropyle but with an oocyst residuum.

Spironucleus columbae

Predilection site: Small intestine

Phylum: Fornicata

Class: Trepanondea

Family: Hexamitidae

Description: Trophozoites are small 5–9 by 2.5–7 μm .

Host: Pigeon

Geographical distribution: Worldwide

Pathogenesis and clinical signs: Infection may cause enteritis in pigeons.

Treatment and control: As for *Trichomonas gallinae*.

Caeca/large intestine

Heterakis gallinarum

Synonyms: *Heterakis papillosa*, *Heterakis gallinae*, *Heterakis vesicularis*

Common name: Poultry caecal worm

Predilection site: Caeca; rarely large and small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: Whitish worms up to 1.5 cm long, with elongated pointed tails. The male is 7–13 mm and the female 10–15 mm long. Gross examination readily indicates the genus, but for specific identification microscopic examination is necessary to determine the shape of the oesophagus and the size and shape of spicules.

Description, microscopic: The oesophagus has a large posterior bulb. Generic identity may be confirmed by the presence of a large circular pre-cloacal sucker in the male and prominent caudal alae supported by 12 pairs of caudal papillae (see Fig. 1.55).

Hosts: Chicken, turkey, pigeon, pheasant, partridge, grouse, quail, guinea fowl, duck, goose and a number of wild galliform birds

Geographical distribution: Worldwide

Capillaria anatis

Synonyms: *Capillaria brevicollis*, *Capillaria collaris*, *Capillaria anseris*, *Capillaria mergi*, *Thornix anatis*

Predilection site: Caeca

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichuroidea

Description, gross: Males measure around 16–24 mm and females 28–38 mm.

Hosts: Chicken, turkey, gallinaceous birds (pheasant, partridge), pigeon, duck, goose

Geographical distribution: Worldwide

Brachylaemus commutatus

Synonyms: *Harmostomum commutatus*, *Postharmostomum gallinum*

Predilection site: Caeca

Phylum: Platyhelminthes

Class: Trematoda

Family: Brachylaemidae

Description, gross: The elongate fluke measures around 4–7 mm in length by 1–2 mm in width and have smooth bodies.

Final hosts: Chicken, turkey, other fowl, pigeon and pheasant

Intermediate hosts: Land snails

Geographical distribution: Southern Europe, Africa, parts of Asia

Echinostoma revolutum

Predilection site: Caeca and rectum

Phylum: Platyhelminthes

Class: Trematoda

Family: Echinostomatidae

Description, gross: Adult flukes can measure up to 2 cm in length but are often 1.0–1.5 cm by 2 mm in width.

Description, microscopic: The adult fluke possesses a head-collar, which is armed with around 37 spines, and the anterior tegument is spiny. The ovary is anterior to the tandem testes.

Final hosts: Duck, goose, pigeon, various fowl and aquatic birds

Geographical distribution: Worldwide

Notes: *Echinostoma revolutum* can also infect humans. *Echinostoma paraulum* occurs in the small intestine of duck and pigeon and can cause weakness, inappetence and diarrhoea in the latter.

Parasites of the respiratory system

Syngamus trachea

Synonyms: *Syngamus parvis*, *Syngamus gracilis*

Common name: Gapeworm

Predilection site: Trachea or lungs

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: The large reddish female, around 1–3 cm, and the small whitish male (up to 0.5 cm) are permanently *in copula* forming a 'Y' shape (see Fig. 1.46).

Description, microscopic: The worms have large shallow cup-shaped buccal capsules, which have up to 10 teeth at their base. There are no leaf-crowns. The bursal rays are short and thick and the two spicules are long and of simple form.

Hosts: Chicken, turkey, gamebirds (pheasant, partridge, guinea fowl), pigeon and various wild birds

Geographical distribution: Worldwide

For more details see Chapter 13.

Cytodites nudus**Common name:** Air sac mite**Predilection site:** Lung, air sac**Class:** Arachnida**Subclass:** Acari**Order:** Astigmata (Sarcoptiformes)**Family:** Cytoditidae**Description, gross:** The mite is oval and about 500 µm long, with a smooth cuticle (see Fig. 3.97).**Description, microscopic:** The chelicerae are absent and the palps are fused to form a soft sucking organ through which fluids are imbibed. Legs are stout and unmodified, ending in a pair of stalked suckers and a pair of small claws.**Hosts:** Birds, particularly poultry and canaries**Geographical distribution:** Worldwide**Pathogenesis:** Small infestations may have no obvious effect; large infestations may cause accumulation of mucus in the trachea and bronchi, leading to coughing and respiratory difficulties, air sacculitis and weight loss. Balance may be affected in infested birds. Weakness, emaciation and death have been described with heavy infections.**Clinical signs:** Coughing, respiratory difficulties, pulmonary oedema, weight loss, loss of balance or coordination**Diagnosis:** Positive diagnosis is only possible at postmortem, when necropsy reveals white spots on the surface of air sacs.**Pathology:** Death is usually associated with peritonitis, enteritis, emaciation and respiratory complications.**Epidemiology:** Infestation may be spread through coughing.**Treatment:** Treatment with topical moxidectin every 3 weeks as necessary may be effective.**Control:** It is important to treat all the birds in an aviary when commencing a preventive programme.***Laminosioptes cysticola***

For more details see Parasites of the integument.

Parasites of the circulatory system***Leucocytozoon marchouxi*****Synonym:** *Leucocytozoon turtur***Predilection site:** Blood**Phylum:** Apicomplexa**Class:** Aconoidasida**Family:** Plasmodiidae**Description:** Macrogametes are rounded or elliptical, stain dark blue with Giemsa and have a compact reddish nucleus (Fig. 16.1). This species forms rounded megalomeronts in nearly all internal organs (Fig. 16.2).**Hosts:** Pigeons and doves**Geographical distribution:** Worldwide**Pathogenesis and clinical signs:** Until recently this species was considered non-pathogenic in pigeons and doves but the parasite has been shown to be pathogenic to pink pigeons (*Columba mayeri*).**Diagnosis:** Demonstration of gametocytes in blood smears.**Epidemiology:** Vectors are members of the genus *Simulium* (black-flies).**Treatment and control:** Not usually required although general insect control or preventive measures may limit infection.***Haemoproteus columbae*****Predilection site:** Blood**Phylum:** Apicomplexa**Class:** Aconoidasida**Family:** Plasmodiidae**Description:** Macrogametes and microgametes present in erythrocytes range from tiny ring forms to elongate crescent shapes that curve around the host cell nucleus in the form of a halter (see Fig. 2.29). Macrogametes stain dark blue with Giemsa stains, the nucleus is red to dark purple and compact, and pigment granules are dispersed throughout the cytoplasm.**Hosts:** Domestic and wild pigeons, doves and other wild birds**Geographical distribution:** North America**Pathogenesis and clinical signs:** Generally considered to be of low pathogenicity in adult birds, but an acute form of infection has been reported in squabs. Clinical signs included anorexia and anaemia.**Diagnosis:** Demonstration of gametocytes in blood smears**Epidemiology:** Vectors are hippoboscid flies in the genus *Pseudolychnia***Treatment and control:** Not usually required although general insect control or preventive measures may limit infection.***Haemoproteus sacharovi*****Predilection site:** Blood**Phylum:** Apicomplexa**Class:** Aconoidasida**Family:** Plasmodiidae**Description:** Macrogametes and microgametes are present in erythrocytes and completely fill the host cell when mature, distorting and pushing the nucleus to one side. Pigment granules are sparse compared with other species.

Fig. 16.1 Macrogamont of *Leucocytozoon marchouxi*.

Hosts: Domestic pigeon, doves

Pathogenesis: Low pathogenicity although there have been reports of hepatomegaly in squabs.

All other details are essentially similar to *H. columbae*, although the vector(s) have not been identified.

Parasites of the nervous system

No parasites of veterinary significance.

Fig. 16.2 Megalomeront of *Leucocytozoon marchouxi* in the spleen.

Parasites of the reproductive/urogenital system

No parasites of veterinary significance.

Parasites of the locomotory system

Toxoplasma gondii

For more details see Chapter 13.

Parasites of the integument

Laminosioptes cysticola

Common names: Subcutaneous mite, fowl cyst mite

Predilection site: Subcutaneous tissues, lung, peritoneum

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Laminosioptidae

Description, gross: *Laminosioptes cysticola* is a small oval mite, approximately 250 μm in length.

Description, microscopic: The posterior two pairs of legs end in a claw and suckerless pedicels, while the anterior two pairs of legs end in claws. This mite has a smooth elongated body and few setae (see Fig. 3.98). The gnathosoma is small and not visible when viewed from above.

Hosts: Chicken, turkey and pigeon, occasionally in wild birds

Geographical distribution: Worldwide. It is abundant in Europe and is also found in the USA, South America and Australia.

Pathogenesis: The mites are found in the subcutaneous muscle fascia and in deeper tissues in the lungs, peritoneum, muscle and abdominal viscera. *Laminosioptes* is not usually associated with clinical signs and is only discovered in pigeons at postmortem. Active mites occur in the deep tissues. The nodules created by the mites reduce the value of meat intended for human consumption.

Clinical signs: The parasites are not usually regarded as pathogenic.

Diagnosis: The nodules may be seen in living birds by parting the breast feathers and sliding the skin back and forth with the fingertips. Examination of the nodules under a dissection microscope usually allows the identification of the mite species.

Pathology: Aggregations of these small oval mites are found in yellow nodules, several millimetres in diameter, in the subcutaneous muscle fascia and in deeper tissues in the lungs, peritoneum, muscle and abdominal viscera. The subcutaneous nodules are often calcified, but these only contain dead mites as the calcareous deposits are produced around the mites after they have died.

Epidemiology: It is estimated that around 1% of free-living urban pigeons harbour *L. cysticola*. The mode of transmission of this mite is unknown.

Treatment: Macrocyclic lactones may be effective.

Control: Destroying or quarantining the infected birds may be required to achieve long-term reduction in infestations within a flock.

Pelecitus clavus

Synonym: *Eulimdana clava*

Predilection site: Subcutaneous and connective tissues

Class: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Small to medium-sized worms which have helical turns. Male worms are 6–7 mm and female worms 17–20 mm long. The male spicules are unequal in length, the left being larger than the right.

Hosts: Pigeon and many other wild birds

Intermediate hosts: Unknown

Geographical distribution: Many species of *Pelecitus* occur worldwide.

Pathogenesis: These parasites are considered to be of low pathogenicity in birds.

Epidemiology: *Pelecitus* spp. can be of zoonotic significance in some areas of the world, infecting the eyes and periorbital region of humans.

Notes: Another species, *Pelecitus mazzanti*, is also found in pigeons.

ECTOPARASITES

Hypodectes propus

Predilection site: Subcutaneous tissue

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Hypoderidae

Description: The deutonymph (hypopus) present in subcutaneous cysts are elongate (~1.5 mm long) with parallel sides and very short legs. The adults present in the nest have reduced palps and gnathosoma and in the female reduced chelicerae.

Hosts: Pigeons and doves

Clinical signs: Presence of the parasite causes itching, feather loss and restlessness.

Dermanyssus gallinae

Common name: Poultry red mite, roost mite

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Mesostigmata

Family: Dermanyssidae

Description: The adults are relatively large at 0.75–1 mm in length, with long legs (see Figs 3.108 and 13.38). The body is usually grey-white, becoming red to black when engorged. A single dorsal shield is present, which tapers posteriorly but is truncated at its posterior margin. The anal shield is relatively large and is at least as wide as the genitoventral plate. Three anal setae are present. The chelicerae are elongate and stylet-like.

Hosts: Domestic poultry and wild birds; occasionally parasitic on mammals, including human

Ornithonyssus sylviarum

Synonym: *Liponyssus sylviarum*

Common name: Northern fowl mite

Predilection site: Base of the feathers, particularly the vent area

Class: Arachnida

Subclass: Acari

Order: Mesostigmata

Family: Macronyssidae

Description: The adults are relatively large, oval-shaped, 0.75–1 mm in length, with long legs that allow it to move (see Fig. 3.106). The body is usually greyish-white, becoming red to black when engorged. A single dorsal shield is wide for two-thirds of its length, then tapers posteriorly to become about half as wide, and is truncated at its posterior margin. The female typically has only two pairs of setae on the sternal shield. The anal shield is relatively large and at least as wide as the genitoventral plate. Three anal setae are present. The chelicerae are elongate and stylet-like. The body carries many long setae and is much more hairy than *Dermanyssus*.

Hosts: Poultry and wild birds

Ornithonyssus bursa

Synonym: *Liponyssus bursa*

Common name: Tropical fowl mite

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Mesostigmata

Family: Macronyssidae

Description: Similar to *O. sylviarum*. However, the ventral plate bears three pairs of setae, while in *O. sylviarum* and *D. gallinae* only two pairs of setae are present on the ventral plate.

Hosts: Poultry and wild birds

Columbicola columbae

Common name: Slender pigeon louse

Predilection site: Wings or anterior part of the body

Class: Insecta

Order: Phthiraptera

Suborder: Ischnocera

Family: Philopteridae

Description: A pale yellow, slender louse usually 2–3 µm in length (Fig. 16.3).

Hosts: Pigeons and doves

Geographical distribution: Probably worldwide

Pathogenesis: Infection may cause a mild pruritus, and in common with most pediculoses, heavy infestations are usually seen only in diseased and debilitated birds causing feather damage and irritation.

Clinical signs: Feather damage and irritation

Diagnosis: Adult lice may be seen moving around the plumage or eggs may be seen attached to feathers.

Pathology: Lice are rarely linked to significant pathology.

Fig. 16.3 *Columbicola columbae*.

Epidemiology: Infection occurs after direct contact with an infested host animal. Cross-contamination between different host species is possible if the animals have physical contact.

Treatment: Topical insecticidal compounds, such as permethrin, carbaryl, malathion and cypermethrin, can be used to kill lice. However, as the insecticides are unable to kill the eggs, two applications are necessary at an interval of 10 days.

Control: Although methods such as dusting the litter or providing insecticide-treated laying boxes are used to avoid undue handling of birds, the results obtained from treating individual birds are undoubtedly better. Regular checking and spraying of birds will enable infestation rates to be controlled. In addition, cross-contamination should be avoided. This is achieved by treating any birds in the environment of the pigeons and restricting contact between wild birds and pigeons. The housing and nesting should be thoroughly cleaned to eliminate sources of reinfestation such as egg-laden feathers.

Pseudolynchia canariensis

Common name: Pigeon louse fly

Predilection site: Skin

Class: Insecta

Order: Diptera

Family: Hippoboscidae

Description: Adult flies are approximately 10 mm in length and are generally pale reddish-brown with yellow spots on the indistinctly segmented abdomen. They have one pair of wings, the veins of which are crowded together towards the anterior margin. Both sexes of adult are blood feeders. The larvae are rarely seen and measure about 5 mm in length.

Hosts: Mainly pigeons but other domestic birds may also be infested.

Geographical distribution: Worldwide

Pathogenesis: The adult flies bite and blood-feed, resulting in nuisance and disturbance. Heavily infested birds may be restless and emaciated and become susceptible to secondary infections. The flies may act as vectors of *Haemoproteus columbae* and *H. sacharovi*.

Clinical signs: The adult flies are clearly visible when feeding on the host animal. Irritation at the feeding sites may be observed.

Diagnosis: The adult flies may be found on the host animal.

Epidemiology: The adult flies are most abundant on the host during the summer months.

Treatment and control: This is best achieved by topical application of insecticides, preferably those with some repellent and residual effect such as the synthetic pyrethroids permethrin and deltamethrin.

Ceratophyllus columbae

Common name: Pigeon flea

Predilection site: Skin

Class: Insecta

Order: Siphonaptera

Family: Ceratophyllidae

Description: Adults of *Ceratophyllus columbae* are typically 2–2.5 mm long with no antennal fossae. Eyes are present. There is a pronotal comb carrying more than 24 teeth, while the genal comb is absent. There is a lateral row of four to six bristles on the inner surface of the hind femur, and there are no spines on the basal section of the legs.

Host: Pigeon

Geographical distribution: Found predominantly in the Old World, but has been introduced into the Americas.

Pathogenesis: Feeding activity may cause irritation, restlessness and, with heavy infestations, anaemia. In wild birds, flea reproduction and feeding activity is synchronised with the breeding season. Adult *C. columbae* may also feed on humans and domestic pets.

Clinical signs: Symptoms include restlessness and scratching of affected areas. The bites may be visible on the skin. Allergic dermatitis may be seen.

Diagnosis: Diagnosis is not easy as adults may leave the host and eggs and larvae are difficult to find. The bites of these fleas are similar to those of mosquitoes, lice and mites, with inflammation and itchiness.

Epidemiology: These fleas are not host-specific and may attack any available mammal or bird for a blood meal. As they are able to survive off the host, transmission can occur from the bedding and housing. This flea is highly mobile on the host and can be especially common in host nesting material. *Ceratophyllus columbae* feeds readily on humans and domestic pets, and is often acquired in the handling of pigeons and wild birds. It has also been known to migrate into rooms from nests under adjacent eaves. When such nests are removed they should be incinerated; otherwise the unfed fleas may parasitise domestic pets and humans.

Treatment: Topical treatment of the affected birds with insecticidal products such as permethrin, carbaryl, malathion and rotenone is effective.

Control: Should fleas become established, drastic measures may have to be adopted to get rid of them. All litter and nest material should be removed and burnt, and the housing sprayed with an insecticide.

Argas reflexus

Common name: Pigeon tick

Predilection site: Skin

Class: Arachnida

Subclass: Acari

Order: Ixodida

Family: Argasidae

Description: Species of the genus are usually dorsoventrally flattened, with definite margins, which can be seen even when the tick is engorged (see Fig. 3.125). The cuticle is wrinkled and leathery. Most species are nocturnal and are parasites of birds, bats, reptiles or, occasionally, small insectivorous mammals. Most species seldom attack humans. Species of this genus are usually found in dry arid habitats.

The adult *Argas reflexus* is between 6 and 11 mm in length. It may be distinguished from the fowl tick, *Argas persicus*, by its body margin, which is composed of irregular grooves, and by the hypostome, which is not notched apically. It is reddish-brown in colour with paler legs.

Hosts: Birds, mainly pigeons

Geographical distribution: Europe, Russia, Asia, North and West Africa

Pathogenesis: Infestation may cause irritation, sleeplessness, loss of egg productivity and anaemia, which can prove fatal. Heavy infestations can remove enough blood to bring about the death of their host. This species transmits *Borrelia anserina*, the cause of fowl spirochaetosis, and *Aegyptianella pullorum*, a rickettsial infection. It may also be a vector of West Nile and Chikungunya viruses and the Quarantaine virus group.

Clinical signs: Inflammation and raised areas will be present from tick bites. Larvae may be found living in the feathers. These ticks can cause sleeplessness, loss of productivity and anaemia, which can prove fatal.

Diagnosis: The adult ticks, particularly the engorged larvae, may be seen on the skin. Nymphs and adult ticks may be found in cracks of the woodwork. Red spots may be seen on the skin where the ticks have fed.

Pathology: Small granulomatous reactions may form at the site of tick bites consisting of a mixed inflammatory cell response with fibrosis.

Epidemiology: *Argas reflexus* eggs show limited levels of cold tolerance; winter temperatures of 3°C cause approximately 50% mortality. This limits its northern distribution through Europe.

Treatment: Argasid ticks, which exist in lofts and enclosures, can be controlled by application of an acaricide to their environment coupled with treatment of the population on the host. Environmental treatment of roosts and lofts may be effected using acaricidal

sprays or emulsions containing organophosphates or pyrethroids. All niches and crevices in affected buildings should be sprayed, and nesting boxes and perches should also be painted with acaricides. At the same time as premises are treated, birds should be dusted with a suitable acaricide or, in the case of larger animals, sprayed or dipped. Treatment should be repeated at monthly intervals.

Control: All new animals should be treated prior to introduction into an existing flock.

RATITES (OSTRICH, RHEA, EMU)

Ostriches (*Struthio camelus*) in the wild are mainly confined to the drier parts of Africa but have been imported into many countries for intensive farming. Emus (*Dromaius novaehollandiae*) occur naturally throughout most regions of Australia. The subspecies of greater rhea (*Rhea americana*) and lesser rhea (*Pterocnemia pennata*) inhabit the open plains of central and southern regions of South America. Captive ratites may be infected with their own specific parasites but may also be carrying parasites from other birds or mammals.

ENDOPARASITES

Parasites of the digestive system

Proventriculus and gizzard

Libyostrongylus

Pathogenesis: The young worms penetrate deeply into the mucosa of the glands of the proventriculus. Adults live on the surface of the epithelium (Fig. 16.4) where they feed on blood, causing a severe inflammatory reaction and anaemia. In severe infections there may be impaction of the proventriculus.

Clinical signs: Chicks are most susceptible to infection and become anaemic, weak and emaciated with heavy mortality in untreated

Fig. 16.4 *Libyostrongylus douglassi*: mucosal surface of proventriculus. Inset shows magnified worm.

cases. There may be lower egg production and constipation. Sometimes chicks are unable to support their head and develop a 'hockey-stick' appearance of the neck as a result of muscular weakness.

Diagnosis: Diagnosis is based on finding eggs in the faeces or by identifying the worms in the proventriculus and gizzard on post-mortem. Larval culture is frequently used to differentiate eggs from the usually non-pathogenic species *Codiostomum struthionis*, which is often also present in ostriches.

Pathology: Hypertrophy and erythema of the glandular mucosa of the proventriculus often occurs. There may also be muscle atrophy and cachexia.

Epidemiology: Eggs and first-stage larvae can survive desiccation for around 30 months in hot arid environments.

Treatment: Levamisole (30 mg/kg), fenbendazole (15 mg/kg), ivermectin orally (200 mg/kg) and ivermectin as a subcutaneous injection (300 mg/kg) are effective in the treatment of wireworm infection in young ostrich.

Control: Appropriate hygiene and husbandry measures, including removal of faeces aimed at limiting pasture contamination, will help limit exposure to dangerous levels of infective larvae. Rotation of pasture is useful where practicable. The exposure of young susceptible birds to infection can be reduced by penning the juveniles separately from the adults. It is important to isolate and treat all new birds to prevent introduction of infection on ostrich farms.

Libyostrongylus douglassi

Common name: Wireworm

Predilection site: Proventriculus, gizzard

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Description, gross: Small yellowish-red nematodes; males 4–6 mm and females 5–6 mm in length.

Description, microscopic: The male bursa is well developed; the dorsal ray is long and split in its distal half forming three small branches either side. The spicules each end in a large and small spine. Eggs measure 59–74 by 36–44 μm . Third-stage larvae are characterised by a small knob at the tip of the tail and measure around 745 μm in length (Fig. 16.5).

Host: Ostrich; *L. douglassi* is the most significant gastrointestinal parasite causing important economic losses.

Geographical distribution: Africa, North and South America, Europe

Libyostrongylus dentatus

Common name: Wireworm

Predilection site: Proventriculus, gizzard

Phylum: Nematoda

Class: Secernentea

Fig. 16.5 *Libyostrongylus douglassi* L₃. Inset shows magnified larval tail tip within the third cuticle.

Superfamily: Trichostrongyloidea

Description, gross: Worms are red-brownish in colour; males are 6–8 mm and females 10–12 mm in length.

Description, microscopic: There is a prominent dorsal oesophageal tooth. There is a large bursa; the dorsal ray is long and bifurcated, extending into a rounded lobe of the bursal membrane. A spicule with dorsal process arises two-thirds from the anterior and the main shaft ends in a rounded point capped by a hyaline sheath.

Host: Ostrich

Geographical distribution: Africa, North and South America

Spiruroid nematodes

Several species of spiruroid worms belonging to the genera *Spirura* and *Odontospirura* are found in the proventriculus of rheas. These species are essentially similar to spiruroid worm species found in the proventriculus of poultry (see Chapter 13). Diagnosis is based on the presence of spiruroid eggs in the faeces or the presence of the worms in the proventriculus on postmortem.

Spirura uncinipenis

Synonym: *Sicarius uncinipenis*

Predilection site: Proventriculus and gizzard

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Males measure 15–20 mm and females 16–26 mm in length.

Description, microscopic: The spicules are short and unequal in length.

Final host: Rhea

Geographical distribution: South America

Spirura zschokkei

Synonym: *Vaznema zschokkei*

Predilection site: Proventriculus

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Males measure 16–17 mm, females are 17–25 mm in length.

Description, microscopic: The spicules are long and filiform.

Final host: Rhea

Geographical distribution: South America

Odontospirura cetiopenis

Predilection site: Proventriculus, gizzard

Phylum: Nematoda

Class: Secernentea

Superfamily: Spiruroidea

Description, gross: Males measure 15–17 mm, females 20–23 mm.

Final host: Rhea

Geographical distribution: South America

Small intestine

Deletrocephalus dimidiatus

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: Adult worms are stout and robust with a well-developed buccal capsule. Male worms are 9–11 mm and females 14–16 mm long.

Description, microscopic: Males are bursate with long thin spicules. The eggs are 160 by 70 μm (Fig. 16.6). Third-stage larvae are approximately 720 μm long, with a rounded head, 28–31 intestinal cells and a short to medium tail.

Final hosts: Greater rhea (*Rhea americana*), lesser rhea (*Pterocnemia pennata*)

Life cycle: The life cycle is thought to be direct, with birds ingesting infective larvae while foraging.

Geographical distribution: South America, North America, Europe

Pathogenesis and clinical signs: There are limited reports on the distribution and pathogenicity of this parasite in rheas. The parasite has become established in domesticated rheas and has been reported to cause weak diarrhoeic chicks in heavy infections.

Fig. 16.6 *Deleetrocephalus dimidiatus* egg.

Diagnosis: Diagnosis is based on finding eggs in the faeces or by identifying the worms in the intestine on postmortem.

Treatment and control: There is little information on the treatment of this parasite in rheas. Benzimidazoles and ivermectin have been used in the treatment of nematodes in ostrich, and therefore may be of benefit. Rearing of chicks away from adult birds and regular cleaning of pens may help limit infection.

Paradeleetrocephalus minor

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: Adult worms are similar in size to *Deleetrocephalus* spp.

Description, microscopic: The buccal capsule has vertical ridges and there are no external or internal coronary rings.

Final hosts: Greater rhea (*Rhea americana*), lesser rhea (*Pterocnemia pennata*)

Geographical distribution: South America

Houttuynia struthionis

Predilection site: Small intestine

Phylum: Platyhelminthes

Class: Cestoda

Family: Davaineidae

Description, gross: These are large, long, flat, white segmented tapeworms (60–120 cm by 9 mm wide).

Description, microscopic: The scolex is 1–2 mm wide and bears a double row of about 160 large and small hooks. The eggs are contained within parenchymatous capsules in the gravid proglottid. There are around 15–25 eggs in each capsule. Genital pores are unilateral.

Final hosts: Ostrich, rhea

Geographical distribution: Africa, South America, imported ostriches in the USA and Europe

Pathogenesis: The tapeworm is seen especially in ostrich chicks but has also been reported in rheas, causing unthriftiness, loss of appetite, emaciation and diarrhoea.

Clinical signs: Affected chicks lose their appetite and may die.

Diagnosis: Diagnosis is based on finding tapeworm segments or eggs in the faeces or by identifying the worms in the proventriculus and gizzard on postmortem.

Treatment: Praziquantel (7.5 mg/kg orally) or niclosamide (100 mg/kg orally) is effective; also fenbendazole (25 mg/kg) or oxfendazole (5 mg/kg orally).

Control: As the intermediate host is not known, specific control measures are not possible. Rearing of chicks away from adult birds, regular cleaning of pens and insect control would seem expedient.

Several protozoa, such as *Cryptosporidium* spp., *Giardia* spp., *Spironucleus* spp. and *Trichomonas* spp., can cause wasting, anorexia, and diarrhoea in ratites.

Large intestine

Codiostomum struthionis

Predilection site: Large intestine and caecum

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: These white strongyloid worms are 13–17 mm in length.

Description, microscopic: The large buccal capsule is subglobular with external and internal leaf-crowns but no teeth. The male bursa has a large projecting dorsal lobe. The third-stage larva has a rounded cephalic region and an acute termination of the tail, beyond which is a long filamentous sheath tail.

Hosts: Ostrich and rheas

Geographical distribution: Africa and South America

Pathogenesis: Infection is reported to impair water absorption in the gut. The intestinal mucosa may be thickened and contain nodules. Some areas can be haemorrhagic and contain small ulcers.

Clinical signs: Small worm burdens are generally considered to be non-pathogenic but heavy infections can cause anaemia and poor growth rates.

Diagnosis: The eggs are identical to those of *L. douglassi* and diagnosis is based on identification of the adult worms in the caeca and colon or on the morphology of the L₃ following larval culture.

Treatment and control: As for *Libyostrongylus*.

Trichostrongylus tenuis

Predilection site: Small intestine, caeca

Phylum: Nematoda

Class: Secernentea

Superfamily: Trichostrongyloidea

Hosts: Gamebirds (grouse, partridge and pheasant), chicken, duck, goose, turkey, emu

Geographical distribution: North America, Asia and Europe

Epidemiology: A common parasite of various galliform and anseriform birds.

For more details see Chapter 13.

Other parasites reported in the intestines of ratites are listed in the parasite checklist at the end of this chapter. Protozoa such as *Balantidium struthionis* and *Histomonas meleagridis* have been reported to cause wasting, anorexia and diarrhoea in ratites.

Parasites of the respiratory system

Paronchocerca struthionis

Predilection site: Pulmonary arteries, lungs

Phylum: Nematoda

Class: Secernentea

Superfamily: Filarioidea

Description, gross: Long abursate nematodes, 3–5 cm in length with bluntly rounded extremities.

Description, microscopic: Male spicules are dissimilar in length; a gubernaculum is absent. Microfilariae are 100–125 µm long with a rounded posterior extremity.

Hosts: Ostrich, rhea

Geographical distribution: Africa

Pathogenicity: Not reported

Syngamus trachea

Common name: Gapeworm

Predilection site: Trachea

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: The large reddish female, around 1–3 cm, and the small whitish male (up to 0.5 cm) are permanently *in copula*, forming a ‘Y’ shape. They are the only parasites found in the trachea of domestic birds (see Fig. 1.46).

Description, microscopic: The worms have large, shallow, cup-shaped buccal capsules which have up to 10 teeth at their base. There are no leaf-crowns. The bursal rays are short and thick and the two spicules are long and of simple form.

Hosts: Chicken, turkey, gamebirds (pheasant, partridge, guinea fowl), pigeon, ostrich, emu and rhea and various wild birds

Geographical distribution: Worldwide

For more details see Chapter 13.

Cyathostoma variegatum

Common name: Gapeworm

Predilection site: Trachea, bronchi

Phylum: Nematoda

Class: Secernentea

Superfamily: Strongyloidea

Description, gross: Adult worms are around 0.4–3 cm long; males are 4–5.8 mm and females 16–31 mm.

Description, microscopic: The buccal capsule is cup-shaped with six to seven teeth at its base. The male bursa is well developed but worms in this species are not permanently *in copula*, which contrasts with the situation in *Syngamus trachea*. Eggs are 74–83 by 49–62 µm.

Hosts: Duck, emu

Geographical distribution: Australia

Pathogenicity: Has been reported to cause severe respiratory distress in young emus.

Epidemiology: A number of paratenic hosts may be involved in transmission.

Treatment and control: Ivermectin is likely to be effective.

Parasites of the circulatory system

Leucocytozoon struthionis

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Description: Gamonts are round and present within erythrocytes.

Final host: Ostrich

Intermediate host: Blackflies (*Simulium*)

Geographical distribution: Africa

Pathogenesis and clinical signs: Thought to be of low pathogenicity, although it has been found in association with myocarditis in young ostrich chicks and may cause anaemia during early parasitaemia.

Epidemiology: A common parasite of ostrich chicks in South Africa transmitted by blackflies, *Simulium*.

Diagnosis: Identification of either gamonts in blood or megalomerozoites in tissue.

Treatment and control: Not reported

Plasmodium struthionis

Predilection site: Blood

Phylum: Apicomplexa

Class: Aconoidasida

Family: Plasmodiidae

Pathogenesis: Reported in ostrich as causing an asymptomatic low, chronic parasitaemia.

Notes: The validity of this species is in question (*nomen dubium*).

Parasites of the nervous system

Philophthalmus gralli

Common name: Oriental avian eye fluke

Predilection site: Conjunctival sac

Phylum: Platyhelminthes

Class: Trematoda

Family: Philophthalmidae

Description, gross: Adult fluke are very small (2–3 mm in size) and fusiform-shaped.

Description, microscopic: The body surface is covered by small spines and the two suckers are orally and subterminally located. The pharynx is located immediately posterior to the oral sucker.

Final hosts: Ostrich, chicken, wild birds, human

Intermediate hosts: Freshwater snails

Geographical distribution: USA, Indo-China, parts of Europe and Africa

Pathogenicity: Infection may cause congestion and erosion of the conjunctivae, and conjunctivitis with persistent lacrimation.

Clinical signs: The flukes can cause lacrimation and conjunctivitis and can be a localised problem in captive farmed ostriches where they have access to standing water.

Bayliascaris procyonis

Predilection site: Brain, spinal cord

Phylum: Nematoda

Class: Secernentea

Superfamily: Ascaridoidea

Description, gross: Adult worms in the definitive host are whitish in colour, and measure 15–20 cm in length and 1 cm in width.

Final host: Raccoon

Intermediate hosts: Ostrich, emu, dog, cat, rodents, lagomorphs

Geographical distribution: North America

Epidemiology: *Bayliascaris procyonis* is found abundantly in its definitive host, the raccoon. The parasite can infect a wide range of wild and domestic animals. Many animals act as intermediate hosts and infection results in the penetration of the gut wall by the larvae and subsequent invasion of tissue, resulting in severe disease. The raccoon plays an important role in the life cycle of the disease.

Raccoons are solitary but will frequently defecate in communal latrines, which are an abundant source of *B. procyonis* eggs. The eggs can remain viable for years.

Pathogenesis: Can cause damage to the central nervous system in ostriches and emus.

Clinical signs: The infected birds show behavioural changes as a result of the visceral larval migration. Ataxia, muscle weakness and recumbency may occur.

Diagnosis: Diagnosis is usually based on the presence of the larvae in tissues at necropsy.

Notes: Visceral larva migrans resulting from infection with *Bayliascaris* species occurs in a range of hosts including various poultry, rabbits and small mammals. The larvae invade the central nervous system of the intermediate host and increase in size as they migrate, causing them to be highly pathogenic. *Bayliascaris* spp. can also infect humans and provoke severe brain damage.

Chandlerella quisicali (superfamily Filarioidea; family Onchocercidae) can infect young emus, often less than 1 year of age, in a similar manner to that of *Bayliascaris* causing damage to the brain and spinal cord. It can cause a progressive ataxia. This parasite is transmitted by *Culicoides* midges.

Dicheilonema spicularia (superfamily Filarioidea) can infect ostriches, parasitising the connective tissue; similarly *Dicheilonema rhea* in rheas.

ECTOPARASITES

Lice

Struthiolipeurus struthionis

Common names: Ostrich louse, feather louse

Predilection site: Feathers and skin

Class: Insecta

Order: Phthiraptera

Suborder: Ischnocera

Family: Philopteridae

Description: Narrow-bodied louse with a large head (Fig. 16.7).

Host: Ostrich

Pathogenesis and clinical signs: This is a chewing louse that damages the feathers, reducing the value of especially white plumes. The damage causes the feathers to have a moth-eaten appearance.

Diagnosis: Lice and eggs may be found in the feathers close to the skin.

Treatment and control: Treatment with pyrethroid is recommended; carbaryl dust (5%) may also be effective.

A variety of other lice may also be found on ostriches including *Struthiolipeurus nandu*, *Struthiolipeurus stresemanni* and *Struthiolipeurus rhaeae*. *Meinertzhageniella lata* and *Meinertzhageniella schubarti* have been reported in rheas, and *Dahlehornia asymmetrica* in emus.

Fig. 16.7 *Struthiolipeurus struthionis*. (Courtesy of Dr Vince Smith.)

Mites

Gabucinia spp.

Common name: Shaft or quill mites

Predilection site: These mites can be found in the ventral groove of the feather shaft and feed on blood and contents of the feather sheath.

Class: Arachnida

Subclass: Acari

Order: Astigmata (Sarcoptiformes)

Family: Gabuciniidae

Description: These are pale elongated mites, about 0.5 µm in length. The dorsal idiosoma appears patterned or sculpted. The first two pairs of legs protrude anteriorly.

Host: Ostrich

Pathogenesis and clinical signs: Quill mites are very common, but occasionally become a problem in ostriches kept under intensive conditions. Large numbers of mites cause severe feather damage, causing scarring of the skin and a reduction in the economic value of the infested animal.

Diagnosis: Mites may be observed at the base of the feathers as small dust-like elongated particles.

Treatment and control: Treatment with ivermectin (0.2 mg/kg) at 30-day intervals has been reported to be effective.

Notes: There are several species in this genus, which infest a range of wild birds, but *Gabucinia sculpturata* and *Gabucinia (Pterolichus) bicaudatus* are the most common and well described in ostriches.

Numerous species of tick have also been reported to infest ostriches in their native ranges. These are summarised in the parasite checklist at the end of this chapter.

REPTILES

Reptiles are represented by four orders of animals comprising approximately 5500 species. Species of reptiles belonging to the Chelononia (tortoises, terrapins, turtles) and Squamata, divided into the suborders Sauria (lizards) and Serpentes (snakes), are increasingly kept and bred in captivity, both in zoological and in private collections, and kept as individual pets.

Reptiles in the wild are infected with a wide range of parasites, especially given the extremely varied range of prey animals and their potential to act as intermediate hosts for many species of parasites. Generally, though, if well fed and non-stressed, parasitised animals can remain comparatively healthy even when carrying burdens of several species of parasites. Parasites with heteroxenous life cycles, requiring two or more hosts, are only likely to be encountered in wild-caught animals.

Parasitic infections are frequently encountered in captive-bred reptiles and this section concentrates only on these infections, rather than those found in wild-caught specimens. Given the range of reptile species kept in captivity, it is beyond the scope of this book to provide detailed descriptions of all the species of parasites that may be encountered. As such, only a general overview is provided with more detailed descriptions of those parasite species considered to be of importance.

It is not uncommon to encounter ‘pseudoparasites’, namely parasites of the prey host (e.g. the oxyurid parasite *Syphacia* of rodents, seen in snake faeces) or normal commensals of the gut flora in herbivorous animals (e.g. the ciliate *Nyctotherus* in iguanas and tortoises). For this reason it is important to know both the taxonomic identification and the diet of captive reptiles prior to attempted parasite identification and instigation of potentially unnecessary treatment.

ENDOPARASITES

Parasites of the digestive system

Helminths

While cestode, trematode and acanthocephalan parasites are commonly found in wild-caught reptiles, their complex life cycles, which may involve one or more intermediate hosts, mean that they are rarely found in captive reptiles and as a consequence these parasite classes are not discussed further.

Nematodes

Reptile digestive tracts can be infected with a wide range of trichostrongylid, strongylid, ascarid and other nematode superfamilies. Both strongyles and trichostrongyles can be found in the alimentary tracts of reptiles, especially snakes.

Kalicephalus spp.

Predilection site: Small intestine

Phylum: Nematoda

Class: Secernentea

Superfamily: Diaphanocephaloidea

Description: Adult worms are 1–5 cm in length.

Hosts: Snakes

Pathogenesis and clinical signs: *Kalicephalus* causes a wide range of signs, including lethargy, regurgitation, diarrhoea, anorexia and debility. The larvae may undergo visceral larva migrans and can cause respiratory problems.

Diagnosis: The embryonated eggs or larvae may be found in faecal smears or on microscopy of oral and oesophageal mucus, or tracheal washings.

Pathology: Adult worms embedded in the oesophageal, gastric and intestinal mucosa cause ulceration, usually with a secondary bacterial infection. Build-up of necrotic debris may cause occlusion of the oesophagus.

Epidemiology: Infection is by ingestion of contaminated food or water or percutaneously. There is low host specificity and many species of snake can be infected, which is important where several species are kept together.

Treatment and control: Treatment is often unsuccessful, although fenbendazole (50–100 mg/kg) or oxfendazole (60 mg/kg) may be tried. Ivermectin 200 mg/kg by subcutaneous injection has also been reported to be effective but should be used with caution in some species of reptiles. Recovery can be very protracted. Good husbandry is very important in controlling and preventing infection.

Within the Ascaridoidea, certain genera and species of worms parasitise particular host groups: *Ophidascaris* and *Polydelphus* are found only in snakes; *Angusticaecum* and *Sulcascaris* are found in chelonia. The pathogenic effects of ascarid nematodes depend on parasite numbers, food availability and an infected animal's overall condition. Clinical signs, such as regurgitation and obstipation, may be seen. The presence of the worms in the gastrointestinal tract may cause gastritis, ulceration and perforation of the stomach wall; and in the intestines, intestinal obstruction, intussusception, necrotic enteritis leading to coelomitis and death. Such sequelae may be seen following treatment with anthelmintics in reptiles with heavy worm burdens.

Diagnosis of these infections is based on microscopic examination of eggs found in the faeces. Ascarid eggs are round with thick heavily pitted walls (Fig. 16.8). Control of ascarid nematodes depends on routine parasitological screening of all new arrivals and treatment of all infected animals with anthelmintics. Fenbendazole

Fig. 16.8 Ascarid (*Angusticaecum* spp.) egg from a Hermann's tortoise (*Testudo hermanni*).

Fig. 16.9 Oxyurid egg (*Tachygonetria* spp.) from a Hermann's tortoise (*Testudo hermanni*).

50–100 mg/kg by mouth or stomach tube is generally reported to be effective.

Oxyurid parasites belonging to the superfamily Oxyuridoidea are commonly found in reptiles and at least 12 different genera have been described in snakes, lizards and chelonia. These small nematodes ('pinworms') may be present in large numbers in the large intestine, colon and rectum, causing discomfort. Some species are viviparous, but the majority are oviparous or ovoviviparous and a common feature of their eggs is an asymmetrical flattening on one side. Diagnosis of oxyurid infections is based on identification of the eggs in faeces (Figs 16.9 and 16.10), or the adults from faeces or postmortem specimens. Treatment is as for ascarid infections.

Strongyloides and *Rhabdias* spp., belonging to the superfamily Rhabditoidea, are slender hair-like worms. Only females are parasitic and these produce larvated, oval and thin-shelled eggs. After hatching, larvae may develop through four larval stages into free-living adult male and female worms and this can be followed by a succession of free-living generations. In *Strongyloides* infection, there is anorexia, weight loss, diarrhoea, dehydration and death. *Rhabdias* are primarily respiratory parasites but can be associated with enteritis. Treatment with fenbendazole, as for other worm species, is usually effective.

Several species of *Capillaria* (Trichuroidea) have been reported in reptiles. These are very fine filamentous worms found mainly

Fig. 16.10 Oxyurid egg from a snake.

in the gastrointestinal tract but may also infest other organs such as the liver and reproductive organs. Transmission is direct from one infected reptile to another via the larvated egg, which is barrel-shaped with bipolar plugs.

Protozoa

Flagellate protozoa are commonly seen in the faeces of reptiles (Fig. 16.11). *Spironucleus* (*Hexamita*) has been reported to cause fatal renal disease in aquatic chelonia (terrapins). A number of other flagellates have been reported in reptiles. These include *Chilomastix*, *Enteromonas*, *Trichomonas* and *Pentatrichomonas*. *Monocercomonas* has been recorded in both Old World and New World lizards and snakes of several different genera and species. Definitive diagnosis is made by identifying the organisms by their characteristic flagella, nuclear complement and other morphological characteristics. Most of these organisms are sensitive to oral metronidazole (100–275 mg/kg).

Several other types of protozoa can often be present in clinically normal reptiles and may become pathogenic only if and when the host is stressed or becomes immunologically incompetent for one reason or another. *Nyctotherus* and other protozoa, such as *Balantidium* and *Paramecium*, are thought to serve as beneficial commensals required for the processing of dietary cellulose and complex carbohydrate constituents (Fig. 16.12). Correct identification is essential otherwise they become the objects of unnecessary (and possibly harmful) treatment. Neonatal common iguanas, for example, acquire their intestinal microflora by actively seeking out and ingesting the fresh stools of older lizards. When the normal microflora is substantially disturbed or destroyed, the gut must be re-inoculated with a culture or other source of bacterial and protozoan organisms from a healthy animal as close to the genus and species of the sick reptile as possible.

Entamoeba invadens

Predilection site: Large intestine

Phylum: Amoebozoa

Class: Archamoebae

Family: Entamoebidae

Fig. 16.11 Flagellate protozoa (arrows) in snake faeces (wet mount $\times 400$).

Fig. 16.12 Ciliate (*Nyctotherus*) from an iguana.

Description: Trophozoites are 11–20 μm and cysts approximately 16 μm .

Pathogenesis: *Entamoeba invadens* usually lives as a commensal symbiont in turtles, some tortoises and crocodylians that serve as healthy reservoirs of the organism. Contamination of the water supply of snakes and lizards with *Entamoeba* can sometimes lead to enteritis, hepatitis and, occasionally, nephritis. It has been reported in cases of human and animal amoebic meningoencephalitis.

Clinical signs: There are few specific or pathognomonic signs attributable to amoebosis in reptiles. The clinical signs of infection are usually related to regurgitation of undigested food, weight loss, dehydration, lethargy and severe diarrhoea, sometimes accompanied with blood or bile-tinged green mucus and/or tags of intestinal mucosa. Rupture of hollow viscus organs has been reported in some cases. Occasionally, rectal or cloacal prolapse occurs.

Diagnosis: Positive diagnosis of amoebosis depends on finding elongated uninucleate trophozoites and/or cysts containing four nuclei in the faeces. Cysts are more easily detected if stained with Lugol's iodine.

Pathology: Microscopically, the characteristic lesions produced by *E. invadens* are severe intestinal erosion, inflammation and, often, ulceration. The affected gut wall is thickened, ulcerated and focally

necrotic, and often a fibrinonecrotic pseudomembrane is found in the intestinal lumen overlying the foci of inflammation. Typically, the ileum and colon are the most severely affected intestinal segments. The liver shows focal areas of necrosis and evidence of fatty degeneration. Pulmonary abscessation has also been associated with more chronic infections.

Epidemiology: There does not appear to be any particular host susceptibility or resistance, although it is seen more commonly in captive boas and pythons. Cysts can survive for 7–14 days in the environment.

Treatment and control: Metronidazole 275 mg/kg as a single oral treatment has been reported to be effective. An alternative treatment is 160 mg/kg orally for 3 days. Supportive medical care, consisting of fluid and multivitamin complex therapy and increased ambient environmental temperature, should also be provided. Strict hygiene and quarantine are important in preventing the transmission of *E. invadens* cysts. All cages and water containers should be cleaned routinely with disinfectant.

Reptiles and amphibians may serve as natural hosts to other amoebae. *Acanthamoeba* has elongate filiform pseudopodia and a large nuclear karyosome. Amoeboid forms of the genus *Naegleria* have broad pseudopodia but may also exist as flagellate forms with two flagella and a large central nuclear karyosome. It is thought that the flagellate form is infective for both vertebrates and invertebrates. Many of these organisms appear to share a commensal relationship with their hosts, but some infections have been associated with gastric, intestinal, hepatic, brain and renal lesions. Because of the potential for human infection, care must be taken when working with reptiles harbouring these organisms.

Several genera of coccidia (Eimeriidae) have been reported from reptiles. These include *Eimeria*, *Isoospora*, *Caryospora*, *Cyclospora*, *Hoarella*, *Octosporella*, *Pythonella*, *Wenyonella*, *Dorisiella* and *Tyzzeria*. *Eimeria*, *Isoospora* and *Caryospora* are the most frequently observed genera in reptiles, particularly lizards and snakes. *Isoospora* has also been reported in crocodylians. Only *Eimeria* have been found in chelonians. *Wenyonella* has only been reported in snakes. Determining the number of sporocysts and sporozoites present within the sporulated oocysts is used for differentiating the genera (see Table 2.2).

However, it is important to be aware that in some species of carnivorous snakes and lizards, some of the *Isoospora* recorded may in fact be *Toxoplasma* and *Sarcocystis*. *Eimeria* species recorded in snakes may similarly be parasites of the prey host.

Parasites of the genus *Cryptosporidium* are of increasing importance in reptiles. Two species have been reported: *C. serpentis* in snakes and lizards and *C. saurophilum* in lizards.

Cryptosporidium serpentis

Predilection site: Stomach

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Description: Oocysts, passed fully sporulated, are ovoid, 5.9 by 5.1 µm, with a length/width ratio of 1.17.

Hosts: Snakes, lizards

Geographical distribution: Presumed worldwide

Pathogenesis: Infection has been reported in snakes belonging to a number of species and genera, with infected animals showing a severe chronic hypertrophic gastritis. Signs include postprandial regurgitation and firm mid-body swelling. Infection usually occurs in mature snakes, the clinical course is usually protracted, and once infected most snakes remain infected. *Cryptosporidium serpentis* apparently also infects lizards and has been found in savannah monitors.

Clinical signs: Postprandial regurgitation, mid-body swelling and chronic weight loss

Diagnosis: Oocysts may be demonstrated using Ziehl–Neelsen-stained faecal smears in which the sporozoites appear as bright-red granules. Speciation of *Cryptosporidium* is difficult, if not impossible, using conventional techniques. A range of molecular and immunological techniques has been developed that includes immunofluorescence and enzyme-linked immunosorbent assay (ELISA). More recently, DNA-based techniques have been used for the molecular characterisation of *Cryptosporidium* species.

Pathology: Oedema and thickening of gastric mucosa with exaggeration of normal longitudinal rugae with copious mucus adhesion. Histologically, there is mucosal petechiation, ecchymotic haemorrhages and focal necrosis. There is hypertrophy of mucous neck cells with excess mucus in the gastric pits and adherent to the surface epithelium. The lamina propria is oedematous with lymphocyte and scattered heterophil infiltration. Trophozoites can be seen on the brush border of surface and glandular epithelial cells. In some animals there may be replacement of glandular cells by cuboidal or columnar epithelial cells, epithelial hyperplasia and mucosal necrosis with abscess formation and oedema.

Epidemiology: Transmission appears to be mainly by the faecal-oral route.

Treatment and control: There is no effective treatment. Strict hygiene and quarantine on imported or captive reptiles is required. Chronically infected animals showing weight loss, emaciation and gastric enlargement should be culled.

Cryptosporidium saurophilum

Predilection site: Intestine, cloaca

Phylum: Apicomplexa

Class: Conoidasida

Family: Cryptosporidiidae

Description: Oocysts, passed fully sporulated, are ovoid, 4.4–5.6 by 4.2–5.2 µm (mean 5.0 × 4.7 µm), with a length/width ratio of 1.09.

Hosts: Lizards, snakes

Geographical distribution: Presumed worldwide

Pathogenesis: No pathological changes have been found in the intestine and cloaca of infected adult lizards, but weight loss, abdominal swelling and mortality have occurred in some colonies of juvenile geckos (*Eublepharis macularius*).

Clinical signs: Weight loss and abdominal swelling have been reported.

Fig. 16.13 *Cryptosporidium saurophilum* in lizard intestine (Phase contrast).

Diagnosis: As for *C. serpentis*.

Pathology: Cryptosporidia are found on the mucosal surfaces of the lower intestine and cloaca of lizards and are associated with mucosal thickening and hyperplastic and hypertrophic epithelia (Figs 16.13 and 16.14). *Cryptosporidium saurophilum* infection in snakes is not totally restricted to the intestine and may also infect the stomach.

Epidemiology: As for *C. serpentis*.

Treatment and control: As for *C. serpentis*.

Parasites of the respiratory system

Rhabdias spp.

Predilection site: Lungs

Phylum: Nematoda

Class: Secernentea

Fig. 16.14 Scanning electron micrograph of lizard intestine showing several stages of *Cryptosporidium saurophilum* and flagellated trichomonad (foreground).

Superfamily: Rhabditoidea

Hosts: Snakes, squamate reptiles

Pathogenesis and clinical signs: Infection often causes minimal damage, but may result in inflammation, hypoxia and pneumonia and secondary bacterial infection of the oral/respiratory mucosa with production of mucous exudate. Percutaneous infections may cause skin lesions.

Diagnosis: The larvae may be found in faecal smears or on microscopy of tracheal washings.

Treatment and control: Levamisole 10 mg/kg into the coelomic cavity and repeated after 2 weeks is effective. Ivermectin 200 μg/kg by subcutaneous injection has also been reported to be effective.

Parasites of the circulatory system

A wide range of haemoprotozoan parasites can be found in the blood of reptiles. The major genera found include *Haemoproteus*, *Leucocytozoon*, *Plasmodium*, *Trypanosoma*, *Hepatozoon* and *Haemogregarina*. As these parasites are transmitted by arthropod vectors, they are unlikely to be found in captive reptiles unless recently caught from the wild.

Parasites of the reproductive/urogenital system

Klossiella boae

Predilection site: Kidney

Phylum: Apicomplexa

Class: Conoidasida

Family: Klossiellidae

Description: Sporocysts contain about 30 sporozoites.

Host: *Boa constrictor*

Geographical distribution: Unknown

Pathogenesis and clinical signs: Not reported

Diagnosis: Sporocysts may be detected in urine sediments or trophozoite stages may be found on postmortem in the kidney. The site and location are pathognomonic.

Pathology: Vegetative forms develop in renal tubular epithelial cells.

Epidemiology: Sporocysts are passed in the urine and infection takes place by the ingestion of the sporulated sporocysts.

Treatment and control: Not required, although some of the sulphonamide antibiotics, such as sulphaquinoxaline or sulphamethoxazole–trimethoprim, should be effective.

Sarcocystis, *Besnoitia* and *Toxoplasma* are occasionally found in reptiles in histological sections of postmortem material. Occasionally, oocysts of *Sarcocystis* are seen in the faeces of a predator reptile. The intermediate host is often a higher vertebrate such as a rodent, but can include other reptile species.

ECTOPARASITES

Reptiles can be affected by a wide range of ectoparasites in the wild. Both ticks and mites are frequently encountered in wild-caught specimens but are generally less of a problem in captive-bred reptiles with a few exceptions.

Mites

Mesostigmata

One of the most commonly encountered mites is the snake mite, *Ophionyssus natricis*, which is described in detail in the following text. Other species of mesostigmatid mites found on snakes and occasionally lizards include *Ophionyssus lacertinus*, *Ophionyssus mabuya* and *Neoliponyssus saururum*.

Entonyssus, *Entophionyssus* and *Mabuyonyssus* mites belonging to the family Entonyssidae are parasites of the trachea and lungs of snakes.

Ophionyssus natricis

Synonyms: *Ophionyssus serpentium*, *Serpenticola serpentium*

Common name: Snake mite

Predilection site: Skin, scales

Class: Arachnida

Subclass: Acari

Order: Mesostigmata

Family: Macronyssidae

Description, gross: Adults are 0.6–1.3 mm long. Unfed females are yellow–brown (Fig. 16.15); engorged females are dark red, brown or black.

Description, microscopic: The cuticle bears only a few short bristle-like hairs.

Hosts: Snakes, lizards

Geographical distribution: Presumed worldwide

Pathogenesis and clinical signs: The number of mites on captive snakes is frequently large. The mites feed on blood and are found at several locations, usually on the rim of the eye or beneath scales anterior to the neck. Heavy infestations are characterised by irritation, listlessness, debilitation, anaemia and death.

Diagnosis: Mite infestations are often diagnosed by direct visualisation of the mites or mite faeces on the snake.

Epidemiology: This mite is the most serious ectoparasite of captive snakes and lizards. The source of infection is other snakes or contaminated equipment or cages.

Treatment and control: Newly acquired snakes should be quarantined, inspected and placed in clean sterilised cages. If cages or cage contents become infested, thorough cleaning and treatment with acaricides or steam sterilisation are necessary. Infected animals may be treated with insecticides applied sparingly to skin by wiping with a cloth sprayed with an insecticidal flea spray preparation used on

Fig. 16.15 *Ophionyssus natricis*.

small animals (e.g. containing permethrin). Injectable ivermectin 200 µg/kg has also been reported to be effective.

Prostigmata

Trombiculid mites (family Trombiculidae), during their larval stages only, feed on reptiles for 2–10 days before dropping off, moulting to protonymphs and then to deutonymphs, which feed on insects and spiders. The adult mites feed on detritus in the environment.

The family Pterygosomatidae are specialised parasitic mites of lizards, parasitising only certain species that include the agamids (Agamidae), geckoes (Gekonidae), iguanas (Iguanidae) and zonures (Zonuridae). *Geckobiella* and *Pimeliaphilus* infest primarily geckoes; *Hirstiella* infests iguanas and geckoes; *Ixodiderma* infests zonures; *Scapothrix* and *Zonurobia* infest zonures, with some infections causing severe dermatitis.

Cloacarus (family Cloacaridae) are found in the cloacal mucosa of aquatic terrapins; members of the family Ophioptidae are found beneath the scales of snakes.

Ticks

At least seven genera of ticks have been found on reptiles and include *Amblyomma*, *Aponomma*, *Hyalomma*, *Haemaphysalis*,

Ixodes, *Argas* and *Ornithodoros*. These tick genera are covered in more detail in Chapters 3 and 17.

Hyalomma aegyptium was seen frequently in northern Europe on tortoises imported from southern Europe for the pet trade. This practice has now ceased and there is no evidence of establishment outside its natural range. The relapsing fever tick, *Ornithodoros turicata*, native to the USA and Mexico, has been reported on box turtles (*Terrepenne* spp.).

More detailed descriptions of these ticks are given in Chapter 17.

Insects

Several fly species are known to attack reptilian hosts and may be responsible for transmission of diseases in the wild. Phlebotomine sandflies are known to transmit *Leishmania* to reptiles, and mosquitoes transmit a range of haemoparasites, filarial worms and arboviruses to reptiles.

Myiasis has been reported in tortoises, with blowfly larvae causing lesions especially around the cloaca, following diarrhoea or trauma

to the cloaca. Treatment is by cleaning and debriding the lesion, followed by disinfection and application of a topical insecticide.

HOST–PARASITE CHECKLISTS

In the following checklists, the codes listed below apply:

Helminths

N, nematode; T, trematode; C, cestode; A, acanthocephalan.

Arthropods

F, fly; L, louse; S, flea; M, mite; Mx, maxillopod; Ti, tick.

Protozoa

Co, coccidia; Bs, blood sporozoa; Am, amoeba; Fl, flagellate; Ci, ciliate.

Miscellaneous ‘protozoal organisms’

B, blastocyst; Mi, microsporidian; My, *Mycoplasma*; P, Pneumocystidomycete; R, *Rickettsia*.

Facultative ectoparasites and arthropod vectors

INSECTS

ORDER HEMIPTERA (BUGS)

Cimex

Common name: Bed bugs

Predilection site: Skin

Class: Insecta

Order: Hemiptera

Family: Cimicidae

Description, adult: Bed bugs have oval flattened bodies, with the forewings reduced to hemelytral pads, and the hindwings absent. Adult bed bugs measure 5–7 mm when unfed, with females being slightly larger than males. They are generally red–brown in colour, although they appear darker following a blood meal (Fig. 17.1). The distinguishing morphological differences between the two species of importance are the broader prothorax (located behind the head) of *Cimex lectularius* compared with *Cimex hemipterus* and that *Cimex hemipterus* is about 25% longer than *C. lectularius*.

The head bears long four-segmented antennae, of which the last three segments are long and slender, and a pair of widely separated compound eyes, laterally placed at the sides of the head; there are no ocelli. The labium has three obvious segments and is reflected backwards under the head reaching as far as the coxae of the first pair of legs. The abdomen is 11-segmented, with segments 2–9 being easily recognisable dorsally. When the bed bug engorges, the abdomen increases greatly in volume. There are seven pairs of spiracles located ventrally on abdominal segments 2–8.

Description, nymphs: Smaller than adults, lack mature genitalia but also blood-feed.

Hosts: The Cimicidae are blood-feeding temporary ectoparasites of birds and mammals.

Pathogenesis: Although bed bugs have been suspected in the transmission of many disease organisms, in most cases conclusive evidence is lacking, or experimental data have demonstrated that bed bugs are incompetent vectors. Scratching of the site can lead to secondary bacterial infection. The primary concern is the disturbance caused by nuisance biting which with heavy infestations may be significant.

Geographical distribution: Species ranked within the Cimicidae are widespread in the northern hemisphere. No bird-feeding cimicids occur in tropical Africa or Central America and no native cimicids occur in Australia.

Clinical signs: The bite causes irritation and swelling. Heavy infestations in poultry houses may result in chronic blood loss and mortality in young birds.

Diagnosis: Bugs may be found in cracks and crevices in the housing, or rarely may be seen on the host.

Pathology: Bed bugs are obligate blood feeders and will seek out humans to acquire a blood meal, but they do not live on humans or burrow into their skin. They are nocturnal and their activity peaks before dawn. They are negatively phototactic which, combined with positive thigmotaxis, ensures that they hide away in cracks and

Fig. 17.1 *Cimex* (bed bug).

crevices during the day, including under and within the seams of mattresses, bed frames and other furniture, floorboards, paintings and carpets, behind skirting boards, in various cracks and crevices of walls, and behind loose wallpaper. Bed bugs are attracted by body heat and carbon dioxide (and perhaps skin odours) of a host, mainly coming out at night to bite the sleeping victim; temperature receptors are probably located on the basal segments of the antennae.

Epidemiology: Twenty-one species of *Cimex* are mainly parasites of bats, with one species associated with birds. The bed bugs, *Cimex lectularius* and *Cimex hemipterus*, feed principally on humans. While *C. lectularius* is a cosmopolitan species of temperate and subtropical regions feeding on humans, bats, chickens and other domestic animals, *C. hemipterus* is tropicopolitan and subtropical and feeds on humans and chickens and rarely bats. *Leptocimex boueti* is a parasite of bats and humans in West Africa.

Treatment: Dogs may be treated with pour-on formulations of pyrethroid insecticide to repel or kill host-seeking bugs.

Control: Bed bugs, once rife all over the world, had been made rare in many countries by the domestic (and commercial) use of chlorinated hydrocarbon pesticides such as DDT from the 1950s. However, more recently, populations of bed bugs are becoming increasingly widespread and problematic once again. As bed bugs are cryptic in their habits and insecticides do not kill the eggs, complete control is usually not possible with an initial treatment. A post-control treatment evaluation and retreatment, approximately 10–12 days (dependent on ambient temperatures) following the initial treatment, is essential and, in some cases, more than two evaluations and treatments may be necessary.

Triatoma and Rhodnius

Common name: Assassin bugs, kissing bugs, conenoses

Predilection site: Skin

Class: Insecta

Order: Hemiptera

Family: Reduviidae

Subfamily: Triatomatinae

Description, adult: The adults range in length from 10 to 40 mm; the majority of species are around 20–30 mm in length. They are usually dark brown to black in colour, with contrasting patterns of red, orange or yellow marks around the edge of the abdomen. The body is flattened and elongated. The forewings have a hardened basal section and a distal membranous section and overlie the entirely membranous hindwings. The antennae are elbowed with four segments. They also have a piercing proboscis that is three-segmented, tapered and slender and bent back under the body when not in use.

Description, nymphs: Nymphs are smaller than adults, lack mature genitalia or wings, but also blood-feed.

Hosts: Dog, cat, cattle, sheep, goat, human and wild mammals.

Geographical distribution: Over 100 species are found in South and Central America, and the southern and midwestern USA, predominantly in the tropical regions. However, five species of *Linshcosteus* are found in India and seven species of *Triatoma* are found in Southeast Asia and one in Africa.

Pathogenesis: Triatomines are important vectors of the protozoan *Trypanosoma cruzi*. This causes Chagas' disease in humans and a disease of similar pathology in dogs. Although cats are susceptible to infection there are no reports of clinical disease. As it feeds, the bug defecates and the parasite is transmitted in the faeces which is rubbed into the feeding wound or into the eyes or the mouth. Infection may also be transmitted by the ingestion of infected bugs or infected prey.

Clinical signs: The bite causes irritation and swelling. Heavy infestations in poultry houses may result in chronic blood loss and mortality in young birds.

Diagnosis: Bugs may be found in cracks and crevices in the housing, or rarely may be seen on the host.

Pathology: The lesions produced at the feeding site may vary considerably between individual hosts. The wounds created are usually seen as erythematous papules or wheals surrounding the central puncture site. The wheals may persist for several weeks. Pruritis may be intense, resulting in secondary traumatic lesions.

Epidemiology: Some species of triatomine bug, including *Triatoma infestans*, live in and near human dwellings and poultry houses where they hide in cracks and crevices in the structure. During the night, they emerge to search for warm-blooded hosts. The interval between feeding and defecation is critical in determining the effectiveness of disease transmission. Infected dogs provide a reservoir of infection for the vector and thus human infection.

Treatment: Dogs may be treated with pour-on formulations of pyrethroid insecticide to repel or kill host-seeking bugs.

Control: Long-term control of bugs in the domestic environment or animal house can be achieved by spraying dwellings with formulations of pyrethroid insecticide. This is often enough to eliminate existing populations of the bugs within a house, although reintroductions are possible.

Notes: Important species include *Triatoma infestans* and *Rhodnius prolixus*.

ORDER DIPTERA

FAMILY CERATOPOGONIDAE (MIDGES)

Culicoides

Common name: Biting midges

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Nematocera

Family: Ceratopogonidae

Description: *Culicoides* midge adults are 1.5–5 mm in length with the thorax humped over a small head (see Fig. 3.16a). The wings are generally mottled in pattern, and at rest are held like a closed pair of scissors over the grey or brownish-black abdomen. The legs are relatively short, particularly the forelegs, and the small mouthparts hang vertically. The short piercing proboscis consists of a sharp labrum, two maxillae, two mandibles, a hypopharynx and a fleshy

labium, which does not enter the skin during feeding by the adult female. In the male, the long antennae are feathery or plumose, whereas those of the female possess only short hairs and are known as pilose antennae. Microscopic hairs cover the wings. Ceratopogonids have a forked medial vein (M_1 , M_2) and species of the genus *Culicoides* usually have a distinct pattern of radial cells and an r-m cross-vein on their wings (see Fig. 3.16b).

Hosts: All domestic animals and humans.

Geographical distribution: Worldwide

Pathogenesis: In large numbers, biting midges can be a serious source of irritation and annoyance to livestock. The main areas affected are usually the head and neck. The biting of midges has been linked to an immediate-type hypersensitivity reaction which causes an intensely pruritic skin disease of horses, described as seasonal equine pruritic dermatitis. Symptoms include pruritus, crusting and alopecia of the face, ears, withers, mane, rump and tail. The lesions are exacerbated by self-trauma and scratching, resulting in hyperpigmentation and skin thickening. This is one of the most common allergic skin diseases in horses worldwide; it is known as 'sweet itch' in the UK and 'Queensland itch' in Australia. In the UK, the disease is particularly a problem of native ponies and the tendency to develop a hypersensitivity reaction is likely to be inherited. Several species are involved in this condition: *C. pulicaris* in Europe, *C. robertsi* in Australia and *C. insignis*, *C. stelfer* and *C. venustus* in the USA.

Culicoides biting midges act as vectors of more than 50 arboviruses, which are transmitted across their broad host range, including those responsible for the important livestock diseases causing bluetongue in sheep, African horse sickness, bovine ephemeral fever and, in the USA, eastern equine encephalitis. Species of *Culicoides* may act as mechanical vectors for the filarioid nematodes *Onchocerca reticulata* and *Onchocerca gibsoni* to cattle, *Onchocerca cervicalis* to horses and several species of protozoa (*Haemoproteus*, *Leucocytozoon*) to poultry and other birds.

Clinical signs: The host animal's reaction to a bite of a *Culicoides* midge typically consists of a localised stinging or burning sensation and a well-defined reddened area around the bite site. These may remain itchy from a few minutes to 2–3 days, and will cause the host animal to rub and scratch at the area.

Diagnosis: The bite of the adult flies leaves a characteristic reddened area and may remain itchy for several days. Flies may be seen on the host animal.

Epidemiology: *Culicoides* adults are crepuscular or nocturnal feeders, particularly prevalent in dull humid weather. Flight activity can be influenced by temperature, light intensity, lunar cycles, relative humidity, wind velocity and other weather conditions. The mean distance travelled by *Culicoides* females is about 2 km, although males travel significantly shorter distances. Adult *Culicoides* are usually found close to larval habitats in small and inconspicuous swarms. Females are attracted to the smell and warmth of their hosts, and different species may be host-specific to varying degrees, for example *C. brevitarsis* feeds mainly on cattle and *C. imicola* on horses.

There are a large number of species of *Culicoides* of varying importance as nuisance pests and vectors. Of particular note in Europe and Asia are *Culicoides pulicaris*, *Culicoides obsoletus* (a complex of four separate species), *Culicoides impunctatus* and *Culicoides sibirica*. *Culicoides imicola* is found throughout Africa and southern Europe and is the key vector of African horse sickness and

bluetongue virus. In North America, *Culicoides furens* and *Culicoides denningi* inflict painful bites and *Culicoides variipennis* is the primary vector of bluetongue virus.

Treatment: Flies spend limited time on their hosts and are difficult to control using insecticides unless these have rapid killing or repellent ability. Applications of pyrethroid insecticides may give effective, though short-term, local control.

Control: This is difficult because of the usually extensive breeding habitat and depends on the destruction of breeding sites by drainage or spraying with insecticides. Repellents or screens may be used, but the latter have to be sufficiently fine to reduce airflow, so screens impregnated with insecticides (originally designed to exclude larger flies) have been recommended instead. For 'sweet itch', antihistamine treatment may give immediate relief and the regular application of synthetic pyrethroid dressings may help prevent recurrence of the condition. It is also recommended that susceptible animals be housed when fly activity is maximal, usually in late afternoon and early morning.

Notes: Bluetongue virus (BTV) exists as a number of distinct serotypes, 24 of which have been recognised to date. These viruses can infect a wide range of ruminant species, but usually only cause severe disease in certain breeds of sheep, particularly the fine-fleeced species such as Merino and Dorset Horn. In sheep it causes fever, enteritis, upper respiratory tract infection, ulceration of the tongue and lameness. BTV can cause very high mortality, in excess of 25%, and morbidity in excess of 75%. Bluetongue occurs generally in Africa, the Middle East, Asia, Australia and parts of North America, and serious outbreaks have occurred in the past 50 years in southern Europe. In one such outbreak, between 1956 and 1960, over 180,000 sheep died in Spain and Portugal. In the USA, bluetongue is estimated to cost the livestock industry over US\$100 million per year.

African horse sickness is caused by a retrovirus (AHSV) and is among the most lethal of equine diseases. It frequently causes mortality rates in excess of 90%. It is enzootic in Africa. A series of epizootics in Spain and Portugal from 1987 to the present have resulted in the deaths of over 3000 equines. *Culicoides imicola* is one of the members of the genus able to transmit the virus and occurs widely in Spain, Portugal and southern Greece.

Eastern equine encephalitis is a viral disease of horses and humans found only in the New World. It is caused by a species of the *Alphavirus* genus which is part of the *Togaviridae*. The disease is present throughout North and South America as far south as Argentina. The wild reservoir hosts are birds, and the primary midge vector is *Culicoides melanura*.

Bovine ephemeral fever, also known as three-day sickness, is caused by an arbovirus. It is found throughout Africa, the Oriental region and occasionally causes epizootics in Australia. It affects cattle causing morbidity, but usually not mortality, resulting in reduced milk yields.

FAMILY SIMULIIDAE (BLACKFLIES)

Simulium spp.

Common name: Blackflies, buffalo gnats

Predilection site: Adult *Simulium* feed all over the body, but particularly the head, abdomen and legs.

Class: Insecta

Order: Diptera

Suborder: Nematocera

Family: Simuliidae

Description: More than 1700 species of blackflies have been described worldwide, although only 10–20% of these are regarded as pests of humans and their animals. As their common names indicate, these flies are usually black with a humped thorax. The adults are 1.5–5 mm in length, relatively stout-bodied, with broad colourless wings that show indistinct venation and which are held at rest like the closed blades of a pair of scissors. The wings are short, typically 1.5–6.5 mm long, broad with a large anal lobe and have veins which are thickened at the anterior margin of the wing (see Fig. 3.17). The first abdominal tergite is modified to form a prominent basal scale, fringed with fine hairs. Morphologically, adult male and female flies are similar, but can be differentiated by the fact that in the female the eyes are distinctly separated (dichoptic), whereas in males the eyes are very close together (holoptic) with characteristic enlarged ommatidia in the upper part of the eye. This enables males to locate females against the blue backdrop of the sky. Compared with other closely related flies, the antennae, although 11-segmented, are relatively short, stout and devoid of bristles. The mouthparts resemble those of the biting midges except for the presence of conspicuous segmented maxillary palps. The body is covered with short golden or silvery hairs.

Hosts: Warm-blooded vertebrates.

Geographical distribution: Worldwide except New Zealand, Hawaii and some minor island groups.

Pathogenesis and pathology: In domestic animals, especially cattle, mass attack by these flies may be associated with an acute syndrome characterised by generalised petechial haemorrhages, particularly in areas of fine skin, together with oedema of the larynx and abdominal wall. The painful bites of swarms of *Simulium* may interfere with grazing and cause production loss. In certain areas of central Europe it is often impossible to graze cattle during the spring due to the activity of these flies. Horses are often affected by the flies feeding inside the ears, and poultry may become anaemic from blood loss when attacked. Even at relatively low population densities the painful bites may cause considerable disturbance and reduced productivity. Some host animals may suffer from allergic reactions to saliva secreted by the flies as they feed. Certain areas of the tropics are rendered uninhabitable by *Simulium*.

Simulium spp. may transmit the viruses causing eastern equine encephalitis and vesicular stomatitis and the avian protozoan *Leucocytozoon*. They also act as vectors for filarioid helminths, such as the nematodes *Onchocerca gutturosa* and *O. dukei* of cattle and *Onchocerca cervicalis* of horses. Bovine and equine onchocercosis produce nodules containing adult worms in various regions of the skin, particularly the withers of cattle, resulting in hide damage. From a medical perspective Simuliidae are particularly important as vectors of the filarioid nematode *Onchocerca volvulus*, which causes river blindness in humans in Africa and Central and South America.

Clinical signs: Simuliids cause severe irritation to livestock when they occur in large numbers and herds will often stampede. Bites are inflicted on all parts of the body and give rise to vesicles, which burst, exposing the underlying flesh. These skin wounds heal very slowly.

Diagnosis: The attacking swarms of adult flies are characteristic of most *Simulium* species. If the flies are seen on the host animal they may be collected and identified.

Epidemiology: Only the adult females blood-feed, and different species have different preferred feeding sites and times. Generally they feed on the legs, abdomen, head and ears, and most species are particularly active during the morning and evening in cloudy, warm weather. Although flies may be active throughout the year, there may be a large increase in their numbers in the tropics during the rainy season. In temperate and arctic regions the biting nuisance may be seasonal, since adults die in the autumn with new generations in spring and summer. The adult flies are found in swarms near free-running, well-aerated streams, which are their breeding sites. Some rivers can produce nearly a billion flies per kilometre of riverbed per day. Adults are strong fliers and are highly responsive to carbon dioxide and other host-animal odours. They may fly as much as 6.6–13.3 km in search of a host, before returning to the breeding site to commence oviposition.

Treatment: Flies spend limited time on their hosts and are difficult to control using insecticides unless these have rapid killing or repellent activity. Applications of pyrethroid insecticides may give effective, though short-term, local control.

Control: Blackfly control is extremely difficult since immature larval stages are found in running well-aerated water, often some distance from the farm or housing, and adult flies are capable of flying over 5 km. The most practical control method is the application of insecticides to breeding sites to kill larvae. This technique has been developed for the control of *Simulium* species that are vectors of river blindness in human in Africa, and entails the repeated application of insecticides to selected watercourses at intervals throughout the year. The insecticide is then carried downstream and kills larvae over long stretches of water.

Alternatively, bush clearing will remove adult resting sites and aerial application of insecticides may help in areas where breeding occurs in networks of small streams and watercourses. In horses, insecticides or repellents may be applied topically, and poultry can be provided with insecticidal dust baths.

Species of importance: Possibly the most damaging simuliid of temperate latitudes in the New World is *Simulium arcticum* which can be a major livestock pest in western Canada. Populations can reach densities which are high enough to kill cattle. In the USA, *Simulium venustum* and *Simulium vittatum* may be common and widespread pests of livestock, particularly numerous in June and July. *Simulium pecuarum*, the southern buffalo gnat, may cause losses in cattle in the Mississippi valley. The turkey gnat, *Simulium meridionale*, is common in southern USA and the Mississippi valley, where it may be a significant pest of poultry. *Simulium equinum*, *Simulium erythrocephalum* and *Simulium ornatum* may cause problems in western Europe and *Simulium kurenze* in Russia. Particularly damaging in central and southern Europe is *Simulium colombaschense*, which may cause heavy mortality of livestock.

FAMILY PSYCHODIDAE (SANDFLIES)

Phlebotomus/Lutzomyia spp.

Common name: Phlebotomine sandflies

Predilection site: Skin; sandflies primarily bite areas of exposed skin such as the ears, eyelids, nose, feet and tail.

Class: Insecta

Order: Diptera

Suborder: Nematocera

Family: Psychodidae

Description, adults: These small flies, up to 5.0 mm long, are characterised by their hairy appearance, their large black eyes and long legs (see Fig. 3.19). The wings, which unlike those of other biting flies are lanceolate in outline, are also covered in hairs and are held erect over the body at rest. As in many other nematoceran flies, the mouthparts are of short to medium length, hang downwards and are adapted for piercing and sucking. The maxillary palps are relatively conspicuous and consist of five segments. In both sexes the antennae are long, 16-segmented, filamentous and covered in fine setae.

Larvae: The mature larva is greyish-white with a dark head. The head carries chewing mouthparts, which are used to feed on decaying organic matter. The antennae are small. The abdominal segments bear hairs and ventral unsegmented leg-like structures (pseudopods) which are used in locomotion. A characteristic feature of phlebotomine larvae is the presence of long caudal setae, one pair in first-stage larvae and two pairs in second-, third- and fourth-stage larvae.

Hosts: Many mammals, reptiles, birds and humans.

Geographical distribution: Widely distributed in the tropics, subtropics and the Mediterranean area. Most species prefer semi-arid and savannah regions to forests.

Pathogenesis: These flies inflict a painful bite, causing irritation and blood loss, which may lead to a reduction in weight gain. Apart from their biting nuisance in localised areas, phlebotomine sandflies are important as vectors of various pathogens. Of particular importance is leishmaniosis in humans and dogs, caused by the protozoan *Leishmania* spp. The diseases caused in humans are commonly classified as either visceral (kala-azar) or cutaneous infections. Dogs, cats, rodents and other wild animals act as reservoirs of infection. Dogs affected with cutaneous leishmaniosis have a non-pruritic exfoliative dermatitis with alopecia and peripheral lymphadenopathy. Systemic leishmaniosis leads to splenomegaly, hepatomegaly, generalised lymphadenopathy, lameness, anorexia, weight loss and death. The disease has also been reported in cats. In North America, sandflies may also act as vectors of vesicular stomatitis of cattle and horses, which is caused by a rhabdovirus.

Clinical signs: The bites of these flies are painful and irritating to the host, giving rise to wheals in soft-skinned animals. Sandflies particularly bite areas of exposed skin such as the ears, eyelids, nose, feet and tail.

Diagnosis: Sandflies may be visible on the host during the night. During the day sandflies can most often be collected in the field and are not usually seen on animals.

Epidemiology: In common with many other small biting flies, only the females suck blood. They prefer to feed at night, resting in shaded areas during the day. Since they are capable of only limited flight, nuisance due to biting may be confined to certain areas near the breeding sites. There is some seasonality in activity, the numbers of flies increasing during the rainy season in the tropics, whereas they

are only present during the summer months in temperate zones. Adults often accumulate in the burrows of rodents or in other shelters, such as caves, where the microclimate is suitable.

Treatment: The most effective method to prevent fly bites and transmission of infection is to ensure that animals avoid areas of high fly density and are kept indoors when fly activity is highest. Flies spend limited time on their hosts and are difficult to control using insecticides unless these have rapid killing or repellent activity. Permethrin and deltamethrin are the only insecticides with sufficient repellent activity and rapidity of action to make them suitable for the control of sandfly biting in dogs. Neither drug is suitable for cats.

Control: There have been few large-scale attempts to control phlebotomine sandflies, probably due to the fact that leishmaniosis has merited insufficient attention as a disease, and also because little is known in detail of the biology and ecology of the developing stages of these flies. The adults are, however, susceptible to most insecticides, and where there have been spraying campaigns to control the mosquito vectors of malaria these have effectively controlled *Phlebotomus*. Removal of dense vegetation may reduce the suitability of the environment for the breeding of these flies.

Notes: The large family Psychodidae, subfamily Phlebotominae contains a single genus of veterinary importance in the Old World, *Phlebotomus*, and a single genus of veterinary importance in the New World, *Lutzomyia*. In some areas of the world, the term 'sandflies' includes some biting midges and blackflies, so phlebotomines should be distinguished by referring to them as 'phlebotomine sandflies'.

FAMILY CULICIDAE (MOSQUITOES)

The mosquitoes, family Culicidae, are a diverse group of over 3000 species. They occur worldwide from the tropics to the Arctic. There are three genera of medical and veterinary importance: *Anopheles*, *Aedes* and *Culex*.

Description: Mosquitoes vary from 2 to 10 mm in length and have slender bodies, prominent eyes and long legs (see Fig. 3.20c). The long narrow wings are held crossed flat over the abdomen at rest and bear scales, which project as a fringe on the posterior margin. The mouthparts consist of a conspicuous, forward-projecting, elongated proboscis adapted for piercing and sucking. Individual elements comprise a long U-shaped fleshy labium containing paired maxillae, mandibles and a hypopharynx, which carries a salivary duct that delivers anticoagulant into the host's tissues (see Fig. 3.15). The labrum forms the roof of the proboscis. All the elements, with the exception of the labium, enter the skin during feeding by the females, forming a tube through which blood is sucked. In the non-parasitic males the maxillae and mandibles are reduced or absent. The maxillary palps of different species are variable in length and morphology. Both sexes have long, filamentous, segmented antennae, pilose in females and plumose in males.

Geographical distribution: Worldwide

Pathogenesis: Mosquitoes may cause considerable annoyance by biting. Mosquito populations can reach large sizes, especially in parts of the southern USA, and the persistent feeding activity of adult females may cause significant nuisance and reduce the productivity of livestock. Females preferentially feed on large mammals

and are so persistent that livestock will be driven away from areas where they are numerous. Sensitivity to mosquito bites varies with individuals; most hosts will suffer only a minor reaction, showing local swelling, redness and irritation. Other hosts can exhibit severe hypersensitivity reactions to mosquito saliva and, if the bites are scratched, a secondary bacterial infection may ensue.

Epidemiology: In temperate climates the population size peaks during the summer, while in tropical countries large populations are usually present all year round.

Clinical signs: The bite of mosquitoes may cause a localised inflammatory reaction with intense itching. Sensitivity to mosquito bites varies with individuals; most hosts will suffer only a minor reaction, showing local swelling, redness and irritation.

Diagnosis: The bite appears as a reddened, raised area on the skin.

Treatment: Although synthetic pyrethroids have been available for some time as short-acting space sprays, some are now being developed as residual insecticides. Insecticides with a residual action are effective against the adult stages, particularly if applied indoors. Organophosphate compounds and carbamates are recommended for this purpose.

Control: Measures, largely developed for the control of human malaria, are directed either against the developing larvae or adults, or against both, simultaneously. The various measures used against larvae include the removal or reduction of available breeding sites by drainage or other means, which makes these sites unsuitable for larval development. This is not always practicable, economical or acceptable and the feasibility of these methods must always be assessed locally. Biological control has been attempted by, for example, introducing predatory fish into marshy areas and rice fields, but these methods are unsuitable for those mosquito species breeding in small temporary collections of water. The isolation and development of mosquito pathogens including microorganisms, protozoa and nematodes is mainly experimental at present, as are genetic methods of control.

Probably the most widely used measures against mosquito larvae are those which involve the repeated application of toxic chemicals, mineral oils or insecticides to breeding sites, but these have to be continuously applied. Since such measures may lead to environmental pollution and may also accelerate the development of insecticide resistance, the only permanent solution is the destruction of breeding sites. Essential water sources can be rendered unsuitable as breeding sites by spreading inert polystyrene beads to cover the surface of the water.

Fly-screens, nets and repellents are available for protection.

Aedes spp.

Common name: Mosquito

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Nematocera

Family: Culicidae

Subfamily: Culicinae

Description: The genus *Aedes* belongs to the subfamily Culicinae. The culicine adult rests with its body angled and its abdomen directed towards the surface. The palps of female culicine mosquitoes are usually only about one-quarter the length of the proboscis.

Hosts: A wide variety of mammals (including humans), reptiles and birds.

Geographical distribution: Worldwide

Pathogenesis: Several species can be vectors of the dog heartworm, *Dirofilaria immitis*, although this occurs mainly in tropical and subtropical regions. Species of *Aedes* transmit avian malaria, caused by *Plasmodium*. Mosquitoes can act as vectors of various viral diseases, including arboviruses, such as equine encephalitis (a togavirus), rabbit myxomatosis and infectious equine anaemia (a retrovirus). *Aedes* spp. transmit yellow fever and the human filarial nematodes *Wuchereria* and *Brugia*.

Species of importance: There are about 900 species in the genus *Aedes*. *Aedes sierrensis* is one of the main carriers of *Dirofilaria immitis* and will attack mammals of all sizes. A particularly important aggressive biting species is *Aedes vigilax*. *Aedes taeniorhynchus*, *Aedes sollicitans*, *Aedes vexans* and *Aedes dorsalis* may be important vectors of the equine encephalitis virus.

Culex spp.

Common name: Mosquitoes

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Nematocera

Family: Culicidae

Subfamily: Culicinae

Geographical distribution: Worldwide

Pathogenesis: Species of *Culex* transmit *Dirofilaria immitis*, and avian malaria caused by *Plasmodium*. They also act as vectors for the filarioid worm *Setaria labiato-papillosa*, cause of ovine abdominal filariosis, *Setaria equina*, the equine abdominal worm, and *Setaria congolensis* in pigs.

Species of importance: *Culex tarsalis* is the most important carrier of western equine and St Louis encephalitis in California and the western USA. It is frequently found living alongside wild birds, the natural reservoir of infection. *Culex pipiens molestus* is a 'bridge vector' and can transmit West Nile virus to mammals including humans.

Anopheles spp.

Common name: Mosquito

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Nematocera

Family: Culicidae

Subfamily: Anophilinae

Description: Living anopheline adults can readily be distinguished from culicine mosquitoes when resting on a flat surface. On landing, anopheline mosquitoes rest with the proboscis, head, thorax and abdomen in one straight line at an angle to the surface (see Fig. 3.22). The palps of female anopheline mosquitoes are as long and straight as the proboscis. The abdomen of *Anopheles* bears hairs but not scales.

Geographical distribution: Worldwide

Pathogenesis: Species of *Anopheles* transmit the dog heartworm, *Dirofilaria immitis*. Mosquitoes are also important in the transmission of the arboviruses (arthropod-borne) causing eastern, western and Venezuelan encephalitis in horses and other arbovirus diseases of humans and animals. The genus *Anopheles* contains the only known vectors of human malaria, and transmits the human filarial nematodes *Wuchereria* and *Brugia*.

FAMILY TABANIDAE (HORSE FLIES/DEER FLIES)

Description, adults: These are medium to large biting flies, up to 25 mm in length, with wingspans of up to 65 mm. The head is large and the proboscis prominent. They are generally dark coloured, but may have various stripes or patches of colour on the abdomen or thorax and even the large eyes, which are dichoptic in the female and holoptic in the male, may be coloured. The coloration of the wings and the short, stout, three-segmented antennae, which have no arista, are useful in differentiating the three major genera of Tabanidae (see Fig. 3.26).

The mouthparts, which are adapted for slashing/sponging, are short and strong and always point downwards (see Fig. 3.27). Most prominent is the stout labium, which is grooved dorsally to incorporate the other mouthparts, collectively termed the biting fascicle. The labium is also expanded terminally as paired large labella, which carry tubes called pseudotracheae, through which blood or fluid from wounds is aspirated. The biting fascicle, which creates the wound, consists of six elements: the upper sharp labrum, the hypopharynx with its salivary duct, paired rasp-like maxillae and paired broad pointed mandibles. Male flies have no mandibles and therefore cannot feed on blood. They instead feed on honeydew and the juice of flowers.

Description, larvae: These are spindle-shaped and off-white in colour and clearly segmented. The cuticle has distinct longitudinal striations. Mature larvae may be 15–30 mm in length. There is a distinct head capsule and strong biting mandibles. Abdominal segments have unsegmented leg-like structures (pseudopods) for locomotion (four pairs in *Tabanus* and three pairs in *Chrysops*). A distinct posterior respiratory siphon is usually present, which may be greatly elongated.

Hosts: Generally large domestic or wild animals and humans, but small mammals and birds may also be attacked.

Tabanus spp.

Common name: Horse flies

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Tabanidae

Description: Species of the genus *Tabanus* have transparent wings. Also useful in generic differentiation are the characteristics of short, stout, three-segmented antennae, which have no arista. In species of the genus *Tabanus* the first two antennal segments are small and the terminal segment has a tooth-like projection on its basal part and four annulations (see Fig. 3.26a).

Geographical distribution: Worldwide

Pathogenesis: The adult females locate their prey mainly by sight and their bites are deep and painful. They feed every 3–4 days causing a great deal of annoyance. The pain caused by their bites leads to interrupted feeding, and as a consequence flies may feed on a succession of hosts. They are therefore important in the mechanical transmission of a range of pathogens that cause diseases, such as anthrax, pasteurellosis, trypanosomosis, anaplasmosis and the human filarial disease loaosis.

Epidemiology: These powerful flies may disperse many kilometres from their breeding areas and are most active during hot sunny days.

Notes: In North America in particular, several species of the genus *Tabanus* are especially important pests. These include *Tabanus atratus* (the black horse fly), *Tabanus lineola* and *Tabanus similis* in the eastern states. In the western USA, *Tabanus punctifer* and *Tabanus sulcifrons* are of particular importance. Other common species are *Tabanus quinquevittatus* and *Tabanus nigrovittatus*, which are well known in North America as 'greenheads'.

Chrysops spp.

Common name: Horse flies, deer flies

Predilection site: Preferred feeding sites are the underside of the abdomen, the legs, neck and withers.

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Tabanidae

Description: *Chrysops* have dark banded wings, which are divergent when at rest. The wing venation is characteristic, especially the branching of the fourth longitudinal vein (see Fig. 3.26d).

Geographical distribution: Worldwide, primarily in the Holarctic and Oriental regions.

Pathogenesis: *Chrysops* species are responsible for the mechanical transmission of several diseases and pathogens. *Chrysops discalis* is a vector of *Pasteurella tularensis* in North America. *Chrysops dimidiata*, the mango fly, and *Chrysops siacea* are intermediate hosts of the filarioid nematode *Loa loa*. A number of *Chrysops* species also transmit *Trypanosoma evansi*, the causative agent of surra in equines and dogs; *T. equinum* the cause of mal

de caderas of equines; *T. simiae* of pigs; *T. vivax* and *T. brucei* which cause nagana of equines, cattle, sheep and other ungulates; and *T. gambiense* and *T. rhodesiense* which cause human African trypanosomiasis.

Haematopota spp.

Common name: Horse flies, clegs

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Tabanidae

Description: *Haematopota* have characteristically mottled wings that are held divergent when at rest. In *Haematopota* the first antennal segment is large and the second segment narrower, while the terminal segment has three annulations (see Fig. 3.26b).

Geographical distribution: Worldwide, although there are no *Haematopota* species in Australia. There are five species of *Haematopota* in the Nearctic region; *Haematopota americana* is of the greatest veterinary importance in America and *H. pluvialis* in Europe.

Pathogenesis: *Haematopota* species may feed on a number of hosts in rapid succession. They may therefore act as important mechanical vectors in the transmission of pathogens that cause disease, such as anthrax, pasteurellosis, trypanosomiasis, anaplasmosis and the human filarial disease loiasis.

Epidemiology: These powerful flies may disperse many kilometres from their breeding areas and are most active during hot sunny days.

BITING AND NUISANCE FLIES

Adult flies may feed on blood, sweat, skin secretions, tears, saliva, urine or faeces of the domestic animals to which they are attracted. They may do this either by puncturing the skin directly, in which case they are known as biting flies, or by scavenging at the surface of the skin, wounds or body orifices, in which case they may be classified as non-biting or nuisance flies. These flies may act as biological and mechanical vectors for a range of disease pathogens. Mechanical transmission may be exacerbated by the fact that some fly species inflict extremely painful bites and are therefore frequently disturbed by the host while blood-feeding. As a result, the flies are forced to move from host to host over a short period, thereby increasing their potential for mechanical disease transmission.

Hosts: Flies may feed on almost all warm-blooded vertebrates, but are of particular veterinary importance in cattle and horses.

Pathogenesis: Very little is known about the pathology of the cutaneous lesions produced by most of these pests, which may vary considerably in character and severity. With biting flies, the wounds created are usually seen as erythematous papules or wheals surrounding the central puncture site. The wounds may develop a crust of dried exudate. There may be epidermal necrosis or intraepithelial

eosinophilic spongiform pustules. Pruritis may be intense, resulting in secondary traumatic lesions. The wheals may persist for several weeks.

Saliva injected during feeding may be irritant and allergenic and hypersensitivity reactions may contribute to the severity of the local lesion.

Clinical signs: The activity of both biting and non-biting species of fly results in marked defensive behaviour, described as ‘fly-worry’ in livestock. This is the disturbance caused by the presence and attempted feeding behaviour of flies. Responses by the host may range from dramatic escape behaviour, in which self-injury can occur, to less or increased levels of tail twitching, licking, foot stamping and skin rippling; animals may bunch or seek the shelter of overhanging vegetation. All these changes in behaviour result in reduced time spent feeding and decreased performance. Flies may be observed, often in large numbers, feeding along the back, sides and ventral abdomen, particularly of cattle and horses. Irritation and blood loss can lead to a marked reduction in weight gain.

Diagnosis: Increased levels of disturbance in the host animals; observation of flies on the animals. Precise identification will require microscopic examination of specimens. Identification of the larvae of most species is extremely difficult and, where possible, adults should be collected or samples of live larvae should be retained until adult emergence to confirm the identification, which is more easily accomplished with the adult fly. The detailed description and identification of the larvae of most species is beyond the scope of this text and if identification to species level is required, specimens should be referred to a relevant taxonomic specialist.

Treatment: Insecticide-impregnated ear tags, tail bands and halters, mainly containing synthetic pyrethroids, together with pour-on, spot-on and spray preparations, are widely used to reduce fly annoyance in cattle and horses.

Control: Various types of screens and electrocution grids for buildings are available to reduce fly nuisance, but the best methods of control are those aimed at improving sanitation and reducing breeding places (source reduction). For example, in stables and farms, manure should be removed or stacked in large heaps where the heat of fermentation will kill the developing stages of flies, as well as eggs and larvae of helminths. In addition, insecticides applied to the surface of manure heaps may prove beneficial.

A range of insecticides and procedures is available for the control of adult flies. Aerosol space sprays, residual insecticides applied to walls and ceilings and insecticide-impregnated cards and strips may reduce fly numbers indoors. Insecticides may also be incorporated in solid or liquid fly baits, using attractants such as various sugary syrups or hydrolysed yeast and animal proteins.

Insecticide dust bags (‘backrubbers’) have been used to reduce the numbers of muscid flies associated with fly-worry. These consist of sacking impregnated with or containing insecticide, which is suspended between two posts at a height that allows cattle to rub and thus apply the insecticide to the skin. However, given the high rates of reproduction, high rates of dispersal and multiple generations per year, area-wide control of most dipterous agents of myiasis is impractical.

The appearance of the adult flies *Musca domestica*, *Stomoxys calcitrans* and *Haematobia (Lyperosia)* spp. is shown in Fig. 17.2.

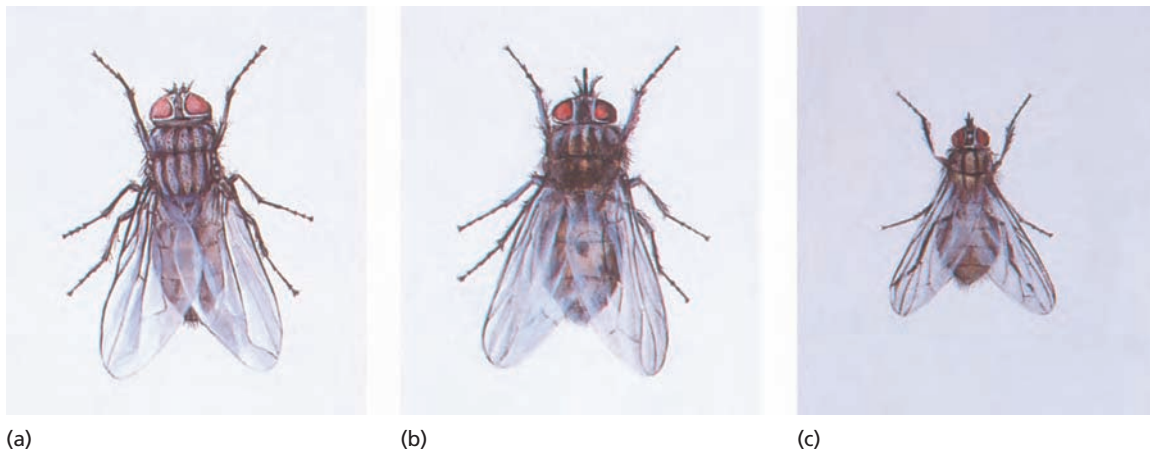

Fig. 17.2 Adult flies: (a) *Musca domestica*; (b) *Stomoxys calcitrans*; (c) *Haematobia (Lyperosia)* spp.

FAMILY MUSCIDAE

Musca autumnalis

Common name: Face fly

Predilection site: Skin, especially eyes, nose and mouth

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Muscidae

Description: Female adults of *Musca autumnalis* are 6–8 mm in length, male adults 5–6 mm, and they vary in colour from light to dark grey. The thorax is usually grey with four dark longitudinal stripes, and there is a sharp upward bend in the fourth longitudinal wing vein. The abdomen is a yellowish-brown background colour with a black median longitudinal stripe. The eyes are reddish and the space between them can be used to determine the sex of a specimen, since in females it is almost twice as broad as in males. The arista are bilaterally plumose at the tip. The face fly, *M. autumnalis*, is very similar to *M. domestica* in size and appearance, although the abdomen of the female is darker, while in the male tergite 2 and 3 are typically yellowish-orange along the sides. The detailed wing venation is of taxonomic importance in the differentiation of *Musca* from similar flies belonging to other genera such as *Fannia*, *Morellia* and *Muscina* and in the identification of different *Musca* species, but is beyond the scope of this text. The eggs of *M. autumnalis* bear a terminal respiratory horn.

Hosts: Cattle

Geographical distribution: Worldwide. *Musca autumnalis* is widely distributed throughout Europe, central Asia and parts of Africa and, since its introduction in the 1950s, can now be found throughout North America.

Pathogenesis: The face fly feeds largely on secretions from the eyes, nose and mouth as well as on wounds left by biting flies. This is often the most numerous of the flies which worry cattle at pasture. These flies are considered to be important in the transmission of infectious bovine keratoconjunctivitis ('pink eye' or New Forest disease) due to *Moraxella bovis*, and they are also intermediate hosts

of *Parafilaria bovicola*. Adults are developmental hosts for *Thelazia* (nematodes which live in the conjunctival sac of cattle and horses, causing conjunctivitis, keratitis, photophobia and epiphora).

Epidemiology: In northern Europe, *M. autumnalis* may often be the most numerous fly worrying cattle in pasture. The eggs of *M. autumnalis* are usually laid in bovine faeces, and if conditions are suitable the resultant large fly populations can cause serious annoyance. This can lead to bunching and so interfere with grazing, contributing to reduced production rates.

Notes: *Musca autumnalis* is one of the most important livestock pests to invade North America. Its introduction from Europe was first detected in 1951 in Nova Scotia. From there it spread southward and, by 1959, many cases were being reported on cattle. It now occurs throughout cattle-rearing areas of the USA and Canada.

Musca domestica

Common name: House fly

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Muscidae

Description: Female adults of *Musca domestica* are 6–8 mm in length, male adults 5–6 mm, and they vary in colour from light to dark grey. The thorax is usually grey with four dark longitudinal stripes, and there is a sharp upward bend in the fourth longitudinal wing vein (see Fig. 3.28). The abdomen has a yellow-brown background colour with a black median longitudinal stripe. The eyes are reddish and the space between them can be used to determine the sex of a specimen, since in females it is almost twice as broad as in males. The arista are bilaterally plumose at the tip.

Hosts: Although *Musca domestica* is not itself a parasite of living animals, it is responsible for the transmission of a variety of important diseases and parasites, particularly to humans and a wide variety of domestic animals.

Geographical distribution: Worldwide

Pathogenesis: House flies, as their name suggests, are closely associated with buildings inhabited by animals and humans. They are not only a source of annoyance, but may also mechanically transmit viruses, bacteria, helminths and protozoa due to their habit of visiting faecal and decaying organic material. Pathogens are either carried on the hairs of the feet and body or regurgitated as salivary vomit during subsequent feeding. A number of *Musca* spp. have been incriminated in the spread of diseases including mastitis, conjunctivitis and anthrax. In humans they are probably most important in the dissemination of *Shigella* and other enteric bacteria. Eggs of various helminths may be carried by the flies, and they may also act as intermediate hosts of a number of helminths such as *Habronema* spp. and *Raillietina* spp. Deposition of *Habronema* larvae in wounds may give rise to skin lesions commonly termed ‘summer sores’ in horses. The house fly, *Musca domestica*, is closely associated with humans, livestock, their buildings and organic wastes. Although it may be of only minor direct annoyance to animals, its potential for transmission of viral and bacterial diseases and protozoan and metazoan parasites is of significance.

Musca sorbens

Common name: Bazaar fly

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Muscidae

Description: Adult flies have two broad longitudinal stripes on the thorax and the first abdominal segment is black.

Geographical distribution: In Africa, the Pacific islands and Oriental regions.

Pathogenesis: *Musca sorbens* is a widespread species, largely replacing *M. domestica* where it occurs, and is an important vector of disease in these regions (see *M. domestica*).

Musca vetustissima

Common name: Bush fly

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Muscidae

Description: Adult flies are grey in colour with two stripes on the dorsal thorax; wing vein M_{1+2} bent forwards at an angle and reaching R_{4+5} .

Geographical distribution: Australia

Pathogenesis: The bush fly, *Musca vetustissima*, which is very closely related to *M. sorbens*, is an important nuisance pest of humans

and livestock. Bush flies have been known to transmit eye infections and other enteric diseases between other animals and humans.

Musca crassirostris

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Muscidae

Description: Adults are about 5.5–7.5 mm in length and vary in colour from light to dark grey. There are four distinct dark longitudinal stripes on the thorax and the greyish abdomen has various light and dark markings.

Geographical distribution: Mediterranean countries

Pathogenesis: *Musca crassirostris* are not obligatory parasites, but they can feed on a wide variety of animal secretions and are especially attracted to wounds. Adult flies may use the prestomal teeth to rasp the skin and draw blood, which is then ingested. This species may act as a mechanical vector for a wide variety of viral and bacterial diseases and protozoan and metazoan parasites (see *M. domestica*).

Hydrotaea irritans

Common name: Sheep head fly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Muscidae

Description: *Hydrotaea irritans* is generally similar in size and appearance to the various species of *Musca* and is characterised by an olive-green abdomen and an orange–yellow coloration at the base of the wings. The thorax is black with grey patches. Adults measure 4–7 mm in length. Specific identification of non-biting muscid flies requires specialist advice.

Hosts: Cattle, sheep and horses.

Geographical distribution: Widespread throughout northern Europe, but not believed to be present in North America.

Pathogenesis: Head flies are attracted to animals and feed on tears, saliva, sweat and wounds, such as those incurred by fighting rams. The mouthparts are adapted for feeding on liquids, but in addition they possess small teeth and the rasping effect of these during feeding leads to skin damage. They are facultative blood-feeders and will ingest blood at the edges of wounds if available. Horned breeds of sheep, such as the Swaledale and Scottish Blackface, are most susceptible to attack (Fig. 17.3). Swarms of these flies around the head lead to intense irritation and annoyance and result in self-inflicted wounds, which then attract more flies. Clusters of flies feeding at the base of the horns lead to extension of these wounds, and the

Fig. 17.3 *Hydrotaea irritans* clustered around the base of the horns in a sheep.

condition may be confused with blowfly myiasis. Secondary bacterial infection of wounds is common, which may encourage blowfly strike. The economic losses due to head fly infection are difficult to assess, but are thought to be substantial.

In cattle, large numbers of *Hydrotaea irritans* have been found on the ventral abdomen and udder and, since the bacteria involved in 'summer mastitis' (*Corynebacterium pyogenes*, *Streptococcus dysgalactiae* and *Peptococcus indolicus*) have been isolated from these flies, there is strong presumptive evidence that they may transmit the disease. In addition, this species has been incriminated in the transmission of infectious bovine keratoconjunctivitis.

Epidemiology: Although commonly known as the sheep head fly, this species may be the most numerous muscid species found on cattle and horses. The populations of *Hydrotaea irritans* peak during midsummer. Adult flies prefer still conditions and are associated with permanent, fairly sheltered pastures that border woodlands or plantations.

Stomoxys calcitrans

Common name: Stable fly

Predilection site: Skin. Location depends on the host: on cattle the legs are preferred, on dogs the ears.

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Muscidae

Description, adults: Superficially, *Stomoxys calcitrans* resembles the house fly *M. domestica*, being similar in size (about 7–8 mm in length) and grey with four longitudinal dark stripes on the thorax. Its abdomen, however, is shorter and broader than that of *M. domestica* with three dark spots on the second and third abdominal segments. Probably the simplest method of distinguishing stable flies from *M. domestica* and other genera of non-biting muscid flies is by examination of the proboscis, which in *Stomoxys* is conspicuous and forward projecting (see Fig. 3.29a). When feeding, the proboscis swings downwards and skin penetration is achieved by the

rasping action of fine teeth on the end of the labium. Stable flies can be distinguished from biting muscid flies of the genus *Haematobia* by the larger size and the much shorter palps of the former.

Description, larvae: Larvae of *Stomoxys* can be identified by examination of the posterior spiracles, which are relatively well separated and each has three S-shaped slits.

Geographical distribution: Worldwide

Pathogenesis: The salivary secretions of this species may cause toxic reactions with an immunosuppressive effect, rendering the host more susceptible to disease.

Stable flies may probe and attempt to feed on a number of hosts in rapid succession. They may therefore act as important mechanical vectors in the transmission of pathogens such as trypanosomes. *Trypanosoma evansi* (causing surra of equines and dogs), *T. equinum* (mal de caderas of equines, cattle, sheep and goats), *T. gambiense* and *T. rhodesiense* (human African trypanosomiasis) and *T. brucei* and *T. vivax* (nagana of equines, cattle, sheep and goats) are all mechanically transmitted by *S. calcitrans*. These flies also act as vectors for anthrax and *Dermatophilus congolensis*. *Stomoxys calcitrans* also serves as an intermediate host of the nematode *Habronema*.

Epidemiology: Approximately 3 minutes is required for a blood meal during which time flies may almost double in weight. The bite of stable flies is painful and as such they are a serious pest of animals. In large numbers these flies are a great source of annoyance to grazing cattle and in some areas there are estimates of milk and meat production losses of up to 20%. Adult flies live for about 1 month and are abundant around farm buildings and stables in late summer and autumn in temperate areas. They largely remain in areas of strong sunlight and they bite mainly out of doors, although they will follow animals inside to feed. They will also enter buildings during rainy weather in the autumn. *Stomoxys calcitrans* are swift fliers but in general do not travel long distances.

Haematobia irritans

Subspecies: *irritans*

Synonym: *Lyperosia irritans*

Common name: Horn fly

Predilection site: Base of horns, back, shoulders and belly

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Muscidae

Description: The adults are 3–4 mm in length and are the smallest of the blood-sucking muscids. They are usually grey, often with several dark stripes on the thorax. Unlike *Musca* the proboscis is held forwards and unlike *Stomoxys* the palps are stout and as long as the proboscis (see Fig. 3.29c). In *H. irritans* the palps are dark greyish, whereas in *H. stimulans* they are yellowish in colour. Eggs are 1–1.5 mm long. The cylindrical larvae are yellow–white and generally about 7 mm long with two D-shaped posterior spiracles. Puparia are dull reddish-brown and 3–4 mm long.

Hosts: Primarily cattle. They also occasionally attack horses, sheep and dogs.

Geographical distribution: Worldwide, particularly Europe, the USA and Australia.

Pathogenesis: The adult flies feed on the host animal's blood, causing injury and irritation due to the constant piercing of the skin. Loss of blood due to horn flies can be considerable. In addition, during feeding the horn fly withdraws and reinserts its mouthparts many times, resulting in considerable irritation to the host. Although less important than many other muscid flies in disease transmission, *Haematobia* may transmit *Stephanofilaria*, the skin filarioid of cattle.

Epidemiology: Hot humid weather, with a temperature of 23–27°C and relative humidity of 65–90%, is ideal for horn fly activity. The flies may be more abundant on cattle with dark coats and dark-coloured areas of bicoloured cattle. When temperatures are above 29°C flies migrate to the shaded skin of the belly and udder.

Haematobia exigua

Synonym: *Haematobia irritans exigua*

Common name: Buffalo fly

Predilection site: Skin, withers, back and sides; occasionally the belly in hot weather.

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Muscidae

Description: See *Haematobia irritans*

Hosts: Buffalo and cattle

Geographical distribution: Worldwide, particularly Asia and Australia.

Pathogenesis: The buffalo fly has a pronounced effect on the health and productivity of buffalo and cattle. Significant blood loss can occur due to the high densities on the host (often several thousand) and because both sexes feed several times per day. The bites are painful and irritating and may cause feeding lesions. Species of *Haematobia* may transmit *Stephanofilaria*, the skin filarioid of cattle.

Notes: The buffalo fly (*Haematobia irritans exigua*) and the horn fly (*H. irritans irritans*) were once recognised as two separate species. However, it has been concluded that they are probably best regarded as subspecies of *H. irritans*.

Haematobia minuta

Synonym: *Lyperosia minuta*

Predilection site: Skin, withers, back and sides. Occasionally the belly in hot weather.

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Muscidae

Description: The adults are up to 4 mm in length. They are usually grey, often with several dark stripes on the thorax.

Hosts: Cattle and buffalo

Geographical distribution: Africa

Pathogenesis: Large numbers of flies cause intense irritation, and the skin wounds made during feeding may attract other muscids and myiasis-producing flies. These flies may have a pronounced effect on the health and productivity of the cattle. Significant blood loss can occur due to the high densities on the host (often several thousand) and also because both sexes feed several times per day. The bites are painful and irritating and may cause feeding lesions. It is difficult to assess the precise economic effect of these flies, but their effective control on grazing cattle can result in significant increases in production. Although less important than many other muscid flies in disease transmission, species of *Haematobia* transmit *Stephanofilaria*, the skin filarioid of cattle and, in some areas, camel trypanosomosis.

Haematobia stimulans

Synonym: *Haematobosca stimulans*

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Muscidae

Description, adult: *Haematobia stimulans* are slightly smaller than *Stomoxys calcitrans* at about 6 mm in length. They are usually grey, often with several dark stripes on the thorax. In *H. stimulans*, the palps are yellow in colour, whereas in *H. irritans* they are dark grey. The eggs are reddish-brown and lack a terminal horn.

Description, larvae: The larvae are cylindrical and yellow–white in colour. They measure approximately 7 mm in length and have two D-shaped posterior spiracles. Puparia are dull reddish-brown and 3–4 mm long.

Hosts: Cattle

Geographical distribution: Europe

Pathogenesis: The bites are painful and irritating and may cause feeding lesions. Although less important than many other muscid flies in disease transmission, species of *Haematobia* transmit *Stephanofilaria*, the skin filarioid of cattle.

FAMILY FANNIIDAE

Fannia canicularis

Common name: Lesser house fly

Predilection site: Skin, mouth, nose, eyes

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Fanniidae

Description, adult: Species of *Fannia* generally resemble house flies in appearance but are more slender and smaller at about 4–6 mm in length. The fourth longitudinal vein is straight (not bent as in the house fly; see Fig. 3.30a). *Fannia canicularis* is greyish to almost black in colour, possessing three dark longitudinal stripes on the dorsal thorax. The palps are black. The arista are bare.

Description, larvae: The larvae are easily recognised by the flattened shape and the branched fleshy projections from the body (see Fig. 3.30b). The brown-coloured puparium resembles the larva in shape.

Hosts: Cattle, poultry

Geographical distribution: Worldwide

Pathogenesis: Species of *Fannia* are of interest as nuisance pests of livestock and humans, especially in caged-layer poultry facilities, cattle-confinement areas and dairies. They rarely feed directly from animals; however, the few that do are attracted to smeared faeces, sweat and mucus. Although it may be of only minor direct annoyance to animals, its potential for transmission of viral and bacterial diseases and protozoan and metazoan parasites is of significance, as for *Musca domestica*.

Epidemiology: Flies may be observed feeding on animal faeces, manure piles, garbage and other types of decomposing organic material, and seen attempting to land and feed on the liquid secretions of exudates of the eyes, nose and mouth. *Fannia canicularis* is the most cosmopolitan species and is commonly found breeding in animal manure and confined livestock facilities

In contrast to *Musca domestica*, the eggs and larvae of most species of *Fannia* are more susceptible to desiccation. Hence, they are more abundant in semi-liquid sites, especially pools of semi-liquid faeces. Adults are more abundant in the cooler months of spring and autumn, declining in midsummer. Adults of *Fannia* are readily attracted into buildings and adult males are familiar as the flies responsible for the regular triangular flight paths beneath light bulbs or shafts of sunlight from windows in buildings.

Fannia scalaris

Common name: Latrine fly

Predilection site: Mouth, nose, eyes

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Fanniidae

Description, adult: As for *F. canicularis* except the halteres are yellow.

Description, larvae: As for *F. canicularis*.

Geographical distribution: Worldwide

Pathogenesis: This species may act as a mechanical vector for a wide variety of viral and bacterial diseases and protozoan and metazoan parasites (see *M. domestica*).

Fannia benjamini

Predilection site: Mouth, nose, eyes

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Fanniidae

Description, adult: As for *F. canicularis* except the palps are yellow.

Description, larvae: As for *F. canicularis*.

Geographical distribution: North America

Pathogenesis: This species may act as a mechanical vector for a wide variety of viral and bacterial diseases and protozoan and metazoan parasites (see *M. domestica*).

FAMILY HIPPOBOSCIDAE

Hippobosca equina

Common name: Forest fly, horse louse fly

Predilection site: Skin; perineum and between the hindlegs

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Hippoboscidae

Description: Adult flies are approximately 10 mm in length and are generally pale reddish-brown with yellow spots on the indistinctly segmented abdomen. They have one pair of wings, the veins of which are crowded together towards the anterior margin (see Fig. 3.31). The major part of the piercing proboscis is usually retracted under the head, except during feeding. Forest flies remain on their hosts for long periods and their preferred feeding sites are the perineum and between the hindlegs. Both sexes of adult are blood feeders. The larvae are rarely seen and measure about 5 mm in length.

Hosts: Mainly horses and cattle, but other domestic animals and birds may be attacked.

Geographical distribution: Worldwide

Pathogenesis: This species is primarily a nuisance and a cause of disturbance. Since they pierce the skin to suck blood, they may be mechanical vectors of blood parasites such as the non-pathogenic *Trypanosoma theileri* in cattle, piroplasmosis of horses, Q fever and other types of rickettsioses. They may also transmit *Haemoproteus* species to birds.

Epidemiology: The adult flies are most abundant on the host during the summer months and attack more frequently in sunny weather.

Hippobosca camelina

Common name: Camel fly

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Hippoboscidae

Description: Adult flies are approximately 10 mm in length and are generally pale reddish-brown with yellow spots on the indistinctly segmented abdomen. They have one pair of wings, the veins of which are crowded together towards the anterior margin. Both sexes of adult are blood feeders. The mature larvae are rarely seen and measure about 5 mm in length.

Hosts: Camels

Geographical distribution: Worldwide in association with camels.

OTHER COMMON HIPPOBOSCIDS

These species are primarily a nuisance and a cause of disturbance; they may be mechanical vectors of pathogens such as *Trypanosoma*.

| Species | Common name | Hosts | Geographical distribution |
|-------------------------------|----------------------------|--------------------------|--|
| <i>Hippobosca maculata</i> | Horse and cattle louse fly | Mainly horses and cattle | Tropics and subtropics, particularly India and Africa |
| <i>Hippobosca variegata</i> | Horse louse fly | Horses and cattle | Tropical Africa |
| <i>Hippobosca rufipes</i> | Cattle louse fly | Cattle | Africa |
| <i>Hippobosca longipennis</i> | Dog fly | Dogs and wild carnivores | East and North Africa; parts of the Mediterranean region |

Lipoptena spp.

Common name: Deer keds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Hippoboscidae

Description: Wings are fully developed and function in newly emerged adults, but are shed once a suitable host has been located (Fig. 17.4).

Hosts: Deer, elk

Geographical distribution: Worldwide (*L. depressa* in North America, *L. cervi* in Europe and Asia, but has been introduced into North America)

Pathogenesis: These species are primarily a nuisance and a cause of disturbance.

Fig. 17.4 Deer ked, *Lipoptena cervi* (note that the wings have been shed).

FAMILY GLOSSINIDAE (TSETSE FLIES)

Glossina spp.

Common name: Tsetse flies

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Glossinidae

Description: In general, adult tsetse are narrow, yellow to dark-brown flies, 6–15 mm in length, and have a long, rigid, forward-projecting proboscis (see Fig. 3.33a). There are 23 known species. When at rest, the wings are held over the abdomen like a closed pair of scissors. The thorax is a dull greenish-brown colour and is marked with inconspicuous stripes and spots. The abdomen is brown, with six segments that are visible from the dorsal aspect (Fig. 17.5). Tsetse flies are easily distinguished from all other flies by the characteristic hatchet-shaped medial cell in the wings. The antenna has a large third segment, with an arista that bears 17–29 dorsal branching hairs.

There are no maxillae or mandibles in the mouthparts of tsetse flies and the long proboscis is adapted for piercing and sucking. The proboscis is composed of a lower U-shaped labium with rasp-like labella terminally and an upper narrower labrum, which together creates a food channel. Within this food channel sits the slender hypopharynx that carries saliva and anticoagulant down into the wound formed during feeding. The proboscis is held horizontally between long palps, which are of an even thickness throughout.

The 23 known species of tsetse flies can be divided into three groups, each with different habits and requirements. The *Glossina palpalis* group are riverine species that feed primarily on reptiles and ungulates. Flies of the *G. morsitans* group are savannah and dry thorn-bush species that feed mainly on large animals. Members of the *G. fuscica* group occur in the rainforest, preferring dense shade and riverine thickets.

Hosts: Various mammals, reptiles and birds.

Fig. 17.5 *Glossina* spp.

Geographical distribution: These flies are confined to a belt of tropical Africa extending from the southern Sahara in the north (latitude 5° N) to Zimbabwe and Mozambique in the south (latitude 20–30° S). The various species are restricted to different geographical areas according to habitat.

Pathogenesis: Although the bites of tsetse flies are very painful and cause marked irritation, their main significance is in the transmission of animal and human trypanosomosis, described as nagana or sleeping sickness, respectively. Flies become infected with protozoan trypanosome parasites during feeding and these then undergo multiplication and maturation within the fly. The fly is then infective to other hosts during subsequent feeding.

Clinical signs: Host animals may scratch and rub bite wound sites, which may result in significant skin trauma. The symptoms of tsetse-transmitted trypanosomosis include hyperthermia, anaemia, rapid emaciation, oedema of the lower parts of the abdomen and thorax, joints and genitalia, keratitis and nasal discharge. Paralysis may also occur.

Diagnosis: Observation and identification of the adult flies feeding on the host animal. The flies are most active at dawn and dusk.

Epidemiology: The normal hosts of tsetse flies are African wild large mammals and reptiles, which experience few or no ill effects from the presence of the trypanosomes in their blood unless subject to stresses such as starvation. These wild animals act as reservoirs of the disease. When humans or domestic animals become infected, however, the pathogenic effects of the trypanosomes can be debilitating or fatal unless treated.

Treatment: Dipping cattle in pyrethroid insecticides such as deltamethrin can effectively protect against tsetse feeding. Trypanocidal drugs can be used to treat trypanosome infection.

Control: In the past, campaigns against tsetse flies to control trypanosomosis both in humans and in animals depended mainly on large-scale killing of the game animals that act as reservoirs of trypanosome infection and as a source of blood for the flies. It was also common to clear large areas of bush in order to destroy the habitats of the adult flies. These methods were fairly successful, but are now largely unacceptable on ecological and economic grounds.

Currently, most anti-tsetse measures rely on the use of insecticides applied from the ground or by aircraft. When the objective is complete eradication of *Glossina*, residual formulations of insecticides are used. It is also essential that the area to be sprayed has economic potential and that agricultural development of the cleared area should proceed contemporaneously. Local eradication of tsetse populations is possible because of the relatively low rate of tsetse reproduction but, because of the inevitable reinvasion of tsetse from surrounding untreated areas, is uneconomic unless the selected area is on the edge of a tsetse belt where the fly population is already under stress because of relatively unfavourable climatic conditions. Advocates of insecticidal spraying argue that, since *Glossina* is highly susceptible to the insecticides used, the sophisticated and selective use of modern chemicals, usually on one occasion only, has no major and permanent effects on the environment. In fact they point out that the changes in land use which should ensue from successful control are much more significant in this respect.

Populations of tsetse flies have been reduced or eradicated in localised areas by the use of traps. These have the advantages of being cheap, can be used by local labour and are harmless to the environment. Essentially they depend on the presentation of a material, such as dark cloth, which attracts the flies and leads into a trap that often incorporates an insecticide. Volatile chemical odours, such as acetone octenol or cattle urine, placed in or near traps attract flies and increase the number caught. However, traps are relatively difficult to deploy and maintain in densely vegetated areas of bush. Some breeds of domestic livestock such as N'dama cattle are relatively trypanotolerant.

Notes: Key species in the *fuscus* and *palpalis* groups include *G. palpalis*, *G. austeni*, *G. fuscipes* and *G. tachinoides*, while key species in the *morsitans* group include *G. morsitans* and *G. palidipes*.

FAMILY CALLIPHORIDAE

MYIASIS FLIES

The appearance of adult flies of the genera *Calliphora*, *Lucilia*, *Phormia* and *Cochliomyia* is shown in Fig. 17.6.

Larval parasites: myiasis

Myiasis is the infestation of the organs or tissues of host animals by the larval stages of dipterous flies, usually known as maggots or grubs. The fly larvae feed directly on the host's necrotic or living tissue. The hosts are usually mammals, occasionally birds and, less commonly, amphibians or reptiles. All the flies that act as economically important agents of veterinary myiasis are members of the superfamily Oestroidea. Within this superfamily there are three major families of myiasis-producing flies: Oestridae, Calliphoridae

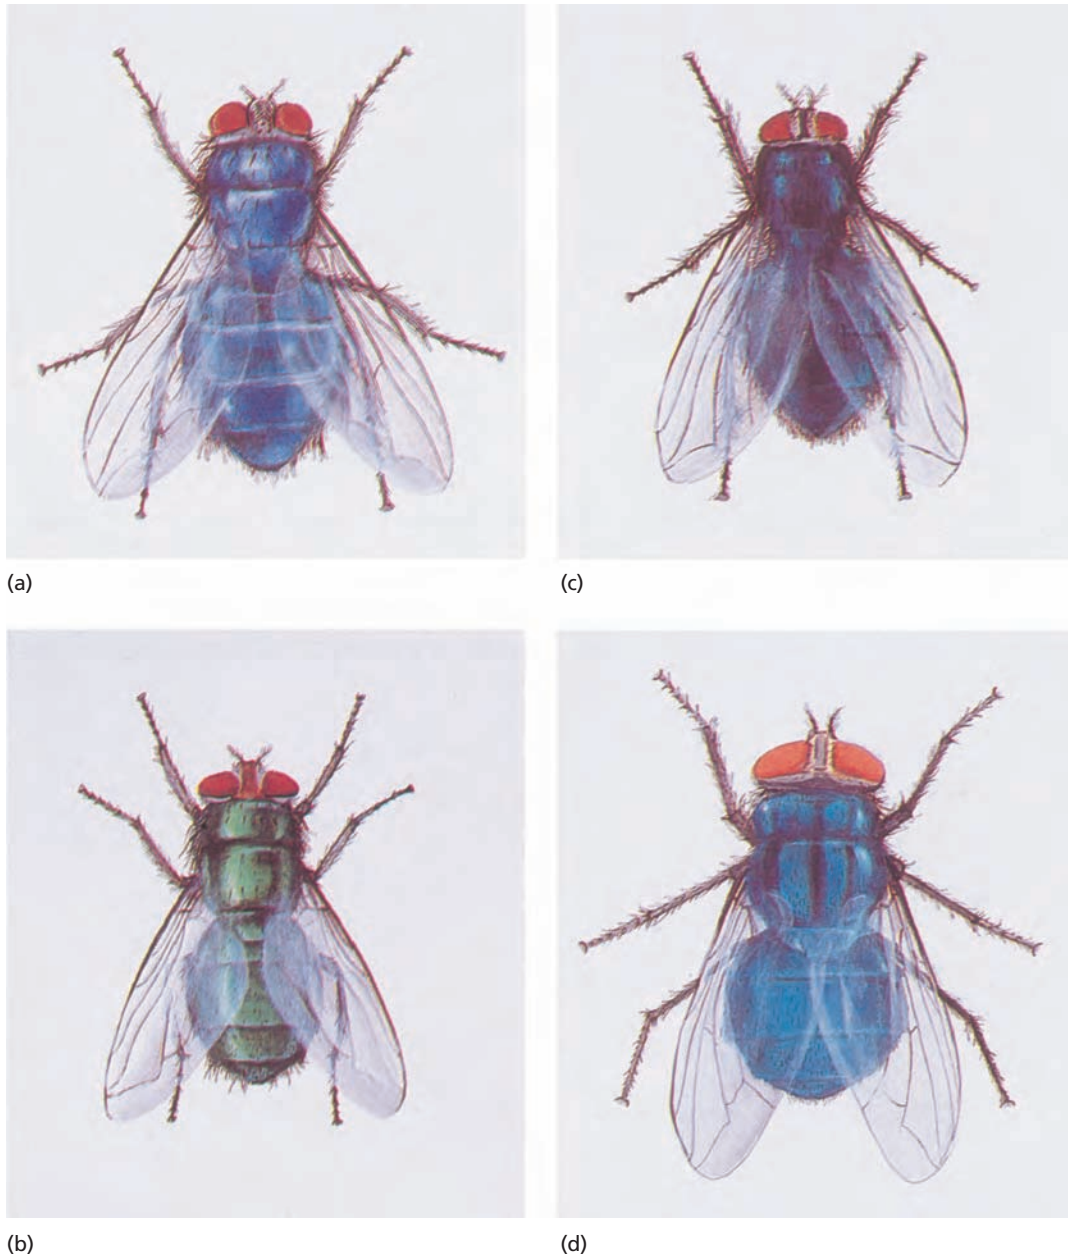

Fig. 17.6 Adult flies: (a) *Calliphora* spp.; (b) *Lucilia* spp.; (c) *Phormia* spp.; (d) *Cochliomyia* spp.

and Sarcophagidae. Oestridae are highly species-specific and are dealt with in their respective host chapters. Calliphoridae and Sarcophagidae are generalists and so are dealt with here.

Description: The body of the larval myiasis species is usually clearly segmented, pointed anteriorly and truncated posteriorly (see Fig. 3.25). However, this shape may be modified, with the larvae of some species being barrel-like or, occasionally, flattened. The cuticle is typically pale and soft but is often covered by spines or scales arranged in circular bands. Although legless, in some species the body may have a number of fleshy protruberances, which aid in locomotion. The true head is completely invaginated into the thorax. The functional mouth is at the inner end of the pre-oral cavity, from which a pair of darkened mouth hooks protrudes. The mouth hooks are part of a complex structure, known as the cephalopharyngeal

skeleton, to which muscles are attached. There is a pair of anterior spiracles on the prothoracic segment, immediately behind the head, and a pair of posterior spiracles on the 12th segment. The structure of the posterior spiracles is of great taxonomic importance. They usually consist of a pair of sclerotised spiracular plates with slits or pores in the surface for gaseous exchange.

Clinical signs: Animals infested with fly larvae may appear dull and lethargic, and separate from the herd. They may cease feeding and show weight loss. Wounds with foul-smelling odour will be observed on inspection.

Diagnosis: Myiasis is diagnosed by removal of the larvae and identification under a dissecting microscope. The larva possesses a pair of oral hooks at the anterior extremity, spiracles on the anterior

segment and, posteriorly, spiracular plates. The arrangement of the mouthparts and posterior spiracles serve to differentiate the species. However, identification of the larvae of most species is extremely difficult and, where possible, samples of live larvae should be retained until adult emergence to confirm the identification, which is more easily accomplished with the adult fly. More details on the identification of larvae are provided in Chapter 4.

Pathogenesis: The direct pathological effects of myiasis may vary considerably and depend on the species of ectoparasite, the number of larvae and the site of the infestation. In many cases infestation by small numbers of fly larvae may have little or no discernible clinical effect on the host. However, a heavier burden of parasites may produce effects including irritation, discomfort and pruritus, resulting in reduced feeding, weight loss, reduced fertility and loss of general condition. Ultimately, heavy infestation may lead rapidly to host death from direct tissue damage, haemorrhage, bacterial infection, dehydration, anaphylaxis and toxæmia. Myiasis from a range of species has also been shown to produce a marked immunological response in the host.

Treatment: For subdermal warble-forming larvae, surgical removal of larvae may be required. Applying heavy oil or petroleum jelly to the opening of the lesions will occlude the airway of the larvae and may cause them to exit the host. Applying a small amount of chloroform or ether to the opening may be helpful before removing the larvae with forceps. Lidocaine hydrochloride can also be injected into the furuncular lesion to facilitate extraction of the larvae. Antibiotics should be prescribed. Great care should be taken during the extraction process to avoid rupturing the larvae *in situ*.

For cutaneous myiasis, the larvae should also be removed and identified, and the wound should be thoroughly cleaned and disinfected. Topical organophosphate and pyrethroid insecticides are effective against newly hatched larvae, immature forms and adult flies. Larvae inside wounds must be treated with a suitable larvicide. Spraying or dipping animals with an approved insecticide and treating infested wounds can protect against new infestations for 7–10 days. Systemic insect growth regulators (cyromazine and dicyclanil) may give highly effective long-lasting prophylactic protection against cutaneous myiasis. The macrocyclic lactones (ivermectin, eprinomectin, moxidectin and doramectin) may also be effective against cutaneous myiasis and are particularly effective against nasopharyngeal, subdermal and gastrointestinal myiasis.

Control: Any wounds should be properly dressed to prevent infection. In areas where fly abundance is seasonal, operations such as branding, dehorning and ear marking should be avoided during the fly season. Given the high rates of reproduction, high rates of dispersal and multiple generations per year, area-wide control of most dipterous agents of myiasis is impractical. However, there are notable exceptions, highlighted subsequently in this chapter.

Lucilia

Description, adults: *Lucilia* blowflies measure up to 10 mm in length and are characterised by a metallic greenish to bronze sheen (Fig. 17.6b; see also Fig. 9.69). The adults are characterised by the presence of a bare stem-vein, bare squamae and the presence of three pairs of post-sutural dorsocentral bristles on the thorax. The sexes are very similar in appearance, but may be distinguished by the distance between the eyes, which are almost touching anteriorly in males and separated in females.

Fig. 17.7 Larvae (maggots) of the blowfly *Lucilia sericata*.

Adult *Lucilia sericata* and *L. cuprina* may be distinguished from most other species of *Lucilia* by the presence of a pale creamy-white basicostal scale at the base of the wing, three post-sutural acrostichal bristles on the thorax and one anterodorsal bristle on the tibia of the middle leg. However, definitive identification to species can only be confirmed using a small number of subtle morphological features, such as the colour of the fore femur, the number of paraverticral setae present on the back of the head and, most reliably, the shape of the male genitalia (see Fig. 3.39).

Larvae: Larvae are smooth, segmented and measure 10–14 mm in length (Fig. 17.7). They possess a pair of oral hooks at the anterior extremity and, at the posterior, peritremes bearing spiracles (see Fig. 3.40).

Hosts: Mainly sheep, but a range of other domestic and wild animals may be affected including humans.

Pathogenesis: Two species, *L. sericata* and *L. cuprina*, are important primary facultative agents of myiasis. Other species of *Lucilia* may be occasional or secondary invaders of established myiasis. After the eggs are deposited on the wool, the larvae emerge and crawl down the wool on to the skin. They secrete proteolytic enzymes, which digest and liquefy the tissues. Second- and third-stage larvae may also abrade the skin with their mouth hooks.

Infestations resulting from a single batch of eggs may be tolerated well by sheep, produce few clinical signs and be difficult to detect without detailed examination. When the larvae cease feeding and leave the host, the lesions created by such small infestations heal well and usually without complications.

However, the odour of an existing infestation may attract more blowflies and induce further oviposition; the high humidity at an active strike lesion may also enhance egg and larval survival. Hence, once infested, sheep become far more likely to receive multiple strikes. At the initial lesion site there may be alopecia and underlying scar tissue formation, while the lesion spreads from its margins as further ovipositions occur and waves of larvae feed under the surrounding wool (see Fig. 9.70). The irritation and distress caused by the expanding lesion is extremely debilitating and sheep can rapidly lose condition.

Pathology: Sheep struck by *Lucilia* show a rapid increase in body temperature and respiratory rate. The animals become anaemic and suffer severe toxæmia, with both kidney and heart tissues affected.

The feeding activity of the larvae may cause extensive tissue damage which, in combination with the larval proteases produced, results in the development of inflamed, abraded or undermined areas of skin. Infested animals become lethargic, appear depressed and cease feeding, resulting in loss of weight and anorexia. If untreated, multiple infestations rapidly lead to death from toxæmia, usually within about 2 weeks of the initial infestation, although the precise time required will depend on the intensity of infestation.

Lucilia sericata

Synonym: *Phaenicia sericata*

Common name: Greenbottle, sheep blowfly

Predilection site: Skin, skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Geographical distribution: Worldwide. Originally *Lucilia sericata* was probably endemic to the Palaearctic. However, as a result of natural patterns of movement and artificial dispersal by humans and livestock in the past few hundred years the species is now found worldwide. *Lucilia sericata* is more common in cool-temperate habitats, such as Europe, and is often replaced by the closely related *Lucilia cuprina* in warm-temperate and subtropical habitats.

Pathogenesis: Blowfly strike by *L. sericata* occurs most commonly in the perineal and tail-head region and is strongly associated with the accumulation of faeces in wool around the anus and tail (Fig. 17.8). There is little recorded involvement of dermatitis in

Fig. 17.8 Breech strike due to accumulation of faeces around the anus and tail.

predisposing sheep to strike by *L. sericata* in northern Europe. Following initial strike by *L. sericata*, secondary blowfly species may also invade the site of infestation. These secondary invaders include other species of *Lucilia*, *Calliphora* spp. and, in some regions, *Chrysomya* spp. *Lucilia sericata* adults may act as passive vectors of *Mycobacterium avium* subsp. *avium*, *M. a. paratuberculosis* and *M. a. hominissuis*.

Epidemiology: The risk of myiasis by *L. sericata* has been shown to increase with increasing flock size and stocking density, and to decrease with increasing farm altitude. Initially in spring, unshorn adults may be most at risk. Immediately following shearing the risk of strike in adult sheep is considerably reduced. However, the susceptibility to strike in lambs increases, peaking in late summer as their fleeces grow and as populations of pasture nematodes increase. This leads to diarrhoea and faecal soiling. In temperate areas under summer conditions, up to four generations may develop per year. In these areas, the final generation overwinters in the soil as larvae, to emerge as adults in the following spring. The precise timing of spring emergence and the growth of the population is highly temperature dependent. In warmer climates the number of generations per annum is greater and up to nine or ten have been recorded in southern Africa and Australia. The period of risk is more prolonged in warm moist weather.

Notes: *Lucilia sericata* is the most important agent of sheep myiasis throughout northern Europe and was first recorded as an ectoparasite in England in the fifteenth century. *Lucilia sericata* arrived in New Zealand over 100 years ago and soon established itself as the primary myiasis fly in the country, occurring in 75% of all cases of sheep strike. However, now *L. cuprina* appears to be displacing *L. sericata* to become the most important primary cause of fly strike in sheep in New Zealand.

Lucilia cuprina

Synonym: *Phaenicia cuprina*, *Phaenicia pallescens*

Common name: Greenbottle, Australian sheep blowfly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Geographical distribution: It is thought that the original distribution of *Lucilia cuprina* may have been either Afro-tropical or Oriental. However, as a result of natural patterns of movement and artificial dispersal by humans and livestock in the past few hundred years, the species is now found worldwide, although in general *L. cuprina* occurs in warm-temperate and subtropical habitats. There are believed to be two subspecies: *L. c. cuprina* is distributed throughout the Neotropical, Oriental and southern Nearctic regions, while *L. c. dorsalis* is found throughout the sub-Saharan, Afro-tropical and Australasian regions. However, the two subspecies interbreed readily in the laboratory and intermediate forms are believed to be common. The simple division into two subspecies is therefore certainly an oversimplification of the complex pattern of genetic variation that occurs between populations of *L. cuprina*.

Pathogenesis: In Australia and New Zealand, body strike caused by *L. cuprina* is frequently the main form of myiasis. Body strike occurs most commonly around the shoulders and back region and is frequently associated with the incidence of bacterial dermatophilosis caused by the bacterium *Dermatophilus congolensis*. Body strike in Australasia is also often associated with bacterial fleece rot, a superficial dermatitis induced by moisture and proliferation of the bacteria *Pseudomonas aeruginosa* on the skin, resulting in a matted band of discoloured fleece. It is possible that dermatophilosis and fleece rot act synergistically in attracting blowflies and their subsequent oviposition. However, where the Merino breed is prevalent, breech and tail strike may also be common due to the conformation of this breed and the wrinkled skin in the breech area that favours the accumulation of urine and faeces.

Following initial strike by *Lucilia cuprina*, a variety of secondary species may also invade the site of infestation. They frequently extend the injury rendering the strike one of great severity. These secondary invaders include *Calliphora* spp. and *Chrysomya* spp. *Lucilia cuprina* is suspected of spreading diseases such as gastroenteritis and anthrax among host animals.

Epidemiology: In warmer parts of its range, nine or ten generations per year have been recorded and *L. cuprina* may be active all year round in some parts of its range.

Notes: *Lucilia cuprina* is absent from most of Europe, although it has been recorded from southern Spain and North Africa. *Lucilia cuprina* was probably introduced into Australia towards the middle or end of the nineteenth century and it is now the dominant sheep myiasis species for mainland Australia and Tasmania, present in 90–99% of fly strike cases. In the early 1980s *L. cuprina* was discovered in New Zealand and was most probably introduced from Australia. Now, despite its low abundance, in northern areas of New Zealand it appears to be displacing *L. sericata* to become the most important primary cause of fly strike in sheep.

Lucilia cuprina is also the primary myiasis fly of sheep in southern Africa. Although this species has been known in South Africa since 1830, little sheep strike was recorded until the early decades of the twentieth century, possibly as a result of the introduction of more susceptible Merino breeds or changes in husbandry practices.

In North America, *L. cuprina* is known to be present, although it does not appear to be important in sheep myiasis.

Calliphora

Description: The larvae are smooth, segmented and measure 10–14 mm in length. They possess a pair of oral hooks at the anterior extremity, spiracles on the anterior segment and, posteriorly, spiracular plates. The arrangement of the posterior spiracles on these plates serves to differentiate the species.

Hosts: Mainly sheep, but any other animal may be affected.

Pathogenesis: When involved in myiasis, secondary blowflies are attracted by the odour of the infestation and their larvae extend and deepen the lesion. The irritation and distress caused by the lesion is extremely debilitating and the host animal can rapidly lose condition. The latter is often the first obvious sign of strike as the lesion

occurs at the skin surface and is sometimes observed only on close examination.

Epidemiology: Secondary flies usually follow an initial strike by a primary fly such as *Lucilia cuprina* and invade the site of infestation. They frequently extend the injury, rendering the strike one of great severity. Clinical signs, diagnosis, pathology, epidemiology, treatment and control as for *Lucilia*.

Calliphora augur

Common name: Lesser brown blowfly, bluebodied blowfly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description: The adult *Calliphora augur* is predominantly brown or brown–yellow in colour with a patch of metallic blue on the medial abdomen. The adult body is approximately 11 mm in length.

Description, larvae: The larvae are smooth, segmented and measure 10–14 mm in length.

Geographical distribution: Australasia, mainly eastern Australia.

Pathogenesis: It breeds mostly in carcasses but will lay into wounds. As a result *Calliphora augur* is an important native Australasian species found as a secondary or tertiary invader of sheep strikes in the Australasian region.

Calliphora albifrontalis

Synonym: *Calliphora australis*

Common name: Western Australian brown blowfly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description: In the adult *Calliphora albifrontalis* the thorax is non-metallic blue–black in colour but the abdomen is predominantly brown or brown–yellow.

Description, larvae: The larvae are smooth, segmented and measure 10–14 mm in length.

Hosts: Mainly sheep, but a range of other warm-blooded animals may also be infested.

Geographical distribution: Australasia

Pathogenesis: *Calliphora albifrontalis* is an important native Australasian species found as a secondary or tertiary invader of sheep strikes in the Australasian region. In Western Australia, *C. albifrontalis* may be responsible for up to 10% of single-species strikes.

Calliphora nociva

Synonym: *Calliphora dubia*

Common name: Lesser brown blowfly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description: The adult *Calliphora nociva* is predominantly brown or brown–yellow in colour and closely resembles *C. augur* except for the colour patch on the abdomen, which is a much brighter blue on *C. nociva* than on *C. augur*. *Calliphora nociva* displaces *C. augur* in Western Australia.

Description, larvae: The larvae are smooth, segmented and measure 10–14 mm in length.

Hosts: Mainly sheep, but any other animal may be affected. It is important to note that only the larvae are responsible for myiasis.

Geographical distribution: Australasia, mainly Western Australia.

Pathogenesis: *Calliphora nociva* is an important native Australasian species found as a secondary or tertiary invader of sheep strikes in the Australasian region.

Calliphora stygia

Synonym: *Pollenia stygia*, *Calliphora laemica*

Common name: Eastern golden haired blowfly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description: The adult *Calliphora stygia* is a large native Australasian blowfly with a grey thorax and yellow–brown mottled abdomen. It is one of the earliest flies to visit a corpse and will also feed on living sheep, causing fly strike.

Description, larvae: The larvae are smooth, segmented and measure 10–14 mm in length.

Hosts: Mainly sheep, but any other animal may be affected. It is important to note that only the larvae are responsible for myiasis.

Geographical distribution: Australasia

Pathogenesis: *Calliphora stygia* is a common secondary invader of ovine myiasis, present in strikes from October to May.

Epidemiology: *Calliphora stygia* is adapted to cooler conditions than other flies and occurs in largest numbers in spring and autumn, but may be found on sunny days in winter as well. This adaptation to the cold gives it an advantage on carrion during the cooler months, and in spring in particular many thousands of

these flies can develop from carcasses. In summer, high temperatures and competition from species such as *Chrysomya rufifacies* reduce its abundance and *C. stygia* becomes scarce. In Western Australia, *C. stygia* is displaced by the very similar *Calliphora albifrontalis*.

Calliphora vicina

Synonym: *Calliphora erythrocephala*

Common name: Bluebottle

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description: Bluebottles are stout and characterised by a metallic blue sheen on the body (Fig. 17.6a). The thoracic squamae have long dark hair on the upper surface. *Calliphora vicina* is distinguished from *C. vomitoria* by the presence of yellow–orange jowls with black hairs.

Description, larvae: The larvae are smooth, segmented and measure 10–14 mm in length. Posterior spiracles are in a closed peritreme (see Fig. 3.41).

Hosts: Predominantly colonisers of decaying carrion but may occasionally be found as a secondary invader of myiasis.

Geographical distribution: Worldwide

Pathogenesis: In addition to acting as a secondary invader of myiasis, *C. vicina* has also been recorded laying eggs on living small mammals. Attempts to induce primary sheep strike by *C. vicina* have proved unsuccessful and it has been suggested that this species may be physiologically unable to infest sound sheep, either because the sheep body temperature is fatally high or because larvae are unable to feed on the animal tissues without the prior activity of *Lucilia* larvae.

Calliphora vomitoria

Common name: Bluebottle

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description, adult: As for *Calliphora vicina* but distinguished by having black jowls with predominantly reddish hairs (Fig. 17.9).

Description, larvae: See *Calliphora vicina*.

Hosts: Predominantly colonisers of decaying carrion but may occasionally be found as a secondary invader of myiasis.

Geographical distribution: Worldwide

Fig. 17.9 The bluebottle *Calliphora vomitoria*.

Phormia regina

Common name: Blackbottle, black blowfly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description, adults: *Phormia regina* is a black-coloured blowfly with an overlying metallic blue–green sheen (Fig. 17.6c). This species is very similar to *Protophormia terraenovae* in appearance. In *P. terraenovae* the anterior thoracic spiracle is black or black–brown and is difficult to distinguish from the general body colour. In contrast, in *Phormia regina* the anterior spiracle is yellow or orange and stands out clearly against the dark background colour of the thorax.

Description, larvae: The third-stage larvae of *P. regina* are characterised by strongly developed, fairly pointed tubercles on the posterior face of the last segment. In third-stage larvae of *P. regina*, the tubercles on the upper margin of the last segment are shorter than those of *P. terraenovae*, and are less than half the width of a posterior spiracle in length (see Fig. 3.42b). There are no dorsal spines on the posterior margins of segment 10.

Hosts: Mainly sheep, but other mammals and birds may be affected.

Geographical distribution: Northern Canada, USA, Europe, Scandinavia, Russia.

Protophormia terraenovae

Synonym: *Phormia terraenovae*

Common name: Blackbottle

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description, adults: *Protophormia terraenovae* is a black-coloured blowfly with an overlying metallic blue–green sheen. This species is very similar to *Phormia regina* in appearance. In *P. terraenovae* the anterior thoracic spiracle is black or black–brown and is difficult to distinguish from the general body colour. In contrast, in *Phormia regina* the anterior spiracle is yellow or orange and stands out clearly against the dark background colour of the thorax.

Description, larvae: The third-stage larvae of *P. terraenovae* (as with *P. regina*) are characterised by strongly developed, fairly pointed tubercles on the posterior face of the last segment. In third-stage larvae of *P. terraenovae* the tubercles on the upper margin of the last segment are longer than half the width of a posterior spiracle (see Fig. 3.42a). The larvae of *P. terraenovae* also possess dorsal spines on the posterior margins of segment 10 (see Fig. 3.42c).

Hosts: Mainly sheep, but may also be a serious pest of cattle and reindeer.

Geographical distribution: Northern Canada, USA, Europe, Scandinavia, Russia.

Cochliomyia hominivorax

Synonym: *Callitroga hominivorax*

Common name: Screwworm

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description, adult: The adult fly has a deep greenish-blue metallic colour with a yellow, orange or reddish face and three dark stripes on the dorsal surface of its thorax (Figs 17.6d and 17.10).

Fig. 17.10 Screwworm *Cochliomyia hominivorax*.

Description, larvae: Mature larvae measure 15 mm in length and have bands of spines around the body segments. The tracheal trunks leading from the posterior spiracles have a dark pigmentation extending forwards as far as the ninth or tenth segment (see Fig. 3.34a). This pigmentation is most conspicuous in fresh specimens.

Hosts: Commonly cattle, pigs and horses but may parasitise any mammal, including humans.

Geographical distribution: *Cochliomyia hominivorax* occurs primarily in tropical areas of southern and central America and the Caribbean islands. Its range formerly extended north into Mexico and the southern states of North America, from where it has now been eradicated.

Pathology and pathogenesis: In cattle, infestation initially causes intermittent irritation and pyrexia, followed by the production of a cavernous lesion. The tissue shows progressive liquefaction, necrosis and haemorrhage, before the larvae leave the wound. If untreated, repeated infestation by *C. hominivorax* and secondary fly species may quickly lead to the death of the host within 1–2 weeks.

Clinical signs: It may be difficult to see screwworm maggots at the wound surface because only the posterior spiracles are exposed. Larvae of other blowflies such as *Lucilia* do not feed in a vertical position or burrow deep into the wound, but instead feed more superficially.

Diagnosis: Screwworm larvae have distinct dorsal tracheal pigmentation that extends from somatic segment 12 to segment 10 or 9.

Epidemiology: Adult females have been reported to fly up to 320 km. The infestation can also be spread by the transport of animals and people from infested areas.

Control: As a result of the economic cost of this pest, large-scale screwworm fly control was initiated in the southeastern states of the USA in 1957–1959. This was achieved by the release of large numbers of male *C. hominivorax* that had been sterilised by radiation. Sterilised males mate with wild females, which are in turn rendered infertile. Subsequent control operations spread the area of sterile male release and by 1980 effective control of *C. hominivorax* in the USA was achieved. Despite a number of sporadic, but significant, outbreaks, effective control has been maintained. The eradication programme has subsequently been successfully directed against the fly in Mexico, Puerto Rico and as far as Panama.

Notes: In 1988, *C. hominivorax* were discovered in an area 10 km south of Tripoli in Libya. This was the first known established population of this species outside the Americas. The fly quickly spread to infest about 25,000 km². In 1989 there were about 150 cases of myiasis by *C. hominivorax* but by 1990 a total of 12,068 confirmed cases of screwworm fly myiasis were recorded and, at its peak, almost 3000 cases were seen in the single month of September 1990. It was estimated that if unchecked the infestation could cost the Libyan livestock industry about US\$30 million per year and the North African region approximately US\$280 million per year. This led to the implementation of a major international control programme, which successfully eradicated the fly from this area, again using the release of sterile males.

Cochliomyia macellaria

Synonym: *Callitroga macellaria*

Common name: Secondary screwworm

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description, adult: These blue–green flies have longitudinal stripes on the thorax and orange–brown eyes. Adults are extremely similar in appearance to *C. hominivorax*, but possess a number of white spots on the last segment of the abdomen.

Description, larvae: The larvae may be distinguished from those of *C. hominivorax* by the absence of pigmented tracheal trunks leading from small posterior spiracles (see Fig. 3.34).

Hosts: Commonly cattle, pigs and horses but may parasitise a range of mammals including humans.

Geographical distribution: Neotropical and Nearctic, from Canada to Argentina, but is more abundant in tropical parts of its range.

Pathogenesis: Mechanical transmission of disease attributed to this species includes botulism in birds, 12 different *Salmonella* types including *Salmonella typhimurium*, poliomyelitis and swine influenza.

Epidemiology: *Cochliomyia macellaria* is often attracted to the wounds initiated by *C. hominivorax*. The two species are commonly found together.

Chrysomya bezziana

Common name: Old World screwworm

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description, adult: These stout blue–green flies have four longitudinal black stripes on the prescutum, orange–brown eyes and a pale coloured face (Fig. 17.11). The flies have dark legs and white thoracic squamae. The anterior spiracle is dark orange or black–brown. The adult flies measure 8–10 mm in length.

Description, larvae: The first-stage larvae are creamy white and measure about 1.5 mm in length. The second- and third-stage larvae are 4–9 mm and 18 mm in length, respectively, and are similar in appearance, each segment carrying a broad encircling belt of strongly developed spines (see Fig. 3.35).

Hosts: Mammals including cattle, sheep, dogs and occasionally humans.

Geographical distribution: This species occurs primarily in tropical areas: Africa and southern Asia including India, the Arabian Peninsula, Southeast Asia, the Indonesian and Philippine islands, and New Guinea.

Fig. 17.11 Old World screwworm *Chrysomya bezziana*.

Pathogenesis: Infestation by *Chrysomya bezziana* causes intermittent irritation and pyrexia, followed by the production of a cavernous lesion. Infested wounds often have a serosanguineous discharge and sometimes a distinctive foul-smelling odour. Sometimes, there may be large pockets of larvae with only small openings in the skin. The tissue shows progressive liquefaction, necrosis and haemorrhage, before the larvae leave the wound. Animals may die from secondary infection or toxicity in 1–2 weeks if the infestation is not treated.

Clinical signs: In the first day or two, screwworm infestations are difficult to detect. Often, all that can be seen is slight motion inside the wound. As the larvae feed, the wound gradually enlarges and deepens. Animals infested with screwworms may appear dull, lethargic and separate from the herd. They may cease feeding and show weight loss. Wounds with foul-smelling odour will be observed on inspection; however, it may be difficult to see the maggots at the wound surface because only the posterior spiracles are exposed. Larvae of other blowflies such as *Lucilia* do not feed in a vertical position or burrow deep into the wound, but instead feed more superficially. Screwworms may be particularly difficult to find inside the nasal, anal and vaginal openings.

Diagnosis: The larvae can be found packed deep inside the wound. Screwworms are diagnosed by the removal of the larvae and identification with a dissecting microscope.

Epidemiology: In temperate regions, screwworm attacks are restricted to the warm seasons, although may occur during mild winters. In the tropics they are continuous. Female screwworms are attracted to all warm-blooded animals. The distance a fly will travel ranges from 10 to 20 km in tropical environments.

Notes: The precise status of *Chrysomya bezziana* as a clinical and economic pest is uncertain, particularly in sub-Saharan Africa, and few studies have been able to obtain quantitative estimates of myiasis incidence and its clinical or economic importance. The absence of livestock throughout much of its range in sub-Saharan Africa, due to the presence of trypanosomiasis and its vector the tsetse fly, may substantially limit its economic impact. However, *C. bezziana* has been inadvertently introduced into several countries in the Middle East, and such an introduction is believed to pose a major economic threat to the pastoral industry of Australia.

Chrysomya megacephala

Common name: Oriental latrine fly

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description, adults: Adults are medium-sized, stout, blue-green flies with longitudinal stripes on the thorax and orange-brown eyes (see Fig. 3.36). *Chrysomya megacephala* can be distinguished from *Lucilia* by the broad bands on its rounder abdomen and by its black forelegs. The face is pale coloured. The anterior spiracle of the thorax of adults is dark coloured.

Description, larvae: The larvae are about 18 mm in length. They have hooked mouthparts and bands of small spines on each segment. There are four to six projections on the anterior spiracle with fleshy projections on the last segment only.

Hosts: A range of warm-blooded animals may be infested.

Geographical distribution: Worldwide. *Chrysomya megacephala* is a native of Australasian and Oriental regions. However, this species has been introduced inadvertently into the New World and entered Brazil around 1975. Since then it has dispersed rapidly to reach Central and North America.

Chrysomya rufifacies

Common name: Hairy maggot blowfly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description, adult: These bluish-green flies have longitudinal stripes on the thorax and orange-brown eyes. The hind margins of the abdominal segments have blackish bands and the anterior spiracle is white or pale yellow.

Description, larvae: Third-stage larvae are about 18 mm in length. The larvae bear a number of thorn-like fleshy projections on most of the body segments, which give this species its common name of

hairy maggot blowfly (see Fig. 3.37). These projections become longer on the dorsal and lateral parts of the body. *Chrysomya rufifacies* larvae may be distinguished from *C. albiceps* larvae by the presence of small spines on the stalks of the projections.

Hosts: A range of warm-blooded animals may be infested.

Geographical distribution: *Chrysomya rufifacies* is an Australasian and Oriental species of tropical origin. This species and *C. albiceps* were inadvertently introduced in the Neotropical region in the 1970s and 1980s where, at a dispersal rate estimated at 1.8–3.2 km/day, they have quickly spread and become established throughout much of North and South America.

Chrysomya albiceps

Common name: Hairy maggot blowfly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description, adult: These bluish-green flies have longitudinal stripes on the thorax and orange–brown eyes. The hind margins of the abdominal segments have blackish bands and the anterior spiracle is white or pale yellow.

Description, larvae: *Chrysomya albiceps* larvae may be distinguished from *C. rufifacies* larvae by the absence of small spines on the stalks of the projections.

Hosts: A range of warm-blooded animals may be infested.

Geographical distribution: *Chrysomya albiceps* is predominantly African and Mediterranean in its distribution. However, this species and *Chrysomya rufifacies* were inadvertently introduced in the Neotropical region in the 1970s and 1980s where, at a dispersal rate estimated at 1.8–3.2 km/day, they have quickly spread and become established throughout much of North and South America.

Cordylobia anthropophaga

Common name: Tumbu fly

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description, adults: The adult is a stout yellow–brown fly, 8–12 mm in length. It has a yellow face and legs and two black marks on the thorax. Adult flies feed on decaying fruits, carrion and faeces and have large, fully developed mouthparts. The arista of the antenna has setae on both sides. The thoracic squamae are without setae and the stem vein of the wing is without bristles.

Description, larvae: Third-stage larvae are 12–28 mm in length and are densely, but incompletely, covered with small, backwardly directed, single-toothed spines (see Fig. 3.38). The posterior spiracles have three sinuous slits and a weakly sclerotised peritreme.

Hosts: Humans and other mammals. It is thought that the primary hosts of *C. anthropophaga* are rodents and that the flies have become secondarily adapted to parasitise many other animal species, including humans. The domestic dog is an important host.

Geographical distribution: Sub-Saharan Africa

Pathogenesis: The larvae develop under the skin and produce a painful swelling, 10 mm in diameter, with a small central opening. The swelling is initially pruritic, becoming more painful as the larva grows. Serous fluid may exude from the lesion.

Cordylobia rodhaini

Common name: Tumbu fly, Lund fly

Predilection site: Skin

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Calliphoridae

Description, adult: This species closely resembles *C. anthropophaga* but is larger, measuring 12.5 mm in length. The adult is a stout yellow–brown fly with a yellow face and legs and two black marks on the thorax. Adult flies feed on decaying fruits, carrion and faeces and have large, fully developed mouthparts. The arista of the antenna has setae on both sides. The thoracic squamae are without setae and the stem vein of the wing is without bristles.

Description, larvae: Third-stage larvae are 12–28 mm in length and are densely, but incompletely, covered with small, backwardly directed, single-toothed spines. On the posterior segment the larvae have a pair of spiracular plates and the arrangement of the posterior spiracles on these plates serves to differentiate the species. In *C. anthropophaga* the posterior spiracles have three sinuous slits and a weakly sclerotised peritreme.

Hosts: Mainly antelope and rodents but may parasitise humans.

Geographical distribution: Tropical Africa, particularly rainforest areas.

Pathogenesis: See *Cordylobia anthropophaga*.

FAMILY SARCOPHAGIDAE

The family Sarcophagidae, known as flesh flies, contains over 2000 species in 400 genera. Most species of Sarcophagidae are of no veterinary importance, breeding in excrement, carrion and other decomposing organic matter. The principal genus containing species which act as important agents of veterinary myiasis is *Wohlfahrtia*. Members of the genus *Sarcophaga* may occasionally infest wounds, the most widely distributed species of which is *Sarcophaga haemorrhoidalis*.

Wohlfahrtia magnifica

Common name: Flesh fly, screwworm

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Sarcophagidae

Description, adult: The adult flies are large, measuring 8–14 mm in length, with elongated bodies. They are grey in colour and have three distinct, longitudinal, thoracic stripes. The abdomen is clearly marked with black spots (see Fig. 3.43c). The flies have numerous bristles covering the body and long black legs. The arista of the antennae does not possess setae.

Description, larvae: Larvae possess strongly developed oral hooks.

Hosts: Adult females will oviposit on any warm-blooded animal. This includes most livestock, particularly sheep and camels and also poultry, although cattle, horses, pigs, dogs and humans may also be infested.

Geographical distribution: Northern Africa, the Mediterranean, eastern Europe, the Middle East and Russia.

Pathogenesis: *Wohlfahrtia magnifica* can cause rapid and severe myiasis in most animals. Flies lay their larvae in sores (particularly around the eyes), body orifices, wounds or decomposing flesh. Infestation initially causes intermittent irritation and pyrexia, followed by the production of a cavernous lesion. The tissue shows progressive liquefaction, necrosis and haemorrhage, before the larvae leave the wound. If untreated, repeated infestation by *W. magnifica* and secondary fly species may quickly lead to the death of the host within 1–2 weeks.

Epidemiology: Levels of infestation appear to be high, particularly in sheep in eastern Europe. Faecal soiling in sheep has been recorded as an important predisposing factor for breech myiasis by *W. magnifica*. In a 4-year period, cases of myiasis by *W. magnifica* were recorded in 45 of 195 sheep flocks in Bulgaria, affecting between 23 and 41% of sheep each year. Only 0.5–1% of cows and goats were affected over the same period. In Romania, in one study 80–95% of sheep were infested, with 20% fatalities of newborn lambs.

Wohlfahrtia nuba

Common name: Flesh fly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Sarcophagidae

Description: The adult flies are large, 8–14 mm in length, with elongated bodies, longitudinal black thoracic stripes and a grey and black tessellated abdomen. Larvae possess strongly developed oral hooks.

Hosts: Camels

Geographical distribution: Primarily North Africa and the Near East.

Pathogenesis: When present in an infected wound or as a secondary invader at an existing myiasis, larvae extend and deepen the lesion. The irritation and distress caused by the lesion is extremely debilitating and the host animal can rapidly lose condition. If untreated, repeated infestation may quickly lead to the death of the host within 1–2 weeks.

Clinical signs: Animals infested by fly larvae may appear dull, lethargic and separate from the herd or flock. They may cease feeding and show weight loss. Wounds with foul-smelling odour will be observed on inspection.

Diagnosis: Flesh fly larvae are diagnosed by the removal of the larvae and identification under a dissecting microscope.

Epidemiology: *Wohlfahrtia nuba* may be an occasional secondary facultative invader of wounds, particularly of camels, in North Africa and the Middle East.

Treatment and control: The larvae should be removed and identified and the wound thoroughly cleaned and disinfected. Organophosphate and pyrethroid insecticides are effective against newly hatched larvae, immature forms and adult flies. Larvae inside wounds must be treated with a suitable larvicide. Spraying or dipping animals with an approved insecticide and treating infested wounds can protect against new infestations for 7–10 days.

Wohlfahrtia vigil

Common name: Grey flesh fly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Sarcophagidae

Description, adult: The adult flies are large, 8–14 mm in length, with elongated bodies, longitudinal black thoracic stripes and a grey and black tessellated abdomen.

Description, larvae: Larvae possess strongly developed oral hooks.

Hosts: Mink, fox, rabbit and other wild mammals. Dogs and cats may also occasionally be attacked.

Geographical distribution: North, Central and South America.

Pathogenesis: *Wohlfahrtia vigil* can cause rapid and severe myiasis in most animals. The myiasis caused is furuncular rather than cutaneous. Furuncles similar to those of *Dermatobia* are produced, although those of *W. vigil* can contain up to five larvae with a small pore opening to the outside.

Wohlfahrtia meigeni

Common name: Flesh fly

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Sarcophagidae

Description, adults: The adult flies are large, 8–14 mm in length, with elongated bodies, longitudinal black thoracic stripes and a grey and black tessellated abdomen.

Description, larvae: Larvae possess strongly developed oral hooks.

Hosts: Warm-blooded vertebrates, particularly mink and fox, but may also infest rabbits and dogs.

Geographical distribution: Palearctic, primarily western USA.

Pathogenesis: Flies lay their larvae in wounds, body orifices or existing myiasis. The myiasis caused is furuncular rather than cutaneous. Furuncles similar to those of *Dermatobia* are produced, although those of *W. meigeni* can contain up to five larvae. This species may cause substantial mortality to young mink and foxes in fur farms.

***Sarcophaga* spp.**

Common name: Flesh flies

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Sarcophagidae

Description, adults: Adults are grey–black, non-metallic, medium to large flies with prominent stripes on the thorax and a checkered abdominal pattern (see Fig. 3.43a).

Hosts: Cattle, sheep

Geographical distribution: Worldwide

FAMILY OESTRIDAE

Dermatobia hominis

Common names: Torsalo, berne, human bot fly, ura

Predilection site: Skin wounds

Class: Insecta

Order: Diptera

Suborder: Brachycera

Family: Oestridae

Description, adult: The adult *Dermatobia* fly resembles *Calliphora* in appearance, the short broad abdomen having a bluish metallic sheen, but there are only vestigial mouthparts covered by a flap. The female measures approximately 12 mm in length. Adults have

a yellow–orange head and legs, and the thorax possesses a sparse covering of short setae. The arista of the antennae has setae on the outer side only.

Description, larvae: Mature larvae measure up to 25 mm long and are somewhat oval. They have two to three rows of strong spines on most of the segments. Larvae are narrowed at the posterior end, particularly the second-stage larva. The third-stage larva is more oval in shape with prominent flower-like anterior spiracles (see Fig. 3.51).

Hosts: Humans, most domestic and wild mammals and many types of bird.

Geographical distribution: Latin America from Mexico to northern Argentina and the island of Trinidad.

Pathogenesis: The larvae occur in swellings in various parts of the body and these may suppurate and cause severe pain. In Latin America this condition is often known as ‘ura’.

Dermatobia is a major problem in cattle in South America. Lesions are most numerous on the upper body, neck, back, flanks and tail, and are often grouped together to form large and often purulent swellings. As well as hide damage, the pain and distress of the lesions result in reduced time spent grazing, retarded growth and lowered meat and milk production. The exit holes made by the larvae may also attract myiasis-producing flies, including screwworms.

In humans the most common larval sites are the extremities of the limbs and the scalp. Fatal cerebral damage has occurred in children when larvae have migrated through the fontanelle into the cranial cavity.

Clinical signs: Symptoms include the swellings and lesions made by larvae. Infected animals show reduced weight gain and milk production.

Epidemiology: The most common vectors of *D. hominis* larvae are members of the genera *Psorophora*, *Culex* and *Stomoxys*. These flies breed in forest where both domestic and wild animals are commonly parasitised. Humans are usually infected through association with domestic animals; however, non-insect transmission may occur when *D. hominis* eggs are deposited on damp clothes or laundry.

ORDER SIPHONAPTERA (FLEAS)

The fleas are small, wingless, obligate, blood-feeding insects. Over 95% of flea species are ectoparasites of mammals, while the others are ectoparasites of birds. The order is relatively small, with about 2500 described species, almost all of which are morphologically extremely similar.

Pathogenesis: The wounds created at the feeding site are usually seen as erythematous papules or wheals surrounding the central puncture site. The wounds may develop a crust of dried exudate. The wheals may persist for several weeks. Pruritis may be intense, resulting in secondary traumatic lesions.

Clinical signs: Host animals scratch and bite at the affected area and the bite may produce a small raised wheal on the skin.

Diagnosis: When the signs are indicative of flea infestation, but no parasites can be found, the host should be sprayed with an insecticide, placed on a large sheet of plastic or paper, and vigorously combed or groomed. The combings and debris should be examined for fleas or flea faeces, which show as dark brown–black crescentic

particles. Consisting almost entirely of blood, these will produce a spreading reddish stain when placed on moist tissue.

Another technique is the use of a vacuum cleaner with fine gauze inserted behind the nozzle; the latter is applied to the host or its habitat and the fleas are retained on the gauze.

Treatment: In flea-bite allergy, where there is much distress, corticosteroids may be used topically or systemically as palliative treatment. Since in-contact animals may also harbour fleas without developing allergy, these should also be treated.

For specific treatment, insecticides are available, mainly in the form of powders, sprays, shampoos or spot-on preparations. These historically have generally been organophosphate compounds, pyrethrum and its derivatives, or carbamates. The insect growth regulator lufenuron, a benzoylurea derivative, is given orally for use against fleas in dogs. When ingested by fleas during feeding, the compound is transferred to the eggs and blocks the formation of chitin, thereby inhibiting the development of flea larvae.

Of the newer generation of ectoparasiticides, fipronil is given either by spray or spot-on for the control of fleas and ticks in both dogs and cats, giving protection for 2–3 months. Imidacloprid is a systemic neurotoxic insecticide that is chemically related to the tobacco toxin nicotine. It is highly effective at killing adult fleas for up to 1 month after application. Of importance is that fleas are not required to bite the animal to receive a lethal dose, which can be absorbed through the cuticle.

More newer and recently introduced flea compounds include indoxacarb, which is a pro-insecticide that requires activation in the target insect to an active metabolite that causes paralysis and death. Afoxolaner and fluralaner belong to a new class of insecticide, the isoxazoles, which act as non-competitive g-aminobutyric acid (GABA) receptor agonists, binding to chloride channels in nerve and muscle cells of the target parasites. Given orally they protect against fleas and ticks for up to 3 months.

Control: For optimal control, the adults already infesting the host animal should be killed immediately and reinfestation from the environment prevented. A wide range of products is available. Many of the new chemicals with excellent long-acting flea adulticidal activity also have contact ovicidal and/or larvicidal activity. In addition, combination with insect growth regulators (chitin synthesis inhibitors, juvenile hormone analogues) applied directly to the animal not only increases ovicidal and/or larvicidal activity but also delivers it effectively to the sleeping areas most likely to be infested without unnecessarily contaminating the environment. Insect growth regulators do not kill adult fleas and are not suitable by themselves for flea control, unless used in a completely closed environment. For flea infestations of domestic animals, frequent vacuuming can help to reduce environmental infestation and pet bedding should be washed at high temperatures.

Ctenocephalides felis

Subspecies: *felis*

Subspecies: *strongylus*

Subspecies: *damarensis*

Subspecies: *orientalis*

Common name: Cat flea

Predilection site: Skin

Class: Insecta

Order: Siphonaptera

Family: Pulicidae

Description: Cat fleas are dark brown–black wingless insects with laterally compressed bodies, which have a glossy surface. Females typically measure 2.5 mm in length; males are smaller, sometimes less than 1 mm in length. Eyes are simply dark photosensitive spots, and the antennae, which are short and club-like, are recessed into the head. In the female *C. f. felis* the head is twice as long as high and pointed anteriorly. In the male *C. f. felis* the head is as long as wide but is also slightly elongate anteriorly (see Fig. 3.74). The third pair of legs is much longer than the others and, coupled to elaborate internal musculature, provide an adaptation for jumping to locate their host. The head bears at its posterior (pronotal) or ventral (genal) borders rows of dark spines called ctenidia or ‘combs’, and these are the most important features used in identification (see Fig. 3.74). The genal ctenidium consists of seven to eight spines and the pronotal ctenidium about 16 spines. The teeth of the genal comb are all about the same length. On the dorsal border of the hind (metathoracic) tibia in both sexes of *C. f. felis* there are only six notches bearing setae (see Fig. 3.74c). Between the post-median and apical long setae there is a short subapical spine.

Hosts: Cat, dog, human.

Geographical distribution: Worldwide. However, there are four distinct subspecies of *C. felis*: *C. felis felis* is widespread, *C. f. strongylus* occurs in Africa, *C. f. damarensis* in southwestern Africa and *C. f. orientalis* in India, Sri Lanka and Southeast Asia.

Pathogenesis: The response to a flea bite is a raised, slightly inflamed wheal on the skin, associated with mild pruritus, but though the animal will scratch intermittently there is little distress. However, after repeated flea bites over a period of several months a proportion of dogs and cats develop flea-bite allergy, which is often associated with profound clinical signs (Fig. 17.12).

Since each female *C. f. felis* can ingest as much as 13.6 µL of blood per day, severe infestations may lead to iron-deficiency anaemia. Anaemia caused by *C. f. felis* is particularly prevalent in young animals and has been reported in cats and dogs and, very rarely, goats, cattle and sheep.

Fig. 17.12 The lesions of flea-bite allergy in a cat.

Flea-bite allergy is a hypersensitive reaction to components of the flea saliva released into the skin during feeding. The allergy shows a seasonality in temperate areas, appearing in summer when flea activity is highest, though in centrally heated homes exposure may be continuous. In warmer regions, such as the western states of the USA, the problem occurs throughout the year. As would be expected, the most commonly affected areas in both dogs and cats are the preferential biting sites of the fleas, namely the back, the ventral abdomen and the inner thighs. In the dog the primary lesions are discrete crusted papules which cause intense pruritus. The most important damage, however, is subsequently inflicted by the animals themselves, in scratching and biting the affected areas, to produce areas of alopecia or of moist dermatitis ('wet eczema'). In older dogs which have been exposed for many years, the skin may become thickened, folded and hairless, and in these animals the pruritus is much less intense. In the cat, flea-bite allergy produces the condition commonly known as miliary dermatitis or eczema, readily detectable on palpation, in which the skin is covered with innumerable small, brown, crusty papules that cause marked pruritus. In cats, there are two distinct clinical manifestations associated with flea allergy: miliary dermatitis and feline symmetrical alopecia.

Flea-allergy dermatitis is one of the most common causes of dermatological disease of dogs and cats. Dermatitis associated with allergy to flea bites is characterised by intense pruritus and reddening of the skin, with itching persisting up to 5 days after the bite. The resultant licking, chewing and scratching can lead to hair loss, self-induced trauma and secondary infection. Other symptoms include restlessness, irritability and weight loss, though the intensity of irritation varies greatly with the individual attacked.

All dogs can become allergic to fleas, though atopic dogs are predisposed to developing reactivity. One bite may be sufficient to cause an allergic reaction. Intermittent flea exposure encourages development of a flea allergy, while continual exposure appears to protect against it, as does contact with fleas at an early age. Though little is known about the allergens responsible for evoking the allergic response, recent findings suggest that multiple proteins are important in flea-bite hypersensitivity. In studies which have attempted to determine how flea antigens react with canine IgG or IgE, at least 15 different flea components have been found to bind IgE. No pattern of reactivity or differences in antibody structure have been observed which distinguish dogs with flea allergy from dogs without, suggesting that there is little association between particular antibody responses and allergic reactivity of dogs to fleas. Both immediate and delayed hypersensitivity can be observed, and individuals will vary in the strength and proportion of each type of sensitivity they express. Dogs chronically infested with *C. f. felis* rarely develop a state of natural tolerance resulting in a loss of clinical signs.

Cats kept in a flea-infested environment groom at twice the rate of cats in a flea-free environment. In normal grooming a cat may ingest almost 50% of its resident flea population within a few days and cats fitted with Elizabethan collars, which prevent grooming, harbour much greater populations of fleas than cats free to groom. The removal of fleas during grooming reduces the chance of finding them during a skin and coat examination. This is a particular diagnostic problem in cats with a low flea burden but marked flea-bite hypersensitivity. In such cases, since many of the groomed fleas are ingested, examination of the mouth may reveal fleas caught in the spines of the cat's tongue.

Fleas are vectors of a range of viruses and bacteria, and pathogen transmission is enhanced by their promiscuous feeding habits. Most species of flea are host-preferential rather than host-specific and will

try to feed on any available animal. For example, *C. felis* has been found on over 50 different host species. Other factors which contribute to the potential of *C. felis* as a vector include transovarial transmission of some pathogens (*Rickettsia* species) and the transmission of pathogens such as *Bartonella henselae* through adult flea faeces.

Fleas act as intermediate hosts for the common tapeworm of dogs and cats, *Dipylidium caninum*. Though the adult flea can acquire the filarioid infection by intake of microfilariae in a blood meal, the specialised mouthparts do not allow the ingestion of the eggs of *Dipylidium*, and this infection can only be acquired by the flea larva. Tapeworm eggs, along with general organic debris, are ingested by flea larvae. The tapeworm eggs hatch in the midgut of the flea larva and the worm larvae penetrate the gut wall, passing into the haemocoel. The tapeworm larvae develop within the flea body cavity throughout larval, pupal and adult flea development, eventually encapsulating as an infective cysticercoid. After ingestion of the adult flea by the host, cysticercoids are liberated and develop into tapeworms in the digestive tract.

Ctenocephalides felis felis also acts as an intermediate host of the non-pathogenic subcutaneous filarioid nematode of dogs, *Acanthocheilonema reconditum*, which adults may ingest during blood feeding.

Epidemiology: The cat flea, *C. f. felis*, is the most common species of flea found on domestic cats and dogs throughout North America and northern Europe. Significantly more cats are infested with fleas than dogs, however, perhaps because of their tendency to roam, increasing their contact with other cats. Fleas may be found on pets throughout the year but, in the northern hemisphere, numbers tend to increase around late spring and early autumn when ambient conditions are favourable for larval development. Since *C. felis* are able to survive for long periods off the host, they therefore do not require direct contact for transmission.

Ctenocephalides canis

Common name: Dog flea

Predilection site: Skin

Class: Insecta

Order: Siphonaptera

Family: Pulicidae

Description: The dog flea, *C. canis*, is closely related and is morphologically very similar to the cat flea, *C. f. felis*, although they cannot interbreed and are therefore truly distinct species. The head of the female dog flea is more rounded on its upper and anterior surface than that of the cat flea and less than twice as long as high (Fig. 17.13; see also Fig. 3.77). Like *C. f. felis*, the dog flea has both genal and pronotal combs (Fig. 17.14). The genal comb consists of seven to eight spines and the pronotal comb about 16 spines (see Fig. 3.77). However, in both female and male *C. canis* the first spine of the genal ctenidium is shorter than the rest. On the dorsal border of the hind (metathoracic) tibia in both sexes of *C. canis* there are eight notches bearing stout setae (see Fig. 3.77c).

Hosts: Dogs, cats, rats, rabbits, foxes and humans have all been recorded as hosts of *C. canis*.

Geographical distribution: Worldwide

Pathogenesis: Similar to that of *C. f. felis*.

Fig. 17.13 Female *Ctenocephalides canis*.

Fig. 17.14 Head of *Ctenocephalides canis* with genal and pronotal combs.

Epidemiology: The behavioural differences between dog and cat fleas seem largely to involve the range of environmental conditions which their larvae are capable of tolerating. While household dogs in northern Europe and North America are more likely to be infested by the cat flea, working dogs in kennels and dogs in rural areas or at higher altitudes are more likely to be infested by *C. canis*.

Archaeopsylla erinacei

Common name: Hedgehog flea

Predilection site: Skin

Class: Insecta

Order: Siphonaptera

Family: Pulicidae

Description: Adults are easily recognised, being 2–3.5 mm long with a genal comb of one to three short spines and a pronotal comb of one short spine (see Fig. 3.82).

Hosts: Hedgehogs, dogs and cats.

Geographical distribution: Europe and North America.

Fig. 17.15 Head of *Pulex irritans* lacking genal and pronotal combs.

Epidemiology: *Archaeopsylla erinacei* occurs on hedgehogs and may be transferred to dogs and cats following contact.

Pulex irritans

Common name: Human flea

Predilection site: Skin

Class: Insecta

Order: Siphonaptera

Family: Pulicidae

Description: *Pulex irritans* has neither genal nor pronotal combs (Fig. 17.15; see also Fig. 3.80). The outer margin of the head is smoothly rounded and there is a pair of eyes. This species can be distinguished from *Xenopsylla cheopis* by the presence of the single ocular bristle below the eye and the absence of a row of bristles along the rear margin of the head. The metacoxae have a patch of short spines on the inner side. The maxillary laciniae extend about halfway down the forecoxae, which distinguishes this species from the closely related *Pulex simulans* found in Hawaii (where the laciniae extend for at least three-quarters the length of the forecoxae).

Hosts: Humans and pigs; may also occur on dogs, cats, rats and badgers.

Geographical distribution: Worldwide, but it is now uncommon in the USA and most of northern Europe.

Pathogenesis: The bites of *Pulex* can cause dermatitis and it may on occasion act as a vector of the plague pathogen *Yersinia pestis*.

Epidemiology: Although described as the human flea, *P. irritans* can infest cats, dogs and many other domestic animals, although it is probably most common on pigs. It breeds profusely in pigsties and is usually the most important species in farm areas. People working with infested pigs can also easily become infested and start infestations in their homes.

Spilopsyllus cuniculi

Common name: Rabbit flea, European rabbit flea

Predilection site: Ears

Fig. 17.16 *Spilopsyllus cuniculi*.

Class: Insecta

Order: Siphonaptera

Family: Pulicidae

Description: The rabbit flea, *S. cuniculi*, has both pronotal and genal combs, the latter being composed of four to six oblique spines (Fig. 17.16; see also Fig. 3.78). Adults are dark brown. Females are, on average, 1 mm in length; males are slightly smaller. Eyes are present and the frons at the front of the head is rounded with the frontal tubercle conspicuous. There are two stout spines beneath the eye.

Hosts: Rabbit, hare, dog, cat.

Geographical distribution: Worldwide

Pathogenesis: When rabbits are not breeding, the distribution of *S. cuniculi* is related to skin temperature, with fleas usually congregating on the ears. Because they assemble here in large numbers, the intensity of bites may cause considerable irritation and tissue damage. Rabbit fleas may also be found on cats and dogs which hunt or frequent rabbit habitats. On these hosts they are commonly found on the face and attached to the pinnae margin. *Spilopsyllus cuniculi* is the main vector of myxomatosis and it also transmits the non-pathogenic *Trypanosoma nabiasi*.

Xenopsylla cheopis

Common name: Oriental or black rat flea

Predilection site: Skin

Phylum: Arthropoda

Class: Insecta

Order: Siphonaptera

Family: Pulicidae

Description: *Xenopsylla cheopis* resembles *P. irritans* in that both genal and pronotal combs are absent (see Fig. 3.81). The head is smoothly rounded anteriorly. The flea has a light amber coloration. The maxillary laciniae reach nearly to the end of the forecoxae. Eyes are present, yet it can only see very bright light. Immediately behind the eyes are two short antennae. The segments of the thorax appear relatively large and the pleural ridge is present in the mesopleuron of the thorax. There is a conspicuous row of bristles along the rear margin of the head and a stout ocular bristle in front of the eye.

Hosts: Rat, humans; this species may also infest mice, cottontail rabbits and ground squirrels.

Geographical distribution: Worldwide. The distribution of the Oriental rat flea, *X. cheopis*, largely follows that of its primary host the black rat, *Rattus rattus*. It has a worldwide distribution and is one of the most abundant fleas in the southern states of the USA. It is particularly common in urban areas.

Pathogenesis: The bites of the flea may prove irritating to the host animal causing it to scratch and rub itself. *Xenopsylla cheopis* is also an intermediate host of helminths such as *Rodentolepis diminuta* and *R. nana*. *Xenopsylla cheopis* is the main vector of *Yersinia pestis*, the cause of bubonic plague in humans. *Xenopsylla cheopis* acquires *Y. pestis* when feeding on its usual hosts. When the bacilli multiply in its gut the proventriculus becomes blocked so that blood cannot be ingested; the hungry flea moves from host to host in attempts to feed, and in its wanderings the infection may be transferred from its endemic base in rodents to the human population. Bacteria secreted in faeces may also enter a host through abrasions. Though now rare in humans, plague still exists in wild rodents ('sylvatic plague') in parts of Africa, Asia, South America and the western states of the USA. *Xenopsylla cheopis* is also a vector of murine typhus (*Rickettsia typhi*). In the case of typhus, the disease is only transmitted by rickettsia in faeces. However, the pathogen can invade the ovary, leading to its transovarial transmission via eggs.

Clinical signs: The adult fleas may be seen on the skin and coat of the host animal. Other signs are the host scratching affected areas.

Diagnosis: Diagnosis can be achieved by identifying the flea species on the host.

Epidemiology: The fleas are able to survive off the host for long periods, making infection possible from the environment. They are uncommon in laboratory or pet rats and mice so their presence may indicate that there is contamination by wild rodents.

Pathology: Flea feeding does not appear to produce histopathology at the flea feeding sites nor does the elevated blood basophil response of infested rats affect subsequent feeding or longevity of the fleas.

Treatment: A wide range of products is available to treat infested hosts. Imidacloprid and fipronil may be used in rats to kill adult fleas on contact. Growth regulators such as methoprene or pyriproxyfen are another effective longer-term alternative.

Control: For optimal control nesting material must be removed and replaced, the housing treated and reinfestation from the environment or introduced animals prevented.

Leptopsylla segnis**Common name:** Mouse flea**Predilection site:** Fur**Phylum:** Arthropoda**Class:** Insecta**Order:** Siphonaptera**Family:** Leptopsyllidae**Description:** In the adult there are both genal and pronotal combs and the genal comb contains only four spines.**Hosts:** Mice and rats.**Geographical distribution:** Europe and on the east and west coasts of the USA.**Pathogenicity:** Bites produce irritation, causing the host to scratch and rub and may provoke allergic responses. This species of flea has been infected experimentally with plague and murine typhus, but generally it is considered a poor disease vector.**Epidemiology:** Found largely in temperate areas and does not survive hot dry conditions.**Treatment and control:** As for *Xenopsylla cheopis*.***Echidnophaga gallinacea*****Common name:** Sticktight flea**Predilection site:** Skin**Class:** Insecta**Order:** Siphonaptera**Family:** Pulicidae**Description:** The sticktight flea, *E. gallinacea*, is a burrowing flea important mainly in domestic poultry. The adult sticktight flea is small: females are commonly about 2 mm in length and the males are less than 1 mm in length. The head is sharply angled at the front (frons). There are no genal or pronotal combs (see Fig. 3.79). On the head behind the antenna there are two setae and, in the female, usually a well-developed occipital lobe. The thoracic segments are narrowed dorsally. Spiracles are present on the second and third abdominal segments. The mouthparts appear large, extending the length of the forecoxae, and project from the head conspicuously. The maxillary laciniae are broad and coarsely serrated. On the anteroventral surface of each hind coxa, there are three rows of minute spiniform bristles.**Hosts:** Poultry, but may also attack cats, dogs, rabbits and humans.**Geographical distribution:** These fleas are most common in tropical areas throughout the world, but may also be found in many subtropical and temperate habitats.**Pathogenesis:** The burrowing of adults and subsequent emergence of larvae through the skin tissue can result in areas of ulceration, leading to secondary bacterial infection. Sticktight fleas can occur at densities of over 100 individuals per bird, all concentrated on the head. As a result, infestation of poultry may reduce growth and egg production. Severe infestation can lead to anaemia. Ocular

ulceration, caused by self-trauma, may result in blindness and starvation. The skin over the nodules often becomes ulcerated, and young birds may be killed by heavy infections.

Sticktight fleas may become abundant in poultry yards and adjacent buildings. They are potentially able to transmit the plague and murine typhus but since the females spend most of their lives attached to a single host, they are not considered to be significant vectors of disease.

Clinical signs: Signs include restlessness and scratching of affected areas. The bites may be visible on the skin. Allergic dermatitis may be seen, but should be differentiated from other similar conditions such as sarcoptic mange.**Diagnosis:** Diagnosis is not easy as adults may leave the host and eggs and larvae are difficult to find. Poultry sometimes have clusters of these fleas around the eyes, comb, wattles and other bare spots. These dark-brown fleas have their heads embedded in the host's flesh and cannot be brushed off. Typically, on dogs and cats, sticktight fleas will be found around the margin of the outer ear or occasionally between the toe pads.**Epidemiology:** These fleas are not host-specific and may attack any available mammal or bird for a blood meal. As they are able to survive off the host, transmission can occur from the bedding and housing. Primarily important as a parasite of birds, the adult sticktight flea is an especially serious pest of chickens. However, it may also be found on humans, rats, cats, dogs, horses and larger insectivores. Infestations on dogs may be persistent if they are continually exposed to a source of infestation, and fleas are found on the poorly haired areas of the ventrum, scrotum, interdigital and periorbital skin and around the pinnae of the ears.**Treatment:** Sticktight fleas can be removed with tweezers by grasping and pulling firmly. An antibiotic ointment should be applied to the area to prevent infection. If fleas are too numerous to remove individually, a flea product registered for on-animal use should be applied according to label instructions. Several organophosphate, carbamate and pyrethrin-based insecticides are effective when applied as a solution.**Control:** Should sticktight fleas become established in a poultry house, drastic measures may have to be adopted to get rid of them. All litter should be removed and burnt and the poultry house sprayed with an insecticide.***Ceratophyllus gallinae*****Common name:** European chicken flea**Predilection site:** Skin**Class:** Insecta**Order:** Siphonaptera**Family:** Ceratophyllidae**Description:** Adults of *Ceratophyllus gallinae* are typically 2–2.5 mm long with no antennal fossae. Eyes are present. There is a pronotal comb, carrying more than 24 teeth, while the genal comb is absent (see Fig. 3.73). There is a lateral row of four to six bristles on the inner surface of the hind femur and there are no spines on the basal section of the legs.

Hosts: Poultry, wild birds, dog, cat, humans.

Geographical distribution: Found predominantly in the Old World but has been introduced into southeastern Canada and northeastern USA.

Pathogenesis: *Ceratophyllus gallinae* is the commonest flea of domestic poultry. However, it is not considered to be an important vector of disease. Feeding activity may cause irritation, restlessness and, with heavy infestations, anaemia.

Clinical signs: Symptoms include restlessness and scratching of affected areas. The bites may be visible on the skin. Allergic dermatitis may be seen, but should be differentiated from other similar conditions such as sarcoptic mange.

Diagnosis: Diagnosis is not easy as adults may leave the host and eggs and larvae are difficult to find.

Epidemiology: These fleas are not host-specific and may attack any available mammal or bird for a blood meal. As they are able to survive off the host, transmission can occur from the bedding and housing. This flea is highly mobile on the host and can be especially common in host nesting material. It will feed readily on humans and domestic pets, and is often acquired in the handling of poultry and from injured wild birds brought into houses. It has also been known to migrate into rooms from nests under adjacent eaves. When such nests are removed they should be incinerated, otherwise the hungry fleas may parasitise domestic pets and humans. In wild birds, flea reproduction and feeding activity is synchronised with the breeding season of the birds; in domestic chickens, flea activity may continue all year round.

Notes: The European chicken flea, *Ceratophyllus gallinae*, is a very common flea of poultry and also infests more than 75 species of wild bird and some mammals. In Europe, the vast majority of its hosts are hole-nesting tits, particularly great tits and blue tits. This species originated in Europe and has spread with poultry operations round the world. It is difficult to eradicate, as it is able to feed on many different species and is highly adaptable.

Tunga penetrans

Common name: Chigger, jigger, chigoe, bicho do pé or sand flea

Predilection site: Skin

Class: Insecta

Order: Siphonaptera

Family: Pulicidae

Description: *Tunga penetrans* has no combs and no spiniform bristles on the metathoracic coxae. The head is angular and has an acute frontal angle. The thorax is short and reddish-brown. The female is about 1 mm long before a blood meal but may increase to a length of up to 7 mm when gravid. The male flea is smaller, about 0.5 mm long, and never embeds in the host.

Hosts: Humans, primates and pigs. In addition, reservoir hosts include cattle, sheep, horses, mules, rats, mice, dogs, and other wild animals.

Geographical distribution: Parts of Africa, Asia and North and South America. The sand flea, jigger or chigoe, is an important parasite of humans in the Neotropical and Afro-tropical regions.

Pathogenesis: Once *T. penetrans* becomes engorged with blood, its presence causes great pain, and may produce inflammation and localised ulcers. Tetanus and gangrene may result from secondary infections. Intense local irritation and pruritus are also symptomatic of more minor infestations.

Tunga penetrans may also pose significant problems in dogs, particularly in the interdigital spaces, under the pads and the scrotum, but infestation tends to be highly localised. The presence of a number of adult *T. penetrans* in the paws can be crippling.

The damage to the skin can facilitate the entry of other pathogens leading to secondary infection and ulceration.

Clinical signs: The presence of the female flea can cause extreme itching, pain and inflammation, and secondary infections may occur. This flea occurs mainly on the feet of humans, causing severe irritation. In pigs the main sites of attachment are the feet and scrotum, but these animals tolerate the infection with no signs of distress.

Diagnosis: The swelling produced by the female is easily visible and often surrounded by eggs. The nodule (usually on the foot in humans) slowly enlarges over a few weeks in a patient who has recently been in an endemic area. The nodule can range from 4 to 10 mm in diameter. Sometimes, a serosanguineous exudate oozes from the central opening.

Epidemiology: The main habitat is warm dry soil and sand of beaches, stables and stock farms. On contact, the fleas invade unprotected skin. The most common site of involvement is the feet (interdigital skin and subungual area). The flea has limited jumping ability.

Treatment: Reported topical treatments in humans include cryotherapy or electro-desiccation of the nodules. Application of formaldehyde, chloroform or dichlorodiphenyltrichloroethane (DDT) to the infested skin has been used. Occlusive petroleum suffocates the organism. These treatments do not remove the flea from the skin, and they do not result in quick relief from painful lesions. The flea may also be gently removed with a needle or a forceps. Surgical removal of the fleas is the recommended treatment. A number of surgical treatment methods are available. The flea can be removed from its cavity with sterile instruments, but this is more difficult when the flea is engorged. The orifice needs to be enlarged, and the entire nodule should be excised. An antibiotic ointment may be applied, along with systemic antibiotic therapy when indicated. Aggressive treatment of secondary infection and tetanus prophylaxis are important. In dogs, footbathing with 0.2% trichlorphon or metrifphonate has been shown to be effective, as has subcutaneous injection of ivermectin (0.2 mg/kg body weight).

Control: Tungiosis can be controlled by treating infested areas with pesticides (malathion and methoprene have been used successfully) and treating infected reservoir hosts.

TICKS

HARD TICKS

Hard ticks belonging to the family Ixodidae are relatively large ticks, between 2 and 20 mm in length, and flattened dorsoventrally. They have a sclerotised dorsal plate known as a scutum (see Fig. 3.110), which extends over the whole dorsal surface of the male, but covers

only a small area behind the gnathosoma in the larva, nymph or female. Other distinguishing features are a series of grooves on the scutum and body and, in some species, festoons on the posterior border of the body (see Figs 3.110 and 3.112). 'Ornate' ticks have coloured enamel-like areas on the body (see Fig. 17.24).

The hard ticks are temporary parasites and most species spend relatively short periods on the host and have developed a variety of complex life cycles, with the number of hosts to which they attach during their parasitic life cycle varying from one to three. Most tick species have a three-host life cycle. For a relatively small number of ixodid ticks (about 50 species) that inhabit areas where hosts are scarce and in which lengthy seasonal periods of unfavourable climate occur, two- and one-host feeding strategies have evolved.

Clinical signs: There are no obvious signs of tick infestation other than the presence of the parasites and the local skin reactions to their bites. Ticks are also important vectors of protozoal, bacterial, viral and rickettsial diseases.

Diagnosis: The adult ticks, particularly the engorged females, are easily seen on the skin, the predilection sites being the face, ears, axilla and inguinal region. Usually, small inflamed nodules are also seen in these areas. Ticks may be collected from the host or directly from the environment and microscopic examination used to identify individual species.

Pathology: The local reaction to tick bites varies considerably; commonly small granulomatous reactions may form at the site of tick bites, consisting of a mixed inflammatory cell response with fibrosis.

Epidemiology: The distribution of ticks in a temperate climate with frequent and non-seasonal rainfall is closely linked with the availability of a microenvironment with a high relative humidity, such as occurs in the mat which forms under the surface of rough grazing. In contrast, in tropical grazing areas the grass cover on pastures is discontinuous and often interspersed with bare or eroded patches. Where suitable grass cover does exist it has been generally accepted, since temperatures are suitable for development throughout a large part of the year, that the distribution of ticks is mainly governed by rainfall and, with the exception of *Hyalomma* spp., a mean annual rainfall of more than 60 cm is required for survival.

However, recent studies have shown that the factors underlying the maintenance of the necessary microclimate with a high relative humidity are rather more complex, and depend on the transpiration of plant leaves. As long as this continues, adequate humidity is maintained in the microclimate despite the dryness of the general environment. However, when the rate of evaporation increases beyond a certain level, the stomata on the leaves close, transpiration ceases and the low humidity created in the microclimate rapidly becomes lethal to the ticks.

In the field, the stability of the microclimate is dependent on factors such as the quantity of herbage or plant debris and the grass species. The various genera of ticks have different thresholds of temperature and humidity within which they are active and feed, and these thresholds govern their distribution. Generally, ticks are most active during the warm season provided there is sufficient rainfall, but in some species the larval and nymphal stages are also active in milder weather. This affects the duration and timing of control programmes.

Treatment: The control of ixodid ticks is largely based on the use of chemical acaricides applied either by total immersion in a dipping

bath or in the form of a spray, shower, spot-on or slow-release ear tags. A wide variety of formulations of organophosphate (e.g. malathion, chlorpyrifos, fenthion, dichlorvos, cythoate, diazinon, propetamphos, phosmet) and pyrethroid insecticides (e.g. permethrin, deltamethrin) are available for application as sprays, dips, spot-on or showers. Macrocytic lactones or closantel given by the parenteral route have also been shown to be a useful aid in control of ticks. Where severely parasitised animals require individual treatment, special formulations of acaricides suspended in a greasy base may be applied to affected areas.

In companion animals, topical acaricidal compounds such as fipronil (phenylpyrazole), imidacloprid (chloronicotiny), selamectin (macrocytic lactone), amitraz (formamidine), afoxolaner and fluralaner (isoxazolines), and the organophosphates (e.g. malathion, ronnel, chlorpyrifos, fenthion, dichlorvos, cythoate, diazinon, propetamphos, phosmet) and carbamates can be used to kill ticks on the host. Pyrethroids (e.g. permethrin, deltamethrin) should not be used on cats.

Control: The long-term control of three-host ticks is geared to the period required for the adult female stage to become fully engorged, which varies from 4 to 10 days according to the species. If an animal is treated with an acaricide which has a residual effect of, say, 3 days, it will be at least 7 days before any fully engorged female reappears following treatment (i.e. 3 days residual effect plus a minimum of 4 days for engorgement). Weekly treatment during the tick season should therefore kill the adult female ticks before they are fully engorged, except in cases of very severe challenge when the treatment interval has to be reduced to 4 or 5 days.

Theoretically, weekly treatment should also control the larvae and nymphs, but in several areas the peak infestations of larvae and nymphs occur at different seasons to the adult females and the duration of the treatment season has to be extended.

Since many ticks occur on less accessible parts of the body, such as the anus, vulva, groin, scrotum, udder and ear, care must be exercised to ensure that the acaricide is properly applied.

Traditional control methods such as burning of cattle pastures are still used in some areas and are generally practised during a dry period before rains, when ticks are inactive. This technique is still a most useful one in extensive range conditions, and provided it is used after seeding of the grasses has taken place, regeneration of the pastures will rapidly occur following the onset of rains. Cultivation of land and, in some areas, improved drainage help to reduce the prevalence of tick populations and can be used where more intensive systems of agriculture prevail. Pasture 'spelling', where domestic livestock are removed from pastures for a period of time, has been used in semi-extensive or extensive areas, but often has the disadvantage that ticks can still obtain blood from a wide variety of other hosts.

Ixodes

Ixodes is the largest genus in the family Ixodidae, with about 250 species. They are small inornate ticks that do not have eyes or festoons. The mouthparts are long and are longer in the female than male (Fig. 17.17). The fourth segment of the palps is greatly reduced and bears chemoreceptor sensilla. The second segment of the palps may be restricted at the base, creating a gap between the palp and chelicerae (see Fig. 3.114a). Males have several ventral plates which

Fig. 17.17 Unfed female *Ixodes ricinus*. Note the relatively long mouthparts.

almost cover the ventral surface. *Ixodes* can be distinguished from other ixodid ticks by the anterior position of the anal groove (see Fig. 3.117). In other genera of the Ixodidae the anal groove is either absent or is posterior to the anus.

Ixodes ricinus

Common name: Sheep tick, castor bean tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: The engorged adult female is light grey, up to 1 cm in length and bean-shaped (Fig. 17.18; see also Fig. 3.115b). However, when engorged the legs are not visible when viewed from above. Adult male *Ixodes ricinus* are only 2–3 mm long, and because they take smaller blood meals than females, the four pairs of legs are readily visible from above (Fig. 17.18).

Nymphs resemble the adults but are less than 2 mm in length (Fig. 17.19). The larvae, often described as ‘seed ticks’ or ‘pepper ticks’, are less than 1 mm in length and usually pale brown or yellowish in colour.

In *Ixodes ricinus*, as compared with *I. canisuga* and *I. hexagonus*, the tarsi are tapered (see Fig. 3.116a) and not humped and the posterior internal angle of the first coxa bears a spur that overlaps the second coxa (see Fig. 3.117a).

Hosts: Sheep, cattle, goat, but can feed on all mammals and birds; juvenile stages may also feed on lizards.

Geographical distribution: Temperate areas of Europe, Australia, South Africa, Tunisia, Algeria and Asia. It is more common in areas of rough grazing moorland and woodland. Although recorded, this species has never become established in North America.

Pathogenesis: *Ixodes* ticks ingest blood and, occasionally, heavy infestations can cause anaemia. Tick bites may damage the host at the site of attachment causing local injury, which may predispose to secondary bacterial infection. The lesions caused during feeding

Fig. 17.18 *Ixodes ricinus*: engorged female with two males (top).

Fig. 17.19 *Ixodes ricinus* nymphs.

may predispose to myiasis. Also, at slaughter the value of the hide or fleece may be reduced.

Most significant of all, this tick transmits a range of pathogens. In western Europe, in cattle it transmits *Babesia divergens* and *B. bovis*, the causes of redwater fever, and *Anaplasma marginale*, the cause of anaplasmosis. In sheep and cattle, it transmits the virus that causes louping-ill and the rickettsia responsible for tick-borne fever. It is also associated with tick pyaemia, caused by *Staphylococcus aureus*, in lambs in Britain and Norway.

Ixodid ticks also transmit *Borrelia burgdorferi*, the spirochaete responsible for Lyme disease in humans. *Ixodes ricinus* has been reported to cause tick paralysis and act as a vector for Czechoslovakian encephalitis, Russian spring–summer encephalitis and *Coxiella burnetii*. This tick may also transmit Bukhovinian haemorrhagic fever.

Ixodes canisuga

Common name: Dog tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: *Ixodes canisuga* is an inornate tick, without festoons or eyes. The palps are long and the ventral surface of the male is almost entirely covered with a series of plates. An anal groove is present anterior to the anus. The engorged female is light grey, up to 10 mm in length and bean-shaped, with four pairs of legs. The males are only 2–3 mm long, and the four pairs of legs are readily visible. *Ixodes canisuga* can be differentiated from *I. ricinus* by the presence of humped tarsi (see Fig. 3.116c) and the smaller size of the spur on the posterior internal angle of the first coxa (see Fig. 3.117c). Nymphs resemble the adults and also have four pairs of legs, but are less than 2.0 mm in size. The larvae ('pepper ticks') are less than 1 mm, usually yellowish in colour and have only three pairs of legs.

Hosts: Mammals, including dogs, foxes, sheep, horses and mules.

Geographical distribution: Throughout Europe, as far east as Russia.

Pathogenesis: Infestation may cause dermatitis, pruritus, alopecia and anaemia, but it is not an important vector of disease. It may be a particular problem in packs of dogs in kennels.

Epidemiology: This species, sometimes called the British dog tick, has been found in a variety of hosts. It is particularly recognised as a problem in kennels, where the tick is capable of survival in crevices and cracks in the floors and walls.

Ixodes hexagonus

Common name: Hedgehog tick

Predilection site: Head, ears

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: Adults are red–brown, with legs that appear somewhat banded in colour. The scutum is broadly hexagonal (hence the name 'hexagonus') and, like *I. ricinus*, the coxae of the first pair of legs bear a spur. However, the spur is smaller than in *I. ricinus* and does not overlap the coxa of the second pair of legs (see Fig. 3.117b). When engorged the female may be up to 8 mm in length. Males are about 3.5–4 mm in length. The tarsi are long (0.8 mm in the

female and 0.5 mm in the male) and sharply humped apically (see Fig. 3.116b).

Hosts: Hedgehog; other mammals, including dogs, cats, foxes, sheep, horse, moles.

Geographical distribution: Europe and northwest Africa.

Pathogenesis: On dogs and cats, adult females usually attach themselves behind the ears, on the jaws, neck and groin, causing localised dermatitis and the risk of wound infection. These ticks are often found to be responsible when dogs become repeatedly infested with ticks, particularly around the head area. It may also become a more significant pest in places where *I. ricinus* is absent. *Ixodes hexagonus* is a biological vector of *Borrelia* spp. and tick-borne encephalitis.

Epidemiology: The main host is the European hedgehog, and the movement of this host to urbanised areas may increase the risk of both people and their animals being exposed to infectious diseases carried by *I. hexagonus*. The ticks may be active from early spring to late autumn, but are probably most active during April and May. This species inhabits sheltered habitats such as burrows and kennels and may infest pets in large numbers when they are exposed.

Ixodes holocyclus

Common name: Paralysis tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: The engorged adult female is light grey, up to 1 cm in length, bean-shaped and has four pairs of legs. The males are only 2–3 mm long, and the four pairs of legs are readily visible. The palps are long and the ventral surface of the adult male is almost entirely covered with a series of plates. An anal groove is present anterior to the anus. Nymphs resemble the adults but are less than 2 mm in size, while the larvae are less than 1 mm in length and usually are yellowish in colour.

Hosts: Cattle, sheep, goat, dog, cat and other mammals and birds.

Geographical distribution: Australia

Pathogenesis: *Ixodes holocyclus* is the main cause of tick paralysis in Australia. Its paralysing toxin has been reported to affect at least 20,000 domestic animals annually. Although infestations usually consist of relatively few individual ticks, *I. holocyclus* infestations can kill cattle, particularly calves, and small domestic animals. Fifty larvae or five nymphs will kill a 40g rat, and larger numbers of either can cause paralysis in dogs and cats.

Generally, only the adult stage infests cattle, with the worst outbreaks in late winter, spring and summer. *Ixodes holocyclus* is also a vector for *Coxiella burnetii* (Q fever) and *Rickettsia australis* (Queensland tick typhus).

Epidemiology: This species is most commonly found among low leafy vegetation since this protects it against sun and wind exposure and maintains the high humidity required for development.

Ixodes persulcatus**Common name:** Taiga tick**Predilection site:** Skin**Class:** Arachnida**Order:** Ixodida**Family:** Ixodidae

Description: The taiga tick, *Ixodes persulcatus*, is morphologically very similar to *I. ricinus*; it is an inornate red–brown tick, without festoons or eyes. The palps are long and the ventral surface of the male is almost entirely covered with a series of plates. The engorged adult female is light grey and up to 10 mm in length. The major difference is that the female adult *I. persulcatus* has a straight or wavy genital opening rather than arched, as in *I. ricinus*.

Hosts: Sheep, cattle, goat, horse, dog, other mammals, birds and human.

Geographical distribution: It has a more easterly distribution than *Ixodes ricinus*, being widespread throughout eastern Europe, Russia and as far east as Japan.

Pathogenesis: *Ixodes persulcatus* is a major vector of the human diseases Russian spring–summer encephalitis virus and Lyme borreliosis.

Epidemiology: Taiga ticks may be dispersed by migrating birds.

Ixodes rubicundus**Common name:** Karoo paralysis tick**Predilection site:** Skin, neck, chest and belly**Class:** Arachnida**Order:** Ixodida**Family:** Ixodidae

Description: Adult ticks have a small internal spine on coxa I and a posterior flap of weakly sclerotized cuticle on coxae I–III. In the male, the ventral ridge on the basis capituli has a central and two smaller lateral lobes and there are two large basal hypostomal teeth. The female scutum has a narrowly rounded posterior margin and flattened oval porose areas.

Hosts: Domestic livestock and wild ungulates.

Geographical distribution: Southern Africa, particularly the Karrooveld.

Pathogenesis: *Ixodes rubicundus*, the Karoo paralysis tick, parasitises domestic stock and wild ungulates in South Africa and may lead to serious losses. Ticks may cause damage at the site of attachment causing local injury, which may predispose to secondary bacterial infection. The adult tick produces a toxin that causes paralysis in sheep and goats. Affected animals become paralysed and some may show signs of incoordination and stumbling. Unless ticks are removed, the animal will remain paralysed and die within days. Most affected animals recover within 24–48 hours once the ticks have been removed or animals have been dipped.

Ixodes scapularis**Synonym:** *Ixodes dammini***Common name:** Shoulder tick, black-legged tick**Predilection site:** Skin**Class:** Arachnida**Order:** Ixodida**Family:** Ixodidae

Description: The identifying characteristics are the black legs, black scutum and long black capitulum.

Hosts: Deer; all mammals and birds.

Geographical distribution: North America, particularly in and around wooded areas.

Pathogenesis: *Ixodes scapularis* inflicts a very painful bite. Nymphal and adult stages of this tick are the most common vector for Lyme disease in North America. They are also implicated in the transmission of *Francisella tularensis*. These ticks are major vectors for the transmission of human babesiosis and human granulocytic ehrlichiosis and are responsible for the transmission of anaplasmosis and piroplasmosis.

Epidemiology: *Ixodes scapularis* requires a high relative humidity to survive, and its patterns of feeding activity reflect this requirement. With feeding restricted to times of year when conditions of temperature and humidity are appropriate, distinct restricted seasonal periods of activity result, usually in spring and autumn. As a result of its requirement for high humidity, in general it is associated with areas of deciduous woodland containing small mammals and deer.

Ixodes pacificus**Common name:** Western black-legged tick**Predilection site:** Skin**Class:** Arachnida**Order:** Ixodida**Family:** Ixodidae

Description: A very similar species to *Ixodes scapularis*. Adult ticks are red–brown in colour and about 3 mm in size. Larvae and nymphs are smaller and paler in colour.

Hosts: Rodents, lizards and large mammals, such as horses, deer and dogs.

Geographical distribution: Commonly found in the western USA and British Columbia.

Pathogenesis: It is known to be a vector of Lyme disease and the rickettsia responsible for equine granulocytic ehrlichiosis.

Epidemiology: It is found in habitats with forest, north coastal scrub, high brush and open grasslands.

Ixodes pilosus**Common name:** Russet tick, bush tick**Predilection site:** Skin

Table 17.1 Other species of *Ixodes*.

| Species | Distribution | Comments |
|------------------------|--------------------------|--------------------------------|
| <i>Ixodes angustus</i> | Northeast USA | |
| <i>Ixodes cookei</i> | USA, southeastern Canada | Found on cattle, dogs and cats |
| <i>Ixodes kingi</i> | Western USA | Found on cattle, dogs and cats |
| <i>Ixodes rugosus</i> | Western USA | Rotund tick |
| <i>Ixodes sculptus</i> | Northeast USA | |
| <i>Ixodes muris</i> | USA | Mouse tick |
| <i>Ixodes texanus</i> | Northern USA, Canada | |

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: Cattle, sheep, goats, horses, dogs, cats and wild ungulates.

Life cycle: This is a three-host tick species.

Geographical distribution: Most areas of South Africa.

Pathogenesis: The feeding activity of this will cause blood loss, local dermatitis and may result in tick paralysis.

Several other species of *Ixodes* have been reported in North America and have been found mainly on dogs (Table 17.1).

Dermacentor

Ticks of the genus *Dermacentor* are medium-sized to large ticks, usually with ornate patterning. The palps and mouthparts are short and the basis capituli is rectangular (see Fig. 3.114c). Festoons and eyes are present. The coxa of the first pair of legs is divided into two sections in both sexes. Coxae progressively increase in size from I to IV. The males lack ventral plates and, in the adult male, the coxa of the fourth pair of legs is greatly enlarged.

Most species of *Dermacentor* are three-host ticks, but a few are one-host ticks. The genus is small with about 30 species, most of which are found in the New World. Several of the species are directly associated with Rocky Mountain spotted fever, Q fever, tularemia and Colorado tick fever. The salivary secretions of some species may produce tick paralysis.

Dermacentor andersoni

Synonym: *Dermacentor venustus*

Common name: Rocky Mountain wood tick

Predilection site: All over the body but especially the axilla, inguinal region, face and ears.

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description, adults: *Dermacentor andersoni* is an ornate tick, with a base colour of brown and a grey pattern (see Fig. 3.118). Males are about 2–6 mm in length and females about 3–5 mm in length when unfed and 10–11 mm in length when engorged. The legs are patterned in the same manner as the body. The coxae of the first pair of legs have well-developed external and internal spurs.

Hosts: Immature stages: small rodents. Adults: wild and domestic herbivores.

Geographical distribution: Widely distributed throughout the western and central parts of North America from Mexico as far north as British Columbia.

Pathogenesis: High infestation levels may cause anaemia. *Dermacentor andersoni* may cause tick paralysis, particularly in calves, and may be responsible for the transmission of bovine anaplasmosis, caused by *Anaplasma marginale*. It also transmits the Colorado tick fever virus, and the bacteria that cause tularaemia. *Dermacentor andersoni* is the chief vector of *Rickettsia rickettsii* (Rocky Mountain spotted fever) in western USA.

Epidemiology: Adult numbers peak in May, then decline by July. Larvae and nymphs appear later and have usually disappeared by late summer. This species is particularly common among damp, grassy, brush-covered areas, since these attract both the small mammals required by the immature stages and the large herbivorous mammals required by the adults. Infection occurs when host animals brush against vegetation harbouring tick larvae.

Dermacentor variabilis

Common name: American dog tick, wood tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: These are ornate, pale brown and grey ticks with eyes and festoons present (see Fig. 3.119). Adult males are about 3–4 mm in length and adult females about 4 mm in length when unfed and 15 mm in length when engorged. *Dermacentor variabilis* can be distinguished by the absence of a posterodorsal spur on palp segment II.

Hosts: Dog, horse, cattle, human. This tick will feed on many species of domestic and wild mammals.

Geographical distribution: North America

Pathogenesis: *Dermacentor variabilis* is an important parasite of wild and domestic carnivores. The feeding activity of *D. variabilis* may cause tick paralysis in dogs. In cattle it may transmit bovine anaplasmosis. It is also an important vector of *Rickettsia rickettsii* (Rocky Mountain spotted fever) in the USA and is able to transmit the bacteria which causes tularaemia (hunter's disease). It also transmits St Louis encephalitis virus and several studies have shown that it may carry the Lyme disease bacterium *Borrelia burgdorferi*.

Epidemiology: The larval and nymphal stages feed on wild rodents, particularly the short-tailed meadow mouse (*Microtus* spp.), while the preferred hosts of adults are larger mammals, particularly wild and domestic carnivores.

Dermacentor albipictus

Common name: Winter tick or moose tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: The adults are ornately patterned ticks with eyes and festoons present. The basis capituli is rectangular and the palps short. The males lack ventral plates and the coxae of the fourth pair of legs are enlarged. In the adults of both sexes the coxa of the first pair of legs has an enlarged spur (bidentate), and in the male the coxae increase in size from I to IV.

Hosts: The preferred host is the moose but they will also feed on a wide variety of domestic and wild mammals, including horses, cattle and humans.

Geographical distribution: Northern USA and Canada, particularly upland and mountainous areas.

Pathogenesis: *Dermacentor albipictus* may cause tick paralysis and is a vector of anaplasmosis, and possibly Rocky Mountain spotted fever. Heavy infestations with *D. albipictus* cause hair loss and a condition known as ‘ghost moose’ in northern parts of the USA. Heavy infection can occur in the long winter coats of mammals such as horses, deer, elk and moose, causing debilitation and anaemia, particularly when there are food shortages.

Epidemiology: This is a one-host species of tick. The larva, nymph and adult all attach to, and develop on, a single host. This species feeds only in winter, usually between October and March/April, on horses, deer and related large mammals. Under normal conditions this tick species produces one generation per year.

Dermacentor marginatus

Common name: Sheep tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: The engorged adult female may be up to 15 mm in length and the genital aperture forms a narrow ‘V’ shape.

Hosts: Adults feed largely on mammals: sheep, cattle, deer, dogs, humans, hares and hedgehogs. Nymphs and larvae feed on small mammals, insectivores and birds.

Geographical distribution: Morocco, Spain, Italy, southern France, Switzerland, western Germany, Poland, eastwards to central Asia.

Pathogenesis: This species is a vector for a wide range of diseases: in dogs, *Babesia canis*; in cattle, *Babesia divergens*; in sheep, *B. ovis*, *Theileria ovis* and *Anaplasma ovis*; in horses, *Babesia caballi*, *Theileria equi* and infectious encephalomyelitis; also *Coxiella burnetii* (Q fever), *Francisella tularensis* (tularemia), *Brucella* spp. and *Rickettsia conorii* (boutonneuse fever).

Dermacentor nitens

Common name: Tropical horse tick

Predilection site: Skin. The preferred site of attachment is the ear; however, it may also infest nasal passages and the mane, ventral abdomen and perianal area.

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: Male ticks are 2–4 mm long, inornate and appear yellowish-brown in colour. Females are 2–5 mm long.

Hosts: Horse, cattle, human, many domestic and wild mammals. Horses are the preferred host of this species.

Geographical distribution: Southern USA, Central and South America and the Caribbean.

Pathogenesis: Heavy infections may lead to suppuration of the ears, and bite wounds may predispose the host to oviposition by screw-worm flies. *Dermacentor nitens* is an important vector of *Babesia caballi*, resulting in equine babesiosis. It is able to transmit this pathogen transovarially to successive generations, and is important in the horse racing industry.

Epidemiology: This is a one-host tick species; the larva, nymph and adult all attach to, and develop on, a single host. Under favourable tropical conditions this tick species can produce several generations per year.

Dermacentor reticulatus

Synonym: *Dermacentor pictus*

Common name: Marsh tick, meadow tick or ornate cow tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: This species is an ornate tick with eyes and festoons present (see Fig. 3.120). Both sexes are white with variegated brown splashes (Fig. 17.20). The basis capituli is rectangular and the palps short. The adult female is 3.8–4.2 mm when unfed and 10 mm in length when engorged. The adult male is approximately 4.2–4.8 mm in length. An unfed nymph is approximately 1.4–1.8 mm in length.

Fig. 17.20 Male and female *Dermacentor reticulatus*: ornate tick with festoons.

Hosts: Sheep, cattle, dog, horse, pig, human. Nymphs and larvae feed on smaller mammals, such as insectivores and occasionally birds.

Geographical distribution: Europe (from the Atlantic coast to Kazakhstan) and Central Africa.

Pathogenesis: *Dermacentor reticulatus* is a vector for the transmission of a wide range of pathogens. It is particularly important as an ectoparasite of cattle and may be found along their backs in early spring. In cattle it is a vector for *Babesia divergens* (redwater), *B. ovis*, *Theileria ovis*, *Coxiella burnetii* (Q fever), *Francisella tularensis* (tularemia), *Brucella*, *Rickettsia conorii* (boutonneuse fever) and *Anaplasma ovis*. In horses it is a vector of *Babesia caballi*, *Theileria equi* and infectious encephalomyelitis of horses. In dogs it is a vector for *Babesia canis*.

Epidemiology: *Dermacentor reticulatus* is a three-host tick, and the life cycle can be completed in only 1–2 years, depending on environmental conditions. The species feeds once in each of the larval, nymphal and adult life-cycle stages, dropping from a host, moulting and then reacquiring a new host between feeds.

Dermacentor silvarum

Predilection site: Skin, all over the body but especially the axilla, inguinal region, face and ears.

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: Cattle, sheep, horses, dogs, humans.

Geographical distribution: Asia (central Siberia and northeastern China to Japan).

Pathogenesis: The salivary secretions of this species may also produce tick paralysis. *Dermacentor silvarum* is a vector for the transmission of Siberian tick typhus (*Rickettsia sibirica*) and also a vector of *Babesia bovis*, *B. caballi*, *Theileria equi*, *B. canis*, *Theileria ovis* and *Anaplasma ovis*.

Epidemiology: This is a three-host species, feeding on a different host in each of its life-cycle stages. Adult females and immature stages overwinter on the ground. However, some males may remain attached to the host during winter. Larvae and nymphs are active from spring to autumn, although there is a general peak in adult activity from early spring to summer with a second, lower peak in autumn. The development of *D. silvarum* from egg to adult may require as little as 45 days at 28°C and 50 days at 25°C. The threshold temperatures for larval and nymphal development are 8 and 10°C, respectively. The life cycle may be completed in 1 year or, more usually in most parts of its range, it is extended by one or more summer or winter diapause to 2–4 years.

Dermacentor nutalli

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Geographical distribution: Siberia, northern Pakistan, China, Mongolia.

Pathogenesis: *Dermacentor nutalli* is a vector of *Rickettsia sibirica*.

Dermacentor occidentalis

Common name: Pacific coast tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: Cattle, horse, other domestic animals and wild mammals.

Geographical distribution: Western USA (Sierra Nevada Mountains and the Pacific coast from Oregon to southern California).

Pathogenesis: *Dermacentor occidentalis* is a vector of anaplasmosis, Colorado tick fever, Q fever and tularemia and may cause tick paralysis.

Haemaphysalis

Ticks of the genus *Haemaphysalis* inhabit humid well-vegetated habitats in Eurasia and tropical Africa. They are three-host ticks, with the larvae and nymphs feeding on small mammals and birds and adults infesting larger mammals and, importantly, livestock. There are about 150 species, found largely in the Old World, with only two species found in the New World.

Most species of the genus are small, with short mouthparts and a rectangular basis capituli (see Fig. 3.114g). Ventral plates are not present in the male. Spiracular plates are rounded or oval in females and rounded or comma-shaped in males. Like *Ixodes* spp., these ticks lack eyes, but they differ in having festoons and a posterior anal groove.

Haemaphysalis punctata

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: Small inornate ticks with festoons; eyes absent (Fig. 17.21; see also Fig. 3.121). The palps and hypostome are short. The adults of both sexes are about 3 mm in length, the female reaching about 12 mm in length when engorged. However, sexual dimorphism is not pronounced. The basis capituli is rectangular, about twice as broad as long. The sensory palps are short and broad, with the second segment extending beyond the basis capituli. The anal groove is posterior to the anus. The coxae of the first pair of legs have a short blunt internal spur, which is also present on the coxae of the second and third pair of legs and which is enlarged and tapering on the coxae of the fourth pair of legs. In the male the spur may be as long as the coxa.

Hosts: Cattle, sheep, goat, horse, deer, wolf, bear, bat, birds, rabbit. The larvae and nymphs may also be found on birds, hedgehogs, rodents and reptiles, such as lizards and snakes.

Fig. 17.21 Female *Haemaphysalis punctata*: note short mouthparts.

Geographical distribution: Europe (including southern Scandinavia and Britain), central Asia and North Africa.

Pathogenesis: *Haemaphysalis punctata* is responsible for the transmission of *Babesia major* and *Babesia bigemina*, *Theileria mutans* (*T. buffeli/orientalis*), *Anaplasma marginale* and *A. centrale* in cattle. In sheep, it transmits *Babesia motasi* and the benign *Theileria ovis*. It has also been reported to cause tick paralysis. In addition to transmitting *Anaplasma* and *Babesia* spp., different *H. punctata* populations are infected by tick-borne encephalitis virus, Tribec virus, Bhanja virus and Crimean–Congo haemorrhagic fever virus.

Epidemiology: *Haemaphysalis punctata* is a three-host tick, feeding once in each of the larval, nymphal and adult life-cycle stages.

Haemaphysalis leachi

Common name: Yellow dog tick

Predilection site: Head and body

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: Inornate elongate ticks with 11 festoons; eyes absent.

Hosts: Dog, domestic and wild carnivores, small rodents and occasionally cattle.

Geographical distribution: Africa, Australia and Asia.

Pathogenesis: This species is responsible for the transmission of canine piroplasmiasis (*Babesia canis*) in dogs, tick-bite fever (*Rickettsia conorii*) and *Coxiella burnetii*.

Epidemiology: *Haemaphysalis leachi* is a three-host tick.

Haemaphysalis longicornis

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: Cattle. All mammals and birds.

Geographical distribution: Widely distributed in the Far East and Australasia.

Pathogenesis: The main result of infestation is tick worry. This lowers production in cattle and tick bites damage hides.

Epidemiology: A three-host tick species. The larvae and nymphs primarily feed on small mammals and birds while adults infest larger mammals.

Haemaphysalis spinigera

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: Adults will feed on monkeys, birds and cattle; immatures feed on small mammals such as shrews and humans.

Geographical distribution: Tropical evergreen/deciduous forests of southern and central India and Sri Lanka.

Pathogenesis: Transmits Kyasanur forest disease (KFD) virus, which affects monkeys and humans. KFD virus has also been isolated from other species of *Haemaphysalis*, *Dermacentor* and *Ixodes* ticks.

Epidemiology: This species is a three-host tick feeding once in each of the larval, nymphal and adult life-cycle stages. After each feed it drops from the host. The larvae and nymphs primarily feed on small mammals and birds while adults infest larger mammals. Cattle may be heavily parasitised by adults of *H. spinigera* and help to maintain the tick population, but neither cattle nor birds are thought to have any significant role in maintenance of the virus.

Haemaphysalis bispinosa

Common name: Bush tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: A variety of mammals; heavy infestations have been recorded on sheep and cattle.

Geographical distribution: Asia and Australasia, particularly problematic in coastal eastern Australia.

Pathogenesis: This species may act as a vector of *Babesia motasi* and *B. ovis* in sheep and goats, *Babesia equi* in horses and donkeys and *Babesia canis* and *Babesia gibsoni* in dogs.

Epidemiology: A three-host tick species.

Notes: Of interest is the suggestion that this tick may reproduce parthenogenetically.

Haemaphysalis concinna

Common name: Bush tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: A variety of mammals; particularly important as a parasite of sheep.

Geographical distribution: Eastern and central Europe, Russia east to China.

Pathogenesis: This species may act as a vector of bunyavirus, the causative agent of Bunya fever.

Epidemiology: A three-host tick species.

Haemaphysalis cinnabarina

Synonym: *Haemaphysalis sanguinolenta*

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: A variety of ruminants.

Geographical distribution: Africa, southern Europe, Asia east to Japan.

Pathogenesis: Anaplasmosis, Q-fever, babesiosis.

Epidemiology: A three-host tick species.

Haemaphysalis leporispalustris

Common name: Rabbit tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: Rabbits, snowshoe hare, birds, rarely feeds on humans.

Geographical distribution: North America, Canada.

Pathogenesis: This species is of limited veterinary or public health concern, but may act as a vector of the Lyme disease spirochaete *Borrelia burgdorferi*.

Epidemiology: A three-host tick species.

Rhipicephalus

The genus is composed of about 60 species, all of which were originally endemic to the Old World and, for the most part, distributed throughout sub-Saharan Africa. However, many species have now been introduced into a range of new habitats worldwide. They act as vectors of a number of disease pathogens. They infest a variety of mammals but seldom birds or reptiles. Most species are three-host ticks but some species of the genus are two-host ticks.

The basis capituli is hexagonal (see Fig. 3.114f) and, in the male, paired plates are found on each side of the anus. They are not ornate. Palps are short and eyes and festoons are usually present. Spiracular plates are comma-shaped. More detailed descriptions of some species are provided in chapter 3, however, the identification of more than the major species is beyond the scope of this text and interested readers will need to consult a relevant taxonomic specialist.

Rhipicephalus appendiculatus

Common name: Brown ear tick

Predilection site: Skin; ears

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: Adult male *R. appendiculatus* are brownish, reddish-brown or very dark, with reddish-brown legs. They vary from 1.8 to 4.4 mm in length. The scutal punctations are scattered and of moderate size; they are evenly dispersed in the centre, but few or none may be found beyond the lateral grooves and in the lateral fields. The cervical grooves are moderately reticulate or non-reticulate. The posteromedian and paramedian grooves are narrow and distinct. The adanal shields are long and have slightly rounded angles, but can be somewhat variable.

Adult female *R. appendiculatus* are also brown, reddish-brown or very dark. The punctations are small to moderate-sized and are similar to those found in the male. The scutum is approximately equal in length and width; its posterior margin is slightly tapering or abruptly rounded. The lateral grooves are short, poorly defined or absent. The cervical grooves are long and shallow and almost reach the posterolateral margins.

Hosts: Cattle, horse, sheep, goat, deer, antelope, dog, rodents. This species of tick will feed on a wide variety of mammals and birds.

Geographical distribution: Africa, south of the Sahara. It occurs particularly in areas with substantial rainfall and shrub cover and it is absent in deserts.

Pathogenesis: This tick is considered a major pest in areas where it is endemic. Heavy infestations on cattle can result in severe damage to the ears and toxemia (Fig. 17.22). The excess blood excreted by the ticks may attract flies leading to secondary myiasis. Tick bites may become infected with bacteria. Tick salivary fluids and salivary toxins can produce host reactions such as toxicosis (sweating sickness and tick paralysis). Heavy infestations can result in fatal toxemia and loss of resistance to other infections as well as severe damage to the host's ears, udder and tail. *Rhipicephalus appendiculatus* is a vector of East Coast fever (*Theileria parva*), *T. lawrencei*, Nairobi sheep disease virus, *Ehrlichia bovis*, *Hepatozoon canis*, *Rickettsia conorii* and Thogoto virus.

Fig. 17.22 Cattle ear infected with *Rhipicephalus appendiculatus*.

Epidemiology: This species is a three-host tick and mating takes place on the host. Adults and immatures feed in the ears of cattle and other livestock and seasonal activity is closely associated with temperature and rain periods. *Rhipicephalus appendiculatus* is more abundant in cool, shaded, shrubby or woody savannah with at least 60 cm of annual rainfall.

Control: Weekly dipping during the tick season should kill the adult female ticks before they are engorged, except in cases of very severe challenge when the dipping interval has to be reduced to 4 or 5 days. Dipping intervals of this latter frequency are also necessary for cattle infested with *R. appendiculatus* in areas where east coast fever is endemic so that the ticks are killed before the sporozoites of *T. parva* have time to develop to the infective stage in the salivary glands of the tick. Theoretically, weekly dipping should also control the larvae and nymphs, but in several areas the peak infestations of larvae and nymphs occur at different seasons to the adult females and the duration of the dipping season has to be extended.

Rhipicephalus bursa

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: Cattle, sheep, horse, dog. All mammals and birds.

Geographical distribution: Africa (south of the Sahara), southern Europe.

Pathogenesis: *Rhipicephalus bursa* is a major vector for the transmission of *Babesia bovis*, *Babesia ovis*, *Babesia motasi*, *Theileria equi*, *Babesia caballi*, *Theileria ovis*, *Anaplasma marginale*, *Anaplasma phagocytophilum*, *Coxiella burnetii*, and Nairobi sheep disease and Crimean–Congo haemorrhagic fever viruses.

Rhipicephalus capensis

Common name: Cape brown tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: Cattle, horse, sheep, goat, deer, antelope, dog. This species of tick will feed on a wide variety of mammals and birds.

Geographical distribution: Africa, south of the Sahara in Afro-tropical humid savannah or bush ecosystems, with temperatures under 30°C.

Pathogenesis: *Rhipicephalus capensis* is a major vector for the transmission of east coast fever (*Theileria parva*) and *Anaplasma marginale*.

Rhipicephalus evertsi

Common name: Red-legged tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: This species can be distinguished from other members of the genus by its red legs. It has a black scutum, which is densely pitted, and in the male leaves a red margin of the opisthosoma uncovered.

Hosts: Cattle, sheep, goat, horse, dog and other mammals and birds.

Geographical distribution: Africa, south of the Sahara.

Pathogenesis: *Rhipicephalus evertsi* is a major vector for the transmission of east coast fever (*Theileria parva*), redwater (*Babesia bigemina*) and *Theileria mutans* in cattle. It also transmits *Borrelia* in various animals, and biliary fever (*Theileria equi*) in horses.

Epidemiology: This is a two-host species of tick. The larvae and nymphs are commonly found in the ears or the inguinal region, while the adults are mainly found under the tail. Unfed larvae can survive for 7 months, while unfed adults can survive for 14 months.

Rhipicephalus sanguineus

Common name: Brown dog tick, kennel tick

Predilection site: On dogs, *R. sanguineus* is often found in the ears and between the toes. Immature stages prefer the hair of the neck.

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: This species is yellow, reddish or blackish-brown in colour and unfed adults may be 3–4.5 mm in length, although size is highly variable and engorged females may reach a length of 12 mm. The palps and hypostome are short and the basis capituli hexagonal dorsally (see Fig. 3.114f). The coxa of the first pair of legs has two spurs. The legs may become successively larger from the anterior

to the posterior pair. The tarsi of the fourth pair of legs possess a marked ventral tarsal hook. The anal groove encircles only the posterior half of the anus and then extends into a median groove. The males have adanal plates and accessory shields. The six-legged larvae are small and light brown in colour, while the eight-legged nymphs are reddish-brown in colour. Recent work has suggested that *Rhipicephalus sanguineus sensu lato* may represent a species complex of morphologically similar but genetically distinct types.

Hosts: Dog, other mammals and birds.

Geographical distribution: Worldwide. This species is believed to have originated in Africa but is now considered to be the most widely distributed tick species in the world.

Pathogenesis: *Rhipicephalus sanguineus* is primarily parasitic on dogs and is responsible for the transmission of *Babesia canis* and *Ehrlichia canis* and can also cause tick paralysis in the dog. There seems little doubt that it can also transmit many protozoal, viral and rickettsial infections of animals and humans. These include *Theileria equi* and *B. caballi* of equines, *Anaplasma marginale* in North America, *Hepatozoon canis* of dogs, *Coxiella burnetii*, *Rickettsia conorii*, *R. canis*, *R. rickettsii*, *Pasteurella tularensis*, *Borrelia hispanica* and the viruses that cause Nairobi sheep disease and other viral diseases of sheep in Africa. *Rhipicephalus sanguineus* is also a vector for East Coast fever (*Theileria parva*) among cattle, *Babesia perroncitoi* and *Babesia trautmanni* among pigs, and also transmits Rocky Mountain spotted fever in some areas of the USA and Mexico.

Rhipicephalus pulchellus

Common name: Ivory-ornamented tick

Predilection site: Ears and on the lower abdomen

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: Male ticks have a pattern of stripes of white enamel on a dark-brown background over their entire conscutum.

Hosts: Zebra; also infests livestock and game animals.

Life cycle: Adults and immatures generally infest the same host; however, immatures also feed on small mammals.

Geographical distribution: Africa, east of the Rift Valley from southern Ethiopia to Somalia and northeastern Tanzania.

Pathogenesis: This tick is a vector of *Babesia equi*, *Theileria* spp., *Trypanosoma theileri*, *Rickettsia conorii*, several *Bunyaviridae* (Crimean–Congo hemorrhagic fever virus, Nairobi sheep disease, kajiado, kismayo and dugbe viruses) and Barur virus.

Epidemiology: Found in savannah habitats with grass, bushes and scattered trees between 300 and 1300 m altitude where the annual rainfall is 250–600 mm. It feeds primarily during wet seasons.

Rhipicephalus simus

Predilection site: Ears and on the lower abdomen

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: Characterised by a shiny black, largely smooth scutum, which in the male has a row of large punctations in the deep marginal groove.

Hosts: Dogs, wild carnivores, livestock, game animals and humans. Immature stages feed on the common burrowing savannah rodents.

Geographical distribution: Central and Southern Africa.

Pathogenesis: It is believed to act as a vector of *Anaplasma marginale*, *A. centrale*, *Rickettsia conorii* and *Coxiella burnetii*. It can also cause tick paralysis in humans.

Notes: In eastern and northern Africa, *R. simus* is replaced by *R. praetextatus*, which ranges from central Tanzania to Egypt and which is a vector of Thogoto virus. West of the Nile, these species are replaced by *R. senegalensis* and *R. muhsamae*.

Rhipicephalus (Boophilus)

Ticks formerly believed to belong to the genus *Boophilus* are now generally considered to be a subgenus of *Rhipicephalus*, and the name *Rhipicephalus (Boophilus)* is used for the five species in the subgenus. They are often known as 'blue ticks', and are important as vectors of *Babesia* spp. and *Anaplasma marginale* in cattle in subtropical and tropical countries.

The palps and hypostome are short. The males have adanal or accessory ventral shields. The basis capituli is hexagonal dorsally. The mouthparts are short and the compressed palps are ridged dorsally and laterally (see Fig. 3.114e). Unfed adults may be only 2 or 3 mm long, reaching lengths of up to 12 mm when engorged.

Control: The basis of successful control is to prevent the development of the engorged female ticks and so limit the deposition of large numbers of eggs. Since species of *Boophilus* have a parasitic life cycle that requires 20 days before adult females become fully engorged, an animal dipped with an acaricide that has a residual effect of 3–4 days should not harbour engorged females for at least 24 days (i.e. 20 + 4). In theory, therefore, treatment every 21 days during the tick season should give good control, but since the nymphal stages appear to be less susceptible to most acaricides, a 12-day interval is often necessary between treatments at the beginning of the tick season. The avermectins/milbemycins may play an increasing role in the control of one-host ticks. A single acaricide treatment can destroy all the ticks on an animal, but will not prevent reinfestation. Hence, to effect long-term control, cattle that have had direct or presumed contact with *Boophilus* must be dipped at regular intervals for at least a year and the movement of animals into the affected farms or ranches strictly controlled.

Rhipicephalus (Boophilus) annulatus

Common name: Blue cattle tick, Texas cattle fever tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: Cattle, horse, goat, sheep, camel, dog. All mammals and birds.

Geographical distribution: Central and South America, Africa, Mexico, Commonwealth of Independent States (CIS, the former USSR), Africa, the Middle East, the Near East, the Mediterranean and Mexico. It has been largely eradicated from North America, but can be sometimes found in Texas or California, in a buffer quarantine zone along the Mexican border.

Pathogenesis: These ticks are the most important vectors of *Babesia* spp. and *Anaplasma marginale* in cattle in subtropical and tropical countries. *Boophilus annulatus* is an important vector of Texas cattle fever caused by *Babesia bigemina* and *B. bovis*. Skin irritation induces scratching and licking, sometimes leading to secondary infections. Severe infestations may cause anaemia.

Epidemiology: This is a one-host tick species. Two to four generations may occur per year, depending on climatic conditions; the entire life cycle of this species can be completed in 6 weeks.

Rhipicephalus (Boophilus) microplus

Common name: Tropical cattle tick, southern cattle tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: Adult ticks have a rectangular body with an oval scutum and pale cream legs. The nymphs of this species have an orange–brown scutum. The body is oval and wider at the front. The body colour is brown to blue–grey, with white at the front and sides.

Hosts: Cattle, sheep, goat, wild ungulates.

Geographical distribution: Asia, Australia, Mexico, Central and South America, West Indies, South Africa.

Pathogenesis: *Rhipicephalus (Boophilus) microplus* is widely distributed in the southern hemisphere and the southern states of the USA and is considered one of the most serious external parasites of Australian cattle. This tick species is an important vector for the transmission of *Babesia bigemina* and *Borrelia theileri* in South America, *Anaplasma marginale* in Australia and South America and *Coxiella burnetii* in Australia. Disease transmission can occur throughout all the parasite stages. Disease organisms may be passed transovarially to be transmitted by the next tick generation. Some disease organisms such as *Babesia* spp. may remain in the body of the ticks for as many as five generations even when fed on non-infected, non-susceptible hosts.

Epidemiology: This species is a one-host tick. Although present all year round, populations reach their peak in summer.

Rhipicephalus (Boophilus) calcaratus

Common name: Blue tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: Cattle, sheep, goat, wild ungulates.

Geographical distribution: Asia, North Africa.

Pathogenesis: *Rhipicephalus (Boophilus) calcaratus* transmits *B. bigemina* and *B. bovis* in North Africa and *Anaplasma marginale* in the northern Caucasus.

Rhipicephalus (Boophilus) decoloratus

Common name: Blue tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: The engorged females have slate–blue bodies with pale yellow legs.

Hosts: Cattle, horse, donkey, sheep, goat, dog, wild ungulates.

Geographical distribution: Africa

Pathogenesis: *Rhipicephalus (Boophilus) decoloratus* is a vector for *Babesia bigemina*, *B. ovis* and *Anaplasma marginale* in cattle. It also transmits spirochaetosis (*Borrelia theileri*) in cattle, horses, goats and sheep and *Babesia trautmanni* in pigs in East Africa.

Hyalomma

Hyalomma spp. are usually two-host ticks, though some species may use three hosts. They are most commonly found on the legs, udder and tail, or perianal region. There are about 20 species, found usually in semi-desert lowlands of central Asia, southern Europe and North Africa. They can survive exceptionally cold and dry conditions. Species of *Hyalomma* are medium-sized or large ticks, usually inornate, but with banded legs (giving them the common name of the ‘bont-legged’ ticks). The palps and hypostome are long (see Fig. 3.114b), eyes are present and festoons sometimes present. The males have ventral plates on each side of the anus.

Hyalomma anatolicum

Subspecies: *anatolicum*

Common name: Bont-legged tick

Predilection site: All over the body but especially the axilla, inguinal region, face and ears.

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: Cattle, horse; all mammals and birds.

Geographical distribution: Steppe and semi-desert environments from central Asia to Bangladesh, the Middle and Near East, Arabia, southeastern Europe and Africa. *Hyalomma anatolicum* is believed to exist as two subspecies: *Hyalomma anatolicum excavatum* in the central European and Asiatic parts of its range and *Hyalomma anatolicum anatolicum* elsewhere. Some authors have suggested that these should be viewed as separate species.

Pathogenesis: This genus is mainly responsible for tick toxicosis in parts of Africa and the Indian subcontinent. The 'toxin' produced by the adult tick causes a sweating sickness in ruminants and pigs characterised by widespread hyperaemia of the mucous membranes and a profuse moist eczema. This is a highly damaging tick species. *Hyalomma anatolicum* transmits *Theileria annulata*, *T. equi*, *Babesia caballi*, *Anaplasma marginale*, *Trypanosoma theileri* and at least five arboviruses.

Epidemiology: This species is a two- or three-host tick. Larvae acquire a host, feed and moult. Nymphs reattach to the same host soon after moulting. The larvae and nymphs feed on birds and small mammals, and the adults on ruminants and equines. When larvae and nymphs infest smaller mammals, birds or reptiles, the life cycle may become a three-host model.

Notes: A closely related species, *H. lusitanicum*, replaces *H. anatolicum* from central Italy to Portugal, Morocco and the Canary Islands. It is believed to be a vector of equine and bovine babesiosis.

Hyalomma excavatum

Synonym: *Hyalomma anatolicum excavatum*

Common name: Brown ear tick

Predilection site: Skin: all over the body but especially the axilla, inguinal region, face and ears.

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: Usually with banded legs; eyes are present and festoons sometimes present. The palps and hypostome are long. The gnathosoma and coxae are dark, reddish or black-brown. The males have adanal shields. The second segment of the palps is less than twice as long as the third segment, and the scutum has no pattern.

Hosts: This species feeds primarily on burrowing rodents, particularly as larvae and nymphs. However, adults will also feed on ruminants and equines, where this species may be of veterinary significance.

Geographical distribution: Africa, Asia Minor and southern Europe.

Pathogenesis: *Hyalomma excavatum* is a vector for the transmission of *Theileria annulata*, causing tropical theileriosis or Mediterranean coast fever in Bovidae species, and of equine and bovine babesiosis.

Hyalomma aegyptium

Common name: Tortoise tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: These are large brown ticks with eyes and long mouthparts. Females 5.5–20 mm; males 3–6 mm. Coxa I has a large divergent spur in females and a prominent, sharply pointed spur in males.

Hosts: Tortoises (*Testudo* spp.), lizards, dog, horse.

Geographical distribution: Southern Europe and southwest Asia.

Epidemiology: This species is a two-host tick. *Hyalomma aegyptium* is found mainly in arid areas, sheltering in burrows of its tortoise host.

Treatment and control: Individual ticks can be removed carefully with forceps.

Hyalomma detritum

Subspecies: *scupense*

Subspecies: *mauretanicum*

Synonyms: *Hyalomma volgense*, *Hyalomma uralense*

Common name: Bont-legged tick

Predilection site: Skin: all over the body but especially the axilla, inguinal region, face and ears.

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: Cattle, sheep, goat, horse. All mammals and birds.

Geographical distribution: Africa; *H.d. scupense* southwestern Russia and former USSR and southeastern Europe

Pathogenesis: This genus is responsible for tick toxicosis in parts of southern Africa. The 'toxin' produced by the adult tick causes a sweating sickness in ruminants and pigs characterised by widespread hyperaemia of the mucous membranes and a profuse moist eczema.

Epidemiology: This species is a mainly two-host tick. *H.d. scupense* is a one-host tick and is unusual in that it overwinters on the host.

Hyalomma dromedarii

Common name: Camel tick

Predilection site: All over the body but especially the axilla, inguinal region, face and ears.

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: *Hyalomma dromedarii* are usually inornate but with banded legs; eyes are present and festoons are sometimes present. The second segment of the palps is usually less than twice as long as the third segment, and the scutum has no pattern.

Host: Camels, but may also be of veterinary significance in ruminants and horses.

Geographical distribution: India to Africa.

Pathogenesis: Tick bites may cause damage at the site of attachment causing local injury, which may predispose to secondary bacterial infection. This genus is mainly responsible for tick toxicosis in parts of Africa and the Indian subcontinent. The ‘toxin’ produced by the adult tick causes a sweating sickness in ruminants and pigs characterised by widespread hyperaemia of the mucous membranes and a profuse moist eczema.

Clinical signs: There are no obvious signs of tick infestation other than the presence of the parasites and the local skin reactions to their bites.

Diagnosis: The adult ticks, particularly the engorged females, are easily seen on the skin. The main predilection sites are the face, ears, axilla and inguinal region.

Pathology: Small granulomatous reactions may form at the site of tick bites, consisting of a mixed inflammatory cell response with fibrosis.

Epidemiology: This is predominantly a two-host species of tick.

Notes: In some circumstances, a variable life cycle has been reported for *H. dromedarii*, with a three-host life cycle observed on sheep or cattle. It appears that the type of host, rearing conditions, density and age of the larvae may influence the life cycle adopted by this species.

Hyalomma marginatum

Subspecies: *marginatum*

Subspecies: *rufipes*

Subspecies: *turanicum*

Subspecies: *isaaci*

Common name: Mediterranean tick

Predilection site: Skin: all over the body but especially the axilla, inguinal region, face and ears.

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: Adult *Hyalomma marginatum* are usually inornate but with banded legs (Fig. 17.23). Eyes are present and festoons sometimes present. The palps and hypostome are long. The males have adanal shields. The second segment of the palps is less than twice as long as the third segment, and the scutum has no pattern.

Hosts: Adults parasitise wild herbivores and livestock (particularly equines and ruminants). Immature stages primarily parasitise small wild mammals, lizards and birds.

Geographical distribution: Africa, Asia Minor and southern Europe:

- *H. marginatum marginatum* (Caspian area of Iran and CIS to Portugal and northwestern Africa).

Fig. 17.23 *Hyalomma marginatum*.

- *H. marginatum rufipes* (south of the Sahara to South Africa, also Nile Valley and southern Arabia).
- *H. marginatum turanicum* (Pakistan, Iran, southern CIS, Arabia, parts of northeastern Africa).
- *H. marginatum isaaci* (Sri Lanka to southern Nepal, Pakistan, northern Afghanistan).

Pathogenesis: The salivary secretions of this species may also produce tick paralysis. *Hyalomma marginatum* subspecies are important vectors of disease: in dogs they transmit *Babesia canis*; in cattle *Babesia ovis*, *Rickettsia aeschlimanii* and Crimean–Congo haemorrhagic fever; and in horses *Babesia caballi* and *Theileria equi*.

Hyalomma truncatum

Common name: Bont-legged tick

Predilection site: Skin: all over the body but especially the axilla, inguinal region, face and ears.

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: Cattle, sheep, goat, pig, horse and other mammals and birds.

Geographical distribution: Africa

Pathogenesis: This species is responsible for tick toxicosis in parts of southern Africa. The ‘toxin’ produced by the adult tick causes a sweating sickness in ruminants and pigs characterised by widespread hyperaemia of the mucous membranes and a profuse moist eczema. This species can act as a vector of *Babesia caballi*, *Theileria equi*, *T. parva*, *T. annulata*, *T. dispar*, *Coxiella burnetii*, *Rickettsia bovis* and *R. conorii*.

Epidemiology: This species is a two-host tick.

Hyalomma impressum

Common name: Bont-legged tick

Predilection site: Skin: all over the body but especially the axilla, inguinal region, face and ears.

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Hosts: Immature stages feed on small mammals and birds. Adults feed on large mammals such as cattle and sheep.

Geographical distribution: Central and West Africa.

Pathogenesis: Of little known pathogenic significance, but may act as a vector of Crimean–Congo haemorrhagic fever virus.

Amblyomma

Members of this genus are large, often highly ornate ticks with long, often banded, legs. Unfed females may be up to 8 mm in length, and when engorged may reach 20 mm in length. They have long mouthparts (see Fig. 3.114d) with which they can inflict a deep painful bite that may become secondarily infected. There are about 100 species of *Amblyomma*, largely distributed in tropical and subtropical areas of Africa, but one important species is found in temperate North America.

Amblyomma americanum

Common name: Lone star tick

Predilection site: Ears, flanks, head and belly.

Description, adults: The lone star tick, *Amblyomma americanum*, is so called because of a single white spot on the scutum of the female (see Fig. 3.123). These are large, usually ornate, ticks whose legs have bands of colour. Eyes and festoons are present. The engorged female is up to 10 mm in length, bean-shaped and has four pairs of legs. The female is reddish-brown in colour, becoming light grey when engorged. On the scutum are two deep parallel cervical grooves and a large pale spot at its posterior margin. The male is small with two pale symmetrical spots near the hind margin of the body, a pale stripe at each side, and a short oblique pale stripe behind each eye. The males are only 2–3 mm in length, and because of the small idiosoma the four pairs of legs are readily visible.

Nymphs and larvae: Nymphs resemble the adults and also have four pairs of legs but are less than 2 mm in size, while the larvae ('pepper ticks') are less than 1 mm in length, usually yellowish in colour and have only three pairs of legs.

Hosts: Wild and domestic animals, particularly cattle, and birds. Larvae are most frequently found on wild small mammals.

Geographical distribution: Widely distributed throughout central and eastern USA.

Pathogenesis: This tick is most commonly found on the ears, flanks, head and belly. Tick infestation is irritating and painful, and infestation has been shown to reduce weight gain in cattle. Each female ingests 0.5–2.0 mL of host blood, so large numbers can cause anaemia. Bites may cause tick paralysis. *Amblyomma americanum* is an important vector of *Rickettsia rickettsii* (Rocky Mountain spotted fever) and *Francisella tularensis* (tularemia). It has also been implicated as a vector of *Borrelia burgdorferi* (Lyme disease), Q fever, canine ehrlichiosis and human monocytic ehrlichiosis.

Epidemiology: Larvae and nymphs feed on rodents, rabbits and ground-inhabiting birds. Adults feed on larger mammals such as deer, cattle, horses and sheep. Feeding larvae, nymphs and adults are active between early spring and late summer in distinct periods corresponding with the feeding activity of each stage. There is usually a single generation per year. This species is particularly common in wooded areas, where hosts become infected as they brush against vegetation harbouring ticks.

Amblyomma variegatum

Common name: Bont tick, variegated or tropical bont tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: Female *A. variegatum* are brown with a large pale patch on the posterior scutum while males are brightly ornamented with orange coloration and a dark-brown border to the idiosoma (Fig. 17.24). Both sexes of *A. variegatum* have hemispherical eyes.

Hosts: Mammals, particularly cattle.

Geographical distribution: Africa

Pathogenesis: *Amblyomma variegatum* transmit the important disease heartwater in cattle, caused by the rickettsia *Ehrlichia ruminantium*. It also transmits the Nairobi sheep disease virus and Q fever, caused by *Coxiella burnetii*.

Amblyomma cajennense

Common name: Cayenne tick

Predilection site: Skin: lower body surface, especially between the legs.

Class: Arachnida

Order: Ixodida

Fig. 17.24 Male *Amblyomma variegatum* (dorsal view).

Family: Ixodidae

Description: In adults the scutum is usually very ornate, lattice patterned often with bright multicoloured iridescent patterns. There may be pale central patches on the festoons.

Hosts: All mammals but most commonly horses.

Geographical distribution: South and Central America, southern USA and the Caribbean.

Pathogenesis: *Amblyomma cajennense* is an important tick in South America, the bites caused by this genus being particularly painful, probably due to the long mouthparts. In severe cases in South America this species has been reported to cause fever and weakness in cattle. The wounds created by this tick may create a suitable site for screw-worm myiasis associated with *Cochliomyia* spp. This species transmits spotted fever in South America as well as *Leptospira pomona*.

Amblyomma hebraeum

Common name: Bont tick

Description: *Amblyomma hebraeum* is an ornate tick with pink to orange ornamentation and pale rings on the legs.

Hosts: All mammals and birds.

Geographical distribution: Mainly Africa.

Pathogenesis: Bont ticks transmit the important disease heartwater in cattle, sheep and goats, caused by the rickettsia *Ehrlichia ruminantium*. This species also transmits *Rickettsia conorii*, the causative agent of boutonneuse fever.

Amblyomma gemma

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Ixodidae

Description: An ornate tick with large amounts of striking pink to orange ornamentation on the dorsal surface. The legs have pale-coloured rings.

Hosts: Mammals, particularly cattle, sheep and goats.

Geographical distribution: Africa, particularly Kenya.

Pathogenesis: *Amblyomma gemma* may be a vector for the transmission of heartwater in cattle, sheep and goats.

Amblyomma maculatum

Common name: Gulf coast tick

Predilection site: Skin, particularly the ears

Family: Ixodidae

Hosts: All mammals and birds.

Geographical distribution: Southern USA, in regions of high temperature and humidity.

Pathogenesis: The Gulf Coast tick, *A. maculatum*, is not known to transmit disease but does cause severe bites and painful swellings and has been associated with tick paralysis. The wounds created by this species may create a suitable site for screwworm myiasis associated with *Cochliomyia* spp.

Other *Amblyomma* tick species are shown in Table 17.2.

SOFT TICKS (ARGASIDAE)

In the soft ticks (Argasidae), the body is leathery and unsclerotised, with a textured surface. The cuticle in unfed ticks may be characteristically marked with grooves or folds. Argasids typically have a multi-host developmental cycle. The single larval instar feeds once, before moulting to become a first-stage nymph. There are between two and seven nymphal stages, each of which feed and then leave the host, before moulting to the next stage. Adults mate away from the host and feed several times. The adult female lays batches of 400–500 eggs after each feed. In contrast to the slow-feeding ixodids, argasid ticks feed for only a few minutes. Argasid soft ticks are more common in deserts or dry conditions. In contrast to the hard ticks, argasid soft ticks tend to live in close proximity to their hosts: in chicken coops, pigsties, pigeon lofts, bird's nests, animal burrows or dens. In these restricted and sheltered habitats the hazards associated with host finding are reduced and more frequent feeding becomes possible.

Clinical signs: The adult ticks, particularly the engorged females, are easily seen on the skin, commonly beneath the wings. Egg laying decreases and may stop altogether as a result of the infestation. However, the ticks only feed for a limited period. Inflammation and raised areas will be present from tick bites.

Table 17.2 Other *Amblyomma* tick species.

| Species | Hosts | Geographical distribution | Pathogenesis |
|----------------------------|---|--|--|
| <i>Amblyomma pomposum</i> | Mammals, particularly cattle, sheep and goats | Africa, mainly western Zambia, southern DRC and Angola | All three species are involved in the transmission of heartwater (<i>Ehrlichia ruminantium</i>) |
| <i>Amblyomma lepidum</i> | Sheep, goats, cattle | Sudan | |
| <i>Amblyomma astrion</i> | Buffalo, cattle | West and Central Africa | |
| <i>Amblyomma sparsum</i> | Reptiles, tortoise | Sub-Saharan Africa | These species are of particular importance because they are vectors of the rickettsia <i>Ehrlichia ruminantium</i> , the causal agent of heartwater in cattle, sheep, goats, deer and buffalo. Infected ticks may be present on imported reptiles, facilitating the transmission of disease into new areas such as the USA |
| <i>Amblyomma marmorium</i> | Tortoise tick | Sub-Saharan Africa | |

Diagnosis: The parasites may be found on the host or found in cracks of the woodwork and walls around the animal housing. Microscopic examination may then be used to identify individual species.

Pathology: Small granulomatous reactions may form at the site of tick bites, consisting of a mixed inflammatory cell response with fibrosis.

Treatment: Argasid ticks, which exist in and around animal housing, poultry houses and enclosures, can be controlled by application of an acaricide to their environment coupled with treatment of the population on the host. Environmental treatment of roosts and poultry houses may be effected using acaricidal sprays or emulsions containing organophosphates and pyrethroids. All niches and crevices in affected buildings should be sprayed, and nesting boxes and perches in poultry houses should also be painted with acaricides. At the same time as premises are treated, birds should be dusted with a suitable acaricide or, in the case of larger animals, sprayed or dipped. Treatment should be repeated at monthly intervals.

Control: In poultry houses, all new birds should be treated prior to introduction into an existing flock. Control of argasid ticks can be assisted by elimination of cracks in walls and perches, which provide shelter to the free-living stages.

Argas

Species of the genus *Argas* are usually dorsoventrally flattened, with definite margins, which can be seen even when the tick is engorged. The cuticle is wrinkled and leathery. Most species are nocturnal and are parasites of birds, bats, reptiles or, occasionally, small insectivorous mammals. Most species seldom attack humans. Species of this genus are usually found in dry arid habitats. Detailed description of only the major species of veterinary importance is presented here.

Argas persicus

Common name: Fowl tick, chicken tick, adobe tick, blue bug

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Argasidae

Description: The unfed adult is pale yellow to reddish-brown turning slate blue when fed. The female is about 8 mm in length and the male about 5 mm. The margin of the body appears to be composed of irregular quadrangular plates or cells, and no scutum is present. Unlike hard ticks, the four segments of the pedipalps are equal in length. The stigmata are situated on the sides of the body above the third and fourth pairs of legs. The integument is granulated, leathery and wrinkled. The hypostome is notched at the tip (see Fig. 3.125f), and the mouthparts are not visible when the tick is viewed from above.

Hosts: Chicken, turkey and wild birds.

Geographical distribution: Worldwide, especially in the tropics.

Pathogenesis: Though common pests of chickens and turkeys, they are not usually a significant veterinary problem, except in small housed flocks. They will bite humans, particularly if living in proximity to an infested flock. Infestation may cause irritation, sleeplessness, loss of egg productivity and anaemia, which can prove fatal. Each tick requires a considerable quantity of blood for engorgement, and therefore heavy infestations can take enough blood to bring about the death of their host. Most species are nocturnal and are parasites of birds, bats, reptiles or, occasionally, small insectivorous mammals and seldom attack humans.

These ticks may transmit *Borrelia anserina*, the cause of fowl spirochaetosis, and *Aegyptianella pullorum*, a rickettsial infection. The spirochaetes may be passed from one generation of ticks to the next through the egg, and transmitted to the host by biting or by faecal contamination.

Argas reflexus

Common name: Pigeon tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Argasidae

Description: The adult *Argas reflexus* is between 6 and 11 mm in length and may be distinguished from the fowl tick, *Argas persicus*, by its body margin, which is composed of irregular grooves, and the hypostome, which is not notched apically (see Fig. 3.125e). It is reddish-brown in colour with paler legs.

Host: Pigeon

Geographical distribution: This tick species is abundant in the Middle and Near East, from where it has spread into Europe and most of Asia.

Pathogenesis: Heavy infestations may cause death from anaemia. It may also transmit fowl spirochaetosis. This tick occasionally bites humans, causing allergy. Its northern distribution through Europe is limited by the temperature requirement of its eggs and oviposition in summer months, since *A. reflexus* eggs show low levels of cold tolerance. Typical winter temperatures of 3°C lead to approximately 50% mortality in *A. reflexus* eggs.

Epidemiology: This species lives in close association with its host, *Columba livia*.

Argas walkerae

Common name: Chicken tick

Predilection site: Skin, commonly beneath the wings.

Class: Arachnida

Order: Ixodida

Family: Argasidae

Host: Chicken

Distribution: Southern Africa.

Pathogenesis: It causes considerable economic losses, especially where it transmits *Aegyptianella pullorum* and *Borrelia anserina*. In addition, it may secrete a neurotoxin during feeding, frequently resulting in fatal paralysis.

Epidemiology: This species lives in close association with its poultry hosts and no wild hosts are known.

Ornithodoros

This genus includes 113 species, almost all of which are found in tropical and subtropical habitats in both the Old and New World. Most *Ornithodoros* species are found in Africa, commonly in the burrows of warthogs and bush pigs, though other species may be found in Central and South America and the Rocky Mountain states of the USA. They are nocturnal and the mouthparts are well developed. The integument has a wrinkled pattern, which runs continuously over the dorsal and ventral surfaces (Fig. 17.25). There is no distinct lateral margin to the body, which appears sac-like. Species of this genus are found largely in habitats such as dens, caves, nests and burrows, and so are not normally a problem for most domestic animals. Only the nymphs and adults are parasitic and may be responsible for considerable irritation; heavy infections can cause mortality of stock from blood loss.

Several species of *Ornithodoros* inflict painful bites and may be major vectors of relapsing fever. Detailed description of only the major species of veterinary importance is presented here.

Ornithodoros erraticus

Synonym: *Ornithodoros maroccanus*

Common name: Sand tampan

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Fig. 17.25 *Ornithodoros* dorsal view.

Family: Argasidae

Hosts: Particularly small mammals, but also domestic livestock and humans.

Geographical distribution: Europe, Africa and the Middle East.

Pathogenesis: *Ornithodoros erraticus* is a vector of the rickettsial parasite *Coxiella burnetii*, the causative agent of Q fever in cattle, sheep and goats. It also transmits *Borrelia hispanica* in the Spanish peninsula and adjacent North Africa, and *B. crocidurae* in Africa, the Near East and Central Asia. These are both spirochaetes which cause tick-borne relapsing fever. This species also acts as a reservoir and vector for African swine fever virus and *Babesia*.

Ornithodoros hermsi

Common name: Sand tampan

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Argasidae

Description: *Ornithodoros hermsi* is a pale, sandy coloured soft tick that appears greyish-blue when engorged. The adult female *O. hermsi* is typically 5–6 mm in length and 3–4 mm wide. The male is morphologically similar, though slightly smaller.

Hosts: Most mammals, particularly rodents.

Geographical distribution: North America (Rocky Mountains and Pacific coast).

Pathogenesis: This species transmits *Borrelia hermsi*, the agent of tick-borne relapsing fever in America, and may also act as a vector for African swine fever virus. Rodents, including deer mice, squirrels and chipmunks, are the primary reservoir hosts for *B. hermsi*.

Epidemiology: *Ornithodoros hermsi* is found in rural areas that are usually mountainous and forested. They live in dark cool places where rodents nest, such as woodpiles outside buildings, under houses, between walls or beneath floorboards inside cabins. They are most active during the summer months.

Ornithodoros moubata moubata

Common name: Eyeless tampan, hut tampan

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Argasidae

Hosts: Most mammals, birds and some reptiles.

Geographical distribution: Africa and the Middle East.

Pathogenesis: This species may be a reservoir host for the virus of African swine fever, or the spirochaete *Borrelia duttoni*, which causes African relapsing fever in humans and for Q fever. It may transmit *Borrelia anserina* and *Aegyptianella pullorum* in fowl.

Ornithodoros moubata porcinus

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Argasidae

Hosts: Warthogs, bushpigs, porcupines and domestic pigs.

Geographical distribution: Africa, Madagascar and southern Europe.

Pathogenesis: An important reservoir and vector of African swine fever virus and other viruses of suidae.

Epidemiology: This tick spends the day sheltered in the burrows of its natural hosts (warthogs), or the cracks and crevices of pig housing, emerging to feed at night.

Notes: The taxonomic position of the two or more known strains of *O. moubata* is not satisfactorily resolved: *O. moubata moubata* is a hut-dwelling strain that feeds on people and chickens, and *O. moubata porcinus* lives in burrows and feeds on warthogs, antbears and porcupines.

Ornithodoros parkeri

Common name: Sand tampan

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Argasidae

Hosts: Most mammals, particularly rodents.

Geographical distribution: Western states and Pacific coast of North America.

Pathogenesis: The bite of this species can cause a severe toxic or allergic reaction in the host, which may involve skin rashes, fever, nausea, diarrhoea, shock and death. *Ornithodoros parkeri* transmits *Borrelia parkeri*, the agent of tick-borne relapsing fever in America, and may also act as a vector for African swine fever virus.

Ornithodoros savignyi

Common name: Sand tampan

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Argasidae

Hosts: Most mammals, particularly camels, and poultry.

Geographical distribution: Africa, India and the Middle East.

Pathogenesis: Toxicosis may occur in response to the tick saliva, characterised by cutaneous oedema, haemorrhage, rapidly progressing weakness and prostration. Toxicosis can suppress the host's immune system, allowing the reactivation of chronic

infections. Such toxicosis with *O. savignyi* occurs in young calves and lambs, especially when there are large tick populations and multiple bites.

Ornithodoros tholozani

Common name: Sand tampan

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Argasidae

Hosts: Most mammals, birds and some reptiles.

Geographical distribution: Africa and the Middle East.

Pathogenesis: This species transmits *Borrelia persica*, the causative agent of Persian relapsing fever in northeast Africa and Asia.

Ornithodoros turicata

Common name: Sand tampan, relapsing fever tick

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Argasidae

Hosts: Most mammals, particularly rodents.

Geographical distribution: North America, particularly southern areas between Florida and California and northward to Colorado and Utah.

Pathogenesis: The bite of this species can cause a severe toxic or allergic reaction in the host, which may involve skin rashes, fever, nausea, diarrhoea, shock and death. This species transmits *Coxiella burnetii*, the causative agent of Q fever in America, and *Borrelia turicatae*, the causative agent of tick-borne relapsing fever. It may also act as a vector for African swine fever virus.

Ornithodoros rudis

Predilection site: Skin

Class: Arachnida

Order: Ixodida

Family: Argasidae

Hosts: Most mammals, particularly rodents and humans.

Geographical distribution: Central and South America.

Pathogenesis: A vector of *Borrelia* spp., pathogenic agents of relapsing fever.

Epidemiology: This tick spends its life in the burrows of its natural hosts, or cracks and crevices of human or animal housing in dry conditions. It emerges only to feed at night.

Ornithodoros lahorensis**Predilection site:** Skin**Class:** Arachnida**Order:** Ixodida**Family:** Argasidae**Hosts:** Wild sheep, domestic sheep and goats.**Geographical distribution:** Eastern Europe, northern India, southern former USSR, Middle East.**Pathogenesis:** An important vector of the agents of piroplasmosis, brucellosis, Q fever and tularaemia. Its feeding activity may also cause paralysis, anaemia and toxicosis.**Epidemiology:** This species is unusual because of its relatively prolonged contact with its host, to which it remains attached over winter. Large populations may build up on sheep and goats that are housed in infested stables and caves over winter.***Otobius***

This small genus contains only two species: *Otobius megnini* and *Otobius lagophilus*.

Otobius megnini**Common name:** Spinose ear tick**Predilection site:** Ears**Class:** Arachnida**Order:** Ixodida**Family:** Argasidae**Description:** The adult body is rounded posteriorly and slightly attenuated anteriorly. Adult females range in size from 5 to 8 mm in length; males are slightly smaller. They have no lateral sutural line, and no distinct margin to the body. Nymphs have spines (see Fig. 3.126). In adults the hypostome is much reduced and the integument is granular. The body has a blue–grey coloration with pale yellow legs and mouthparts. Larvae measure 2–3 mm in length and a fully grown, engorged nymph measures 7–10 mm.**Hosts:** Commonly infests wild and domestic animals, including sheep, cattle, dogs, horses and occasionally humans.**Geographical distribution:** North and South America, India and southern Africa.**Pathogenesis:** The larvae and nymphs feed in the external ear canal of the host, producing severe inflammation and a waxy exudate in the ear canals. Secondary bacterial infections can occur, which may extend up the ear canal. Infested hosts may scratch and shake their heads. Scratching can cause local skin trauma and occasionally perforate the eardrum. This can lead to infection, ulceration and in some cases meningitis. In horses, clinical signs may be mistaken for signs of colic.***Otobius lagophilus*****Common name:** Rabbit ear tick**Predilection site:** Ears**Class:** Arachnida**Order:** Ixodida**Family:** Argasidae**Hosts:** Rabbits**Geographical distribution:** North America, Canada.**Pathogenesis:** The larvae and nymphs feed in the external ear canal of the host, producing severe inflammation and a waxy exudate in the ear canals. Infested hosts may scratch and shake their heads. Scratching can cause local skin trauma.**MITES**

Most mites are relatively host-specific and are discussed in their relevant host chapter.

FAMILY TROMBICULIDAE

Species of the family Trombiculidae are commonly known as chiggers, red bugs, harvest mites and scrub itch mites, and are unique in that only the larval stage is ectoparasitic. In the adult and nymphal stages they are believed to be predators on the eggs and larvae of other arthropods. The principal species of veterinary interest are in the genus *Trombicula*.

Pathogenesis: The mites feed on blood, which they ingest by puncturing the skin. Infestation causes pruritus, erythema and scratching, though there may be considerable individual variation in response. This variation may reflect the development of a hypersensitivity reaction to the mites, which may result in the development of wheals, papules and excoriation leading to hair loss. In some cases, pruritus occasionally may continue long after the larvae have left, and heavy infestations may also induce systemic effects such as fever.**Clinical signs:** Infestation can result in pruritus, erythema, wheals, papules and excoriation leading to hair loss.**Diagnosis:** Small clusters of orange larval mites may be seen on the skin surface. Microscopic examination may then be used to identify individual species.**Treatment:** In most cases, the dermatitis should resolve a few days after the larvae have left the skin, although acarididal treatment may be necessary. Topical acaricides, such as organophosphates (e.g. phosmet, chlorpyrifos, malathion or diazinon), fipronil or lime–sulphur can be used, depending on the host infested.**Control:** Environmental treatment with cyfluthrin, cyhalothrin, deltamethrin, carbaryl and deltamethrin may help to reduce mite abundance in areas such as backyards. However, area-wide control is usually impractical and unnecessary; problems should be managed by avoidance of sites of known mite prevalence.

Trombicula (Neotrombicula) autumnalis

Common name: Harvest mite

Predilection site: Harvest mites are commonly found in clusters on the foot and up the legs of dogs, on the genital area and eyelids of cats, on the face of cattle and horses and on the heads of birds, having been picked up from the grass.

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Trombiculidae

Description: The hexapod larvae are rounded, red to orange in colour and about 0.2 mm in length (see Fig. 3.102). The scutum bears a pair of sensillae and five setae. In *N. autumnalis* the scutum is roughly pentangular and has numerous small punctations. There are two simple eyes on each side of the scutum. The body is covered dorsally with 25–50 relatively long, ciliated, feather-like setae. The chelicerae are flanked by stout five-segmented palps. The palpal femur and genu each bear a single seta. The palpal tibia has three setae and a thumb-like terminal claw, which opposes the palpal tarsus. The palpal claw is three-pronged (trifurcate). Adults and nymphs have a pronounced figure-of-eight shape. They have stigmata that open at the base of the chelicerae and their bodies are covered with setae. Adults are about 1 mm in length.

Hosts: Dogs, cats, cattle, horses, rabbits and birds.

Geographical distribution: Europe

Epidemiology: In Europe the activity of *Neotrombicula autumnalis* is most pronounced in late summer and autumn, and larvae are most active on dry sunny days. They parasitise almost all domestic mammals, including humans, and some ground-nesting birds. *Neotrombicula autumnalis* may be particularly abundant in closely cropped chalk grassland, but it may also be found in wooded areas and scrub.

Trombicula (Eutrombicula) alfreddugesi

Common name: Chigger mite

Predilection site: Commonly face, muzzle, thigh and belly.

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Trombiculidae

Description: The larvae of *E. alfreddugesi*, known as chiggers, are similar in appearance to those of *N. autumnalis*. They are reddish-orange and vary in length between 0.15 mm when not engorged to 0.6 mm when fully fed. However, for the larvae of *E. alfreddugesi* the palpal claws are two-pronged (bifurcate), the scutum is approximately rectangular and 22 dorsal setae are present.

Hosts: Dogs, cats, cattle, horses, rabbits, birds.

Geographical distribution: *Eutrombicula alfreddugesi* is the most important and widespread of the trombiculid mites of veterinary interest in the New World. It is common from eastern Canada through to South America.

Epidemiology: *Eutrombicula alfreddugesi* is particularly common at the margins of woodland, scrub and grassland, but is not highly habitat-specific. In the northern parts of its range it may be most active between July and September, whereas in more southern habitats it may be active all year round. *Eutrombicula alfreddugesi* parasitises a wide range of mammals and birds.

Eutrombicula splendens

Synonym: *Trombicula splendens*

Common name: Chigger mite

Predilection site: Commonly on the face, feet or legs.

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Trombiculidae

Description: *Eutrombicula splendens* is morphologically similar and frequently sympatric with *E. alfreddugesi* in North America.

Geographical distribution: North America; generally confined to the east, from Ontario in Canada to the Gulf States, although it may also be abundant in Florida and parts of Georgia.

Epidemiology: This species generally occurs in moister habitats than *E. alfreddugesi*, such as swamps and bogs.

Trombicula (Eutrombicula) sarcina

Common name: Scrub itch mite, black soil itch mite

Predilection site: Commonly on the face, feet or legs.

Class: Arachnida

Subclass: Acari

Order: Prostigmata (Trombidiformes)

Family: Trombiculidae

Description: The parasitic larvae are small (0.2 mm long) round mites with numerous setae.

Geographical distribution: Australasia

Epidemiology: The scrub itch mite *Eutrombicula sarcina* is an important parasite of sheep in Queensland and New South Wales of Australia. Its principal host, however, is the grey kangaroo. These mites prefer areas of savannah and grassland scrub. They may be particularly abundant from November to February, after summer rain. The primary site of infestation is on the leg, resulting in intense irritation.
